Abstract

Energy-based modeling is a promising approach to unsupervised learning, which yields many downstream applications from a single model. The main difficulty in learning energy-based models with the "contrastive approaches" is the generation of samples from the current energy function at each iteration. Many advances have been made to accomplish this subroutine cheaply. Nevertheless, all such sampling paradigms run MCMC targeting the current model, which requires infinitely long chains to generate samples from the true energy distribution and is problematic in practice. In this paper, we propose an alternative approach to getting these samples avoiding crude MCMC sampling from the current model. We accomplish this by viewing the evolution of the modeling distribution as (i) the evolution of the energy function, and (ii) the evolution of the samples from this distribution along some vector field. We subsequently derive this time-dependent vector field such that the particles following this field are approximately distributed as the current model thereby matching the evolution of the particles with the evolution of the energy function prescribed by the learning procedure. Importantly, unlike Monte Carlo sampling, our method targets to match the current distribution in a finite time. Finally, we demonstrate its effectiveness empirically comparing to MCMC-based learning methods.

1 Introduction

Energy-based modeling has recommended itself as a universal approach learning a single model, which then can be applied in various scenarios: continual learning, missing data imputation, out-of-distribution detection, better uncertainty of discriminative models (Grathwohl et al., 2019; Du & Mordatch, 2019; Li et al., 2020). However, scaling this approach to real-world data such as images encounters many complications, which the community has been approaching trying to get better samples (Tieleman & Hinton, 2009; Du & Mordatch, 2019; Nijkamp et al., 2019) or targeting different objectives (Grathwohl et al., 2020; Arbel et al., 2020; Gao et al., 2020).

In this paper, we approach the subroutine problem of getting samples from the current model, which arises in the learning of the energy-based models. The conventional approach to this is to run an MCMC method targeting the current model. Instead, we update particles deterministically propagating them along the derived vector field such that after time dt the particles are distributed as the evolved density after time dt. This is principally different, since we don't rely on the invariance of the target (the current model density), and are able to match it in a finite amount of time. Our main contribution is the formula (8) for the vector field, which matches the evolution of the model with the evolution of the particles in the space of log-densities. Further, we discuss possible ways to simulate this formula and demonstrate its usefulness empirically.

2 Background and Related Works

Energy-Based Models are usually learned via the maximum likelihood principle. That is, we start with a model density function $q(x)$ parameterized by the energy function $E(x, \theta)$:

$$q_\theta(x) = \frac{1}{Z} e^{-E(x,\theta)}, \quad Z = \int dx \; e^{-E(x,\theta)}, \tag{1}$$

which is then optimized to approximate some target density $p(x)$ (given empirically: as a set of samples). This can be done by the maximization of $\mathbb{E}_p \log q$, or, equivalently, minimization of $\mathrm{KL}(p, q)$ via the gradient-descent methods:

$$\frac{\partial \theta}{\partial t} = -\nabla_\theta \Big[\mathbb{E}_{x \sim p} E(x, \theta) - \mathbb{E}_{x \sim q_\theta} E(x, \theta) \Big], \tag{2}$$

The main obstacle under this approach is the sampling from the current density $q_\theta \propto \exp(-E(x, \theta))$. Our work operates much in the fashion of the Persistent Contrastive Divergence (PCD) (Tieleman & Hinton, 2009): it keeps a set of samples, which are updated at every iterations to match current q_θ. While PCD relies on MCMC methods targeting q_θ, we propagate the particles deterministically along the derived vector field.

Langevin Dynamics is a ubiquitous sampling method. For energy-based models with the continuous state-space, this method is especially attractive due to its cheap iterations (single gradient evaluation per step) and the ability to yield good samples even without Metropolis-Hastings correction (Gelfand & Mitter, 1991). This procedure targeting the distribution p can be written as

$$x_{t+dt} = x_t + dt \frac{1}{2} \nabla_x \log p(x) + \varepsilon, \quad \varepsilon \sim \mathcal{N}(0, dt) \tag{3}$$

Its efficiency, however, is hindered by the random fluctuations that introduce random-walk behaviour, and its deterministic analog is more efficient (see, for instance, (Liu et al., 2019)). This analog is derived by rewriting the Fokker-Planck equation (which describes the evolution of the density) as the continuity equation:

$$\frac{\partial q}{\partial t} = -\langle \nabla, q \frac{1}{2} \nabla \log p \rangle + \frac{1}{2} \Delta q = -\Big\langle \nabla, q (\frac{1}{2} \nabla \log p - \frac{1}{2} \nabla \log q) \Big\rangle. \tag{4}$$

Then the simulation of the particles can be done by propagating them along the new vector field:

$$x_{t+dt} = x_t + \frac{dt}{2} \big[\nabla \log p(x_t) - \nabla \log q_t(x_t) \big]. \tag{5}$$

In Monte Carlo setting, the deterministic simulation is troublesome since we don't have an access to the current density q_t. However, we will see how the EBMs learning naturally allows for this.

3 Matching the particle dynamics with the energy evolution

The motivation of this section is to match two things: the update of the energy and the update of the particles. The former is defined by the learning procedure maximizing the log-likelihood. The particles then should be moved to keep up with the updates of energy and be distributed as the up-to-date model. We match these two dynamics by matching the updates of their log-densities in L^2_q:

$$v^* = \max \cdot \arg\max_{v \in L^2_q : \|v\| = 1} \Big\langle \frac{\partial}{\partial t} \log q_t, \frac{\partial}{\partial t} \log \hat{q}_t \Big\rangle_{L^2_q}, \tag{6}$$

where "$\max \cdot \arg\max$" denotes the scalar multiplication of the maximum and the maximizer, q_t is the prescribed evolution, and $\hat{q}_t$ is the density evolution of particles defined by the vector field v, i.e.

$$\frac{\partial}{\partial t} \log \hat{q}_t = \frac{1}{\hat{q}_t} \frac{\partial \hat{q}_t}{\partial t} = -\langle \nabla \log q_t, v \rangle - \langle \nabla, v \rangle. \tag{7}$$

Proposition 1. *For the evolution of the density $q_t = \exp(-E_t)/Z_t$, the solution of equation* (6) *is*

$$v^* = -\nabla \frac{\partial E_t}{\partial t}. \tag{8}$$

(See proof in Appendix A). This formula is the main development of our work and in the next section we discuss its practical implications. In a similar way, we can project the evolution of the density

$$v^\star = \max_{v \in L^2_q : \|v\|=1} \cdot \arg\max \left\langle \dot{q}, -\langle \nabla, qv \rangle \right\rangle_{L^2} = \max_{v \in L^2_q : \|v\|=1} \cdot \arg\max \left\langle \nabla \dot{q}, v \right\rangle_{L^2_q} = \nabla \dot{q}, \tag{9}$$

which is related to the gradient flows in the Wasserstein Riemannian manifold (Otto, 2001; Benamou & Brenier, 2000). These two vector fields are equivalent when the distribution follows the gradient of some functional F.

Proposition 2. *Consider the functional $F = \int f(q)$, which we can optimize either w.r.t. $q = \exp(-E)/Z$ or w.r.t. E. When the evolution of the density (energy) is defined by the Frechet derivatve of F, we have $v^* = v^\star$.*

(See proof in Appendix B). This preposition gives us a reasonable result. Namely, the dynamics of the particles is independent of the distribution parameterization when the parameterization is dense in the corresponding spaces.

Another motivation for the derived formula is that it can be approximated by the Persistent Contrastive Divergence with the Langevin dynamics.

Proposition 3. *The updates of the particles following $v^* = -\nabla \frac{\partial E}{\partial t}$ can be approximated as*

$$x_{t+dt} = x_t - \nabla_{x_t} E_{t+dt}(x_t) + \sqrt{2}\varepsilon, \quad \varepsilon \sim \mathcal{N}(0,1). \tag{10}$$

(See derivations in Appendix C). In the following section, we will see that the derived formula $v^* = -\partial E / \partial t$ allows for different approximations, which avoid any stochasticity in the updates.

4 Numeric approximations of the particle dynamics

First, we consider the approximations that follow straightforwardly by discretizing the formula (8). Discretizing the energy update, we have

$$v^* = -\nabla \frac{\partial E}{\partial t} \approx \frac{1}{dt}\Big[-\nabla E_{t+dt} + \nabla E_t \Big] = v_\alpha. \tag{11}$$

The update of each individual particle can be written as

$$x_{t+dt} \approx x_t + dt v_\alpha(x_t) = x_t - \nabla_{x_t} E(x_t, \theta(t+dt)) + \nabla_{x_t} E_t(x_t, \theta(t)), \tag{12}$$

We denote this update rule **Method $\boldsymbol{\alpha}$**. This method is basically the simulation of the Langevin dynamics, but in a deterministic way. Indeed, taking $p(\cdot) \propto \exp(-E(\cdot, \theta(t+dt))$ in equation (5), we obtain the same formula up to the choice of the step-size. Intuitively, this procedure tries to match the new log-density following its gradient and, at the same time, unmatch the old log-density.

The second option, for the parametric models, is to discretize the time on a lower level:

$$v^* = -\nabla \frac{\partial E}{\partial t} = -\nabla \Big\langle \nabla_\theta E(\cdot, \theta), \frac{\partial \theta}{\partial t} \Big\rangle \approx -\frac{1}{dt} \nabla \Big\langle \nabla_\theta E(\cdot, \theta), d\theta \Big\rangle = v_\beta. \tag{13}$$

This formula gives us another update rule, which we call **Method $\boldsymbol{\beta}$**:

$$x_{t+dt} \approx x_t + dt v_\beta(x_t) = x_t - \nabla_{x_t} \langle \nabla_\theta E(x_t, \theta), d\theta \rangle. \tag{14}$$

Unlike method α, this method is different from deterministic Langevin, and we will return to its intuition in a bit.

The third option we consider is the non-parametric updates, which we derive approximating the energy gradient in RKHS. To minimize the KL-divergence we first take the Frechet derivative w.r.t. the energy E along some direction h and use the fact that RKHS is actually dense in L^2_q (Duncan et al., 2019). Then, using the reproducing property of k, we can formulate the directional derivative as an action of a linear operator:

$$\mathrm{diffKL}(p,q)[h] = \langle p/q - 1, h \rangle_{L^2_q} = \langle \mathbb{E}_{x\sim p} k(x, \cdot) - \mathbb{E}_{x \sim q} k(x, \cdot), h \rangle_{\mathcal{H}} \tag{15}$$

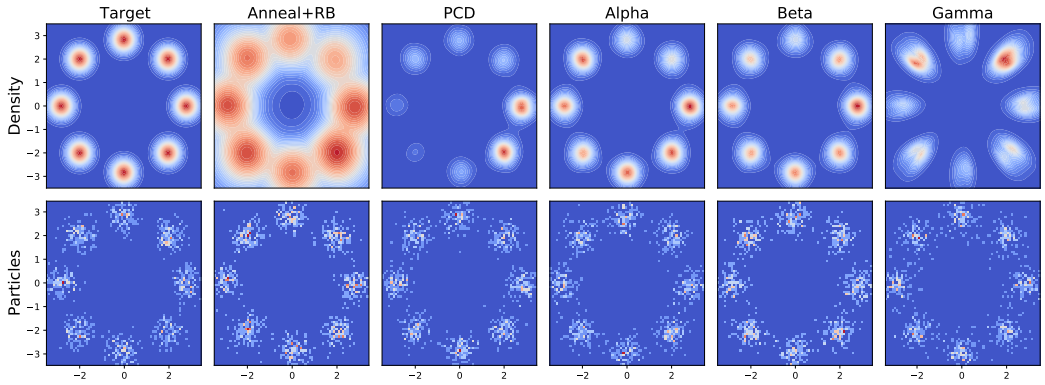

Figure 1: The densities of learned models and the final set of particles. Since method γ doesn't yield the parametric model for the energy, we integrate the energy numerically according to (15).

Following (Gretton et al., 2012), we see that $\mu_p = \mathbb{E}_{x\sim p} k(x, \cdot) \in \mathcal{H}$ if $\mathbb{E}_{x\sim p}\sqrt{k(x,x)} < \infty$. Hence, we can choose the direction $h \in \mathcal{H}$ matching the gradient.

The gradient then defines the vector field, which we denote as **Method $\boldsymbol{\gamma}$**:

$$v^* = -\nabla \frac{\partial E}{\partial t} \approx \underbrace{\mathbb{E}_{x\sim p} \nabla k(x, \cdot)}_{\text{attraction to data}} - \underbrace{\mathbb{E}_{x\sim q_t} \nabla k(x, \cdot)}_{\text{repulsion between particles}} = v_\gamma. \tag{16}$$

Intuitively, the particles are attracted to the dataset and repelled from each other. Also, this vector field coincides with the MMD gradient flow (Arbel et al., 2019), which is derived from a different perspective.

Proposition 4. *The convergence of the dynamics* (16) *is described as:*

$$\frac{d}{dt}\mathrm{KL}(p, q_t) = -\mathrm{MMD}_k(p, q_t)^2. \tag{17}$$

(See proof in Appendix D). Hence, the KL-divergence between the target and the current approximation reduces proportionally to the squared MMD between these distribution. The process stops when $\mathrm{MMD}_k(p, q_t) = 0$. If the kernel is expressive enough (is universal), then q converges to p.

We now return to the intuition of method β. Taking the formula (14) and assuming that the updates of the parameters follows the gradient descent, we have

$$v_\beta = -\frac{1}{dt}\nabla\left\langle \nabla_\theta E(\cdot, \theta), d\theta \right\rangle = \nabla\left\langle \nabla_\theta E(\cdot, \theta), \mathbb{E}_{x\sim p}\nabla_\theta E(x, \theta) - \mathbb{E}_{x\sim q_t}\nabla_\theta E(x, \theta) \right\rangle = \tag{18}$$

$$= \nabla\left[\mathbb{E}_{x\sim p}\langle \nabla_\theta E(\cdot, \theta), \nabla_\theta E(x, \theta)\rangle - \mathbb{E}_{x\sim q_t}\langle \nabla_\theta E(\cdot, \theta), \nabla_\theta E(x, \theta)\rangle\right] = v_\gamma. \tag{19}$$

Thus, we see, that method β is essentially method γ, but with the Neural Tangent Kernel $k_\theta(x, y) = \langle \nabla_\theta E(x, \theta), \nabla_\theta E(y, \theta)\rangle$. Hence, it operates by targeting the distribution of data rather than approximating the current energy model. This surprising connection has two benefits: it would probably allows us to scale this method to higher dimensions, and it allows for efficient parallel batch evaluation. We hope that this connection could help us to overcome two main obstacles hindering the efficiency of kernel methods.

5 Empirical evaluation

We empirically test the proposed methods α, β, γ and compare them against conventional approaches: PCD (Tieleman & Hinton, 2009) and sampling with the Replay Buffer (Du & Mordatch, 2019). We found that, for the Replay Buffer, it is important to reduce the noise magnitude (as also proposed in (Du & Mordatch, 2019)), which yields sampling from an annealed target. For both "PCD" and "Anneal + RB", we make 20 steps of stochastic Langevin on every iteration. For our methods we propagate the particles along the corresponding vector fields and make additional 10 steps of

stochastic Langevin alleviating possible numerical errors. For the target distribution we take toy 2-d distribution, and try to match it with 2-layer fully-connected neural network (300 hidden units, Swish activations (Ramachandran et al., 2017)). For method gamma, we found that using the same parameters θ throughout the learning leads to a degenerate solution. Thus, we sample using the kernel $k_\theta(x, y) = \mathbb{E}_{\theta \sim \pi_0} \langle \nabla_\theta E(x, \theta), \nabla_\theta E(y, \theta) \rangle$, where parameters θ are sampled from the initialization distribution π_0 at each iteration, i.e. we use unlearned random networks to propagate particles.

In Fig. 1, we demonstrate the learned densities and the particles. In Fig. 2, we report the metrics for models and samples averaging over 10 independent runs. We don't report standard errors to keep the plots readable. As we see, only α and β nicely capture all of the modes. We found the learning via PCD to be the most unstable and unable to capture all of the modes in most cases. Annealing with the Replay Buffer is the most stable method in our experiments, however, it yields the density with scaled temperature due to the incorrect noise magnitude. Finally, we conclude, that the proposed methods demonstrate better performance with a lower computational budget. Interestingly, all of the methods manage to match the final set of particles with the target distribution regardless of the learned energy.

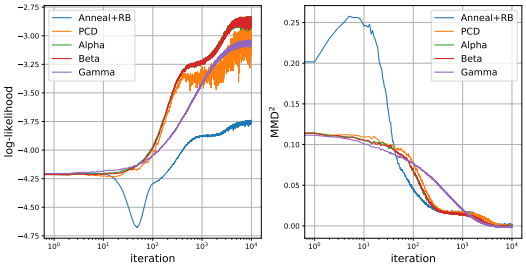

Figure 2: Performance of the models throughout the training. The quality of the energy as measured by the log-likelihood, and the MMD^2 between current set of particles and the training batch. Note that the Alpha's plot is just under the Beta's plot.

6 Conclusion

We approach the problem of sampling from a distribution, which evolves in time, which is especially important in the context of energy-based learning. Our main contribution is the approximate formula for the vector field that propagates the particles matching the evolution of the distribution. We demonstrate that this formula yields several reasonable algorithms connected to deterministic Langevin and MMD gradient flows. Intuitively, method α moves the particles matching the new energy and, at the same time, unmatching the old energy. In contrast, methods β and γ propel particles aiming the target data distribution and repelling particles from each other to cover the space. Finally, we show that our deterministic approach can be favorable in practice for learning energy-based models.

Checklist

1. For all authors...
   (a) Do the main claims made in the abstract and introduction accurately reflect the paper's contributions and scope? [Yes]
   (b) Did you describe the limitations of your work? [No]
   (c) Did you discuss any potential negative societal impacts of your work? [No]
   (d) Have you read the ethics review guidelines and ensured that your paper conforms to them? [Yes]
2. If you are including theoretical results...
   (a) Did you state the full set of assumptions of all theoretical results? [No]
   (b) Did you include complete proofs of all theoretical results? [Yes]
3. If you ran experiments...
   (a) Did you include the code, data, and instructions needed to reproduce the main experimental results (either in the supplemental material or as a URL)? [No] will be included in the final version
   (b) Did you specify all the training details (e.g., data splits, hyperparameters, how they were chosen)? [No] will be included in the final version
   (c) Did you report error bars (e.g., with respect to the random seed after running experiments multiple times)? [No]
   (d) Did you include the total amount of compute and the type of resources used (e.g., type of GPUs, internal cluster, or cloud provider)? [No]
4. If you are using existing assets (e.g., code, data, models) or curating/releasing new assets...
   (a) If your work uses existing assets, did you cite the creators? [N/A]
   (b) Did you mention the license of the assets? [N/A]
   (c) Did you include any new assets either in the supplemental material or as a URL? [N/A]
   (d) Did you discuss whether and how consent was obtained from people whose data you're using/curating? [N/A]
   (e) Did you discuss whether the data you are using/curating contains personally identifiable information or offensive content? [N/A]

5. If you used crowdsourcing or conducted research with human subjects...

A Proof of proposition 1

Proposition. *The solution of*

$$v^* = \max \cdot \arg\max_{v \in L^2_q : \|v\|=1} \left\langle \frac{\partial}{\partial t} \log q_t, \frac{\partial}{\partial t} \log \hat{q}_t \right\rangle_{L^2_q} \tag{20}$$

is $v^* = -\nabla \frac{\partial E}{\partial t}$.

Proof. The evolution of $\hat{q}_t$ is evolution defined by the vector field v, i.e.

$$\frac{\partial}{\partial t} \log \hat{q}_t = \frac{1}{\hat{q}_t} \frac{\partial \hat{q}_t}{\partial t} = -\langle \nabla \log q_t, v \rangle - \langle \nabla, v \rangle, \tag{21}$$

and the first argument of the scalar product is defined by the updates of the energy

$$\frac{\partial}{\partial t} \log q_t = -\frac{\partial E}{\partial t} + \mathbb{E}_{q_t} \frac{\partial E}{\partial t}. \tag{22}$$

We rewrite the scalar product in (20) as

$$\left\langle \frac{\partial}{\partial t} \log q_t, \frac{\partial}{\partial t} \log \hat{q}_t \right\rangle_{L^2_q} = \int dxq \left[\frac{\partial E}{\partial t} - \mathbb{E}_{q_t} \frac{\partial E}{\partial t} \right] \left[\langle \nabla \log q_t, v \rangle + \langle \nabla, v \rangle \right] = \tag{23}$$

$$= \int dxq \frac{\partial E}{\partial t} \left[\langle \nabla \log q_t, v \rangle + \langle \nabla, v \rangle \right] - \mathbb{E}_{q_t} \frac{\partial E}{\partial t} \int dxq \frac{1}{q} \frac{\partial q}{\partial t} = \tag{24}$$

$$= \int dxq \frac{\partial E}{\partial t} \left[\langle \nabla \log q_t, v \rangle + \langle \nabla, v \rangle \right]. \tag{25}$$

Integrating by parts, we have

$$\left\langle \frac{\partial}{\partial t} \log q_t, \frac{\partial}{\partial t} \log \hat{q}_t \right\rangle_{L^2_q} = \int dx \left\langle \frac{\partial E}{\partial t} \nabla q - \nabla \big(q \frac{\partial E}{\partial t} \big), v \right\rangle = \tag{26}$$

$$= \int dxq \left\langle -\nabla \frac{\partial E}{\partial t}, v \right\rangle = \left\langle -\nabla \frac{\partial E}{\partial t}, v \right\rangle_{L^2_q}. \tag{27}$$

□

B Proof of proposition 2

Proposition. *Consider the functional* $F = \int f(q)$*, which we can optimize either w.r.t.* $q = \exp(-E)/Z$ *or w.r.t.* E*. Vector fields* $v^* = v^\star$ *when the evolution of the density (energy) is defined by the Frechet derivatve of* F*.*

Proof. The directional derivative (along the direction $h \in L^2$) is

$$\operatorname{diff} F(q)[h] = \left\langle \frac{\delta F(q)}{\delta q}, h \right\rangle_{L^2}, \quad \frac{\delta F(q)}{\delta q} h = \frac{d}{d\varepsilon} f(q + \varepsilon h)\big|_{\varepsilon=0}. \tag{28}$$

We can think of $\frac{\delta F(q)}{\delta q}$ as of the formal symbolic application of differention rules. Then

$$v^\star = \nabla \frac{\partial q}{\partial t} = \nabla \frac{\delta F(q)}{\delta q}, \tag{29}$$

which coincides with the vector field given by the Otto Calculus (Otto, 2001). For the energy, we consider the direction $h \in L^2_q$, then we have

$$\operatorname{diff} F(E)[h] = \int \frac{\delta F(q)}{\delta q} \frac{\delta q(E)}{\delta E} h = \left\langle -\frac{\delta F(q)}{\delta q} + \mathbb{E}_q \frac{\delta F(q)}{\delta q}, h \right\rangle_{L^2_q}. \tag{30}$$

Finally, we see that the two derivatives yield the same vector-field.

$$v^* = -\nabla \frac{\partial E}{\partial t} = -\nabla \left[-\frac{\delta F(q)}{\delta q} + \mathbb{E}_q \frac{\delta F(q)}{\delta q} \right] = v^\star \tag{31}$$

□

C Proof of proposition 3

Proposition. *The vector field $v^* = -\nabla \frac{\partial E}{\partial t}$ may be approximated by the "conventional update rule" of the particles following the Langevin dynamics targeting the updated density q_{t+dt}.*

Proof. Let's approximate the vector field v^* as

$$v^* \approx -\nabla \frac{1}{dt} \left[E_{t+dt} - E_t \right] = \frac{1}{dt} \left[\nabla \log q_{t+dt} - \nabla \log q_t \right], \tag{32}$$

Then the evolution of the density is described by the FP equation:

$$\dot{q} = -\langle \nabla, q_t v^* \rangle = -\langle \nabla, q_t \frac{1}{dt} \nabla \log q_{t+dt} \rangle + \frac{1}{dt} \Delta q_t. \tag{33}$$

Hence the evolution of particles can be described by the Ito equation

$$x_{t+dt'} = x_t + dt' \frac{1}{dt} \nabla \log q_{t+dt}(x_t) + \sqrt{\frac{2}{dt}} dW_t, \tag{34}$$

where dW_t is the Wiener process, which can be simulated by the normal random variable $\mathcal{N}(0, dt')$. Taking $dt' = dt$, we have the conventional update rule (up to the step size choice)

$$x_{t+dt} = x_t + \nabla \log q_{t+dt}(x_t) + \sqrt{2}\mathcal{N}(0,1) = x_t - \nabla E_{t+dt}(x_t) + \sqrt{2}\mathcal{N}(0,1). \tag{35}$$

□

D Proof of Proposition 4

Proposition. *The convergence of* (16) *is described by the equation:*

$$\frac{d}{dt} \mathrm{KL}(p, q_t) = -\mathrm{MMD}_k(p, q_t)^2. \tag{36}$$

Proof.

$$\operatorname{diff} \mathrm{KL}(p,q)[h] = \langle p/q - 1, h \rangle_{L^2_q} = \langle \underbrace{\mathbb{E}_{x\sim p} k(x,\cdot) - \mathbb{E}_{x\sim q} k(x,\cdot)}_{\partial E/\partial t}, h \rangle_{\mathcal{H}} \tag{37}$$

$$\begin{aligned}
\frac{d}{dt} \mathrm{KL}(p, q_t) = &- \mathbb{E}_{x\sim p} \frac{d}{dt} \log q_t(x) = \mathbb{E}_{x\sim p} \frac{\partial}{\partial t} E(x) - \mathbb{E}_{x\sim q_t} \frac{\partial}{\partial t} E(x) = && (38)\\
=&\mathbb{E}_{x'\sim p} \left[\mathbb{E}_{x\sim q_t} k(x,x') - \mathbb{E}_{x\sim p} k(x,x') \right] - && (39)\\
&- \mathbb{E}_{x'\sim q_t} \left[\mathbb{E}_{x\sim q_t} k(x,x') - \mathbb{E}_{x\sim p} k(x,x') \right] = && (40)\\
=&- \mathbb{E}_{x,x'\sim p} k(x,x') + 2\mathbb{E}_{x\sim p, x'\sim q_t} k(x,x') - \mathbb{E}_{x,x'\sim q_t} k(x,x') = && (41)\\
=&- \mathrm{MMD}_k(p, q_t)^2. && (42)
\end{aligned}$$

□
