DOMAIN GENERALIZATION FOR ROBUST MODEL-BASED OFFLINE RL

Anonymous authors
Paper under double-blind review

ABSTRACT

Existing offline reinforcement learning (RL) algorithms typically assume that training data is either: 1) generated by a known policy, or 2) of entirely unknown origin. We consider multi-demonstrator offline RL, a middle ground where we know which demonstrators generated each dataset, but make no assumptions about the underlying policies of the demonstrators. This is the most natural setting when collecting data from multiple human operators, yet remains unexplored. Since different demonstrators induce different data distributions, we show that this can be naturally framed as a domain generalization problem, with each demonstrator corresponding to a different domain. Specifically, we propose Domain-Invariant Model-based Offline RL (DIMORL), where we apply Risk Extrapolation (REx) (Krueger et al., 2020) to the process of learning dynamics and rewards models. Our results show that models trained with REx exhibit improved domain generalization performance when compared with the natural baseline of pooling all demonstrators' data. We observe that the resulting models frequently enable the learning of superior policies in the offline model-based RL setting, can improve the stability of the policy learning process, and potentially increase exploration.

1 INTRODUCTION

In the standard online reinforcement learning (RL) paradigm, agents often require millions of interactions with the environment in order to learn an optimal policy for completing a task. In many settings, however, the process of exploration in the real-world is undesirable, impractical or unsafe (Levine et al., 2020; Prudencio et al., 2022). It would therefore be preferable to enable learning from *demonstrations*, rather than direct *interaction* with the environment. Datasets targeting activity recognition from ego-centric videos (Damen et al., 2022) highlight the prevalence and ease of collecting demonstrations in our setting. These are provided by one or more *demonstrators*, each executing their own behavioural policy, π_β–their method of achieving the task. Various approaches to performing offline RL have been proposed (Levine et al., 2020; Prudencio et al., 2022). However, to the best of our knowledge, none of these approaches exploit information regarding the collection of data from multiple demonstrators.

A fundamental challenge in off-policy RL is policy-induced *distributional shift*; this is especially problematic in offline RL (Levine et al., 2020; Yu et al., 2020). Standard off-policy RL methods often fail when trained using offline data (Fujimoto et al., 2018). Value-based offline RL algorithms have addressed this by encouraging the agent to stay close to the behaviour policy used when generating the data. Such a constraint can (provably) limit performance (Buckman et al., 2020). Buckman et al. (2020) and other model-based approaches which do not suffer from this weakness have been found to outperform value-based methods (Yu et al., 2020; Kidambi et al., 2020).

Rather than constraining the learning policy's exploration, the aim of our work is to increase the robustness of *environment models*[1] to distributional shifts by applying *Risk Extrapolation (REx)* (Krueger et al., 2020) during training. REx assumes that training data from multiple domains (in our case, demonstrators) is available. While the demonstrator that generated each training record is

[1]We use the term *environment model* to highlight that both dynamics and rewards models are learned. We do not learn an initial state distribution. During policy training, transitions are generated from starting locations sampled from the offline dataset. When evaluating policies, the real initial state distribution is used.

known, no knowledge about the demonstrator's policy is required. REx aims to achieve similar risk on out-of-distribution domains by encouraging the training losses/risks across the domains present in the training data to be equal, even if the distributional shift is more extreme than those observed at training/test time (Krueger et al., 2020).

The primary contribution of our work is a practical algorithm for performing **Domain-Invariant Model-base Offline RL (DIMORL)** using multi-demonstrator datasets. We empirically show that environment models trained with REx exhibit improved average and worst-case performance on out-of-distribution datasets. Furthermore, in a majority of cases, policies trained offline using these models attain higher average returns. We demonstrate that environment models trained with REx can enable more stable offline model-based policy learning, and potentially support increased exploration. We present hypotheses for the benefits observed, and share the supporting evidence gathered thus far. However, further experimentation and analysis are needed to draw firm conclusions.

2 Background and Related Work

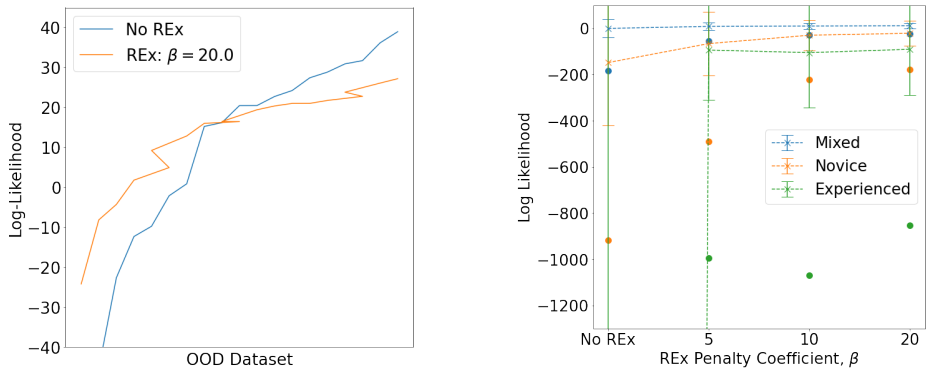
Offline Reinforcement Learning In offline RL, an agent π is trained using *only* a fixed dataset $\mathcal{D}$ of transitions ($\{s, a, r, s'\}$) (Fujimoto et al., 2018), or trajectories ($\{s_1, a_1, r_1, ..., s_T, a_T, r_T\}$) (Agarwal et al., 2019), without any further interaction with the environment (Levine et al., 2020; Prudencio et al., 2022). The data may also include meta-data about the policy or policies used to collect the data. Our aim is to learn the optimal policy, $\pi^*(a|s)$, that maximises the expected sum of discounted rewards $\pi^* = \arg\max_\pi \mathbb{E}_\pi[\sum_{t=0}^{\infty} \gamma^t r(s_t, a_t)]$, using discount factor $\gamma \in (0, 1]$.

Distributional Shift While the transition distribution of a Markov-Decision Process (MDP) is independent of the policy being followed, the state and state-action visitation distributions induced by behavioural policy π_β, $d^{\pi_\beta}(s)$ and $d^{\pi_\beta}(s, a)$ respectively, are not. The data collected for offline policy training is typically assumed to be composed of *iid* samples drawn from $d^{\pi_\beta}(s, a)$, and is likely to cover only a fraction of the total state-action space. In order to learn optimal policies, we would like our learning algorithm to *generalize* to other areas of this space; departing from the support of the training data in order to learn good behaviours that are not exhibited in the static dataset (Yu et al., 2020; Wu et al., 2021). The policy being learned, π_{off}, would therefore induce new state and state-action visitation distributions, $d^{\pi_{\text{off}}}(s)$ and $d^{\pi_{\text{off}}}(s, a)$. Errors made by the learned environment models, such as those arising from poor generalization performance under distributional shift, can result in *model exploitation*: the policy being trained learns to take advantage of model errors when optimizing the reward, leading to poor performance in the real environment (Cang et al., 2021; Rajeswaran et al., 2016; Janner et al., 2019; Clavera et al., 2018; Levine et al., 2020). However, in more extreme cases, model exploitation can cause significant instability in training, preventing a policy from being learned (Kurutach et al., 2018; Matsushima et al., 2020).

Offline Model-Based Reinforcement Learning Kidambi et al. (2020) and Yu et al. (2020) proposed the model-based offline RL algorithms MoREL and MOPO respectively. Both of these methods are conservative in the face of model uncertainty. However, they do not explicitly penalize deviations from the demonstrator's distribution, thus avoiding performance limitations demonstrated by Buckman et al. (2020). Both MoREL and MOPO work by modifying a learned MDP to penalize uncertain transitions. MoREL's pessimistic MDP adjusts $P(s'|s, a)$ to transition to a low-reward terminal state when the dynamics of (s, a) are uncertain, as measured by disagreement within an ensemble of learned dynamics models (Kidambi et al., 2020). In MOPO, Yu et al. (2020) instead penalize uncertain transitions directly in the reward function, and measure uncertainty as the maximum standard deviation across members of an ensemble. MOPO extends MBPO (Janner et al., 2019), which combines the soft-actor critic (SAC) policy gradient algorithm (Haarnoja et al., 2018a;b) with using learned dynamics models to generate short roll-outs.

3 Methods

Our method stems from the observation that different demonstrators in an offline RL setting correspond to different domains in a domain generalization setting. Therefore, **Domain-Invariant Model-based Offline RL (DIMORL)** leverages the MOPO codebase (Yu et al., 2020), and supplements it with domain generalization approaches for training the environment model.



(a) Risks for OOD Datasets

(b) Average and Worst Case OOD Risks

Figure 1: **Left:** We observe that REx increases the similarity of risks across OOD datasets by decreasing the risk (i.e., increasing the log-likelihood) for certain datasets, while increasing it for others. Data has been plotted according to increasing log-likelihood using the environment model trained with $\beta = 0$. **Right:** REx increases the average and worst-case risks across the OOD datasets. Environment models were trained against the HalfCheetah Mixed multi-demonstrator dataset using REx penalty coefficients $\beta \in \{0, 5, 10, 20\}$.

3.1 Risk Extrapolation (REx)

Risk Extrapolation (REx) is a particular domain generalization method that aims to enforce strict equality of risk (i.e., loss) across all training domains (Krueger et al., 2020). This helps guarantee that a model trained with REx will be invariant; i.e., it should also achieve (roughly) the same loss on test domains that are in the *affine span* of the training domains. We focus on REx as the domain generalization method in this paper. However, other domain generalization methods are equally applicable here (Arjovsky et al., 2019).

The resulting "flattening of the risk plane" is demonstrated in Fig. 1a, which shows the evaluation results on a range of OOD datasets using an environment model trained with REx. A simple risk extrapolation approach (**V-REx**) penalizes the variance of the training risks:

$$\mathcal{R}_{\text{V-REx}}(\theta) \doteq \beta \, \text{Var}(\{\mathcal{R}_1(\theta), ..., \mathcal{R}_n(\theta)\}) + \sum_{e=1}^{n} \mathcal{R}_e(\theta) \tag{1}$$

where $\mathcal{R}_e$ is the risk on the e-th domain, and β controls the strength of the variance regularizer.

3.2 Domain-Invariant Model-based Offline RL (DIMORL)

Since DIMORL combines both MOPO and REx, we test it in isolation as well as in conjunction with MOPO's uncertainty penalty term. We use β and λ to denote the REx and MOPO penalty terms, respectively. Environment models $p_{\theta,\phi}(s_{t+1}, r_t | s_t, a_t)$ were trained against multi-demonstrator datasets $\mathcal{D}_{\mathcal{E}} = \bigcup_{e=1}^{M} \mathcal{D}_e$, where the outputs of the models parameterize a Gaussian distribution with diagonal covariance matrix: $\mathcal{N}(s_{t+1}, r_t; \mu_\theta^i(s,a), \Sigma_\phi^i(s,a))$. Individual risks, $\mathcal{R}_e$ were calculated for each demonstrator's data, and REx used to reduce the variance across the demonstrators in the multi-demonstrator dataset. Further details are provided in Appendix A.

4 Experiments

As a proxy for real-world demonstrators, we trained a selection of policies online against the OpenAI Gym MuJoCo Hopper, HalfCheetah and Walker2d environments (Brockman et al., 2016; Todorov et al., 2012) using the soft actor-critic (SAC) algorithm (Haarnoja et al., 2018a;b). Subsets comprising five of these pseudo-demonstrators were used to generate three multi-demonstrator datasets for each environment i.e. Novice, Mixed, and Expert. See Appendix B for details of the SAC pseudo-demonstrators and multi-demonstrator datasets produced.

	Mult-Demonstrator Dataset								
	Novice			Mixed			Experienced		
Environment	**Max Dem. Return**	**DIMORL Return**	(β, λ, h)	**Max Dem. Return**	**DIMORL Return**	(β, λ, h)	**Max Dem. Return**	**DIMORL Return**	(β, λ, h)
HalfCheetah	7663	**9056 ± 122**	(0,1,5)	11032	6687 ± 4888	(0,1,5)	14511	4547 ± 288	(10,5,10)
Hopper	3239	**3482 ± 23**	(20,5,5)	3553	**3569 ± 40**	(20,5,50)	3553	3493 ± 33	(0,5,50)
Walker2D	1587	**1594 ± 1598**	(20,0,10)	5430	2265 ± 141 (2)	(20,0,5)	5430	4796 ± 113	(20,0,10)

Table 1: Environment models trained with REx ($\beta > 0$) yielded policies with the highest average returns in two-thirds of datasets across three MuJoCo environments. For the Novice multi-demonstrator datasets and Hopper Mixed dataset, the policies learned using DIMORL had higher average returns (bolded values) than any of the individual demonstrators used to generate the dataset. The average policy evaluation returns ± one standard deviation over three random seeds are shown, along with the REx penalty coefficient β, MOPO penalty coefficient λ, and roll-out length h used.

4.1 Domain Generalization Performance of Environment Models

We found that environment models trained with REx achieved higher average and worst-case out-of-distribution (OOD) log-likelihoods for each environment and multi-demonstrator dataset. Across all environments, OOD performance was worst for the "Experienced" dataset, and was most greatly improved by the incorporation of REx to model training. As demonstrated by Figure 1b, the average and worst case performance generally continued to improve as the REx penalty coefficient was increased from 5 to 20. While this might encourage the use of larger coefficients, we did not find the domain generalization performance of the models to be well correlated with the average returns of policies trained using them. This is discussed further in Appendix C.

4.2 Offline Agent Training

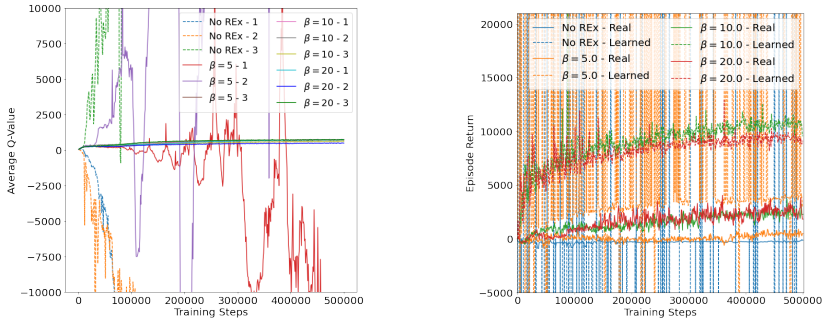
Policies learned using environment models trained with REx obtained the highest average return for two-thirds of multi-demonstrator datasets across the MuJoCo environments investigated. Of these, the largest REx penalty coefficient investigated ($\beta = 20$) yielded the highest return in all but one setting. Across all environments, a policy trained offline obtained a higher average return for the "Novice" multi-demonstrator dataset than any of the individual demonstrators that were used to generate the dataset. However, this was not the case for two of the three "Mixed" datasets, or any of the "Experienced" datasets. Table 1 provides an overview of the results, and the hyperparameter settings used to achieve them. The complete results including further discussion are provided in Appendix D.

We additionally found that environment models trained with REx were more robust to noisy initial state distributions; highlighting the benefits that improved domain generalization performance can bring to policy training (see Appendix F.1). We further attempted to learn policies using roll-out starting locations sampled from datasets that were not used to train the environment models, with the expectation that environment models trained with REx would be much more robust to such distributional shifts. However, no good policies were learned under any settings investigated thus far (see Appending D.2), likely due to the distributional shift being simply too extreme.

4.3 Increased Policy Training Stability

In an attempt to pinpoint the sources of the benefits brought by environment models trained with REx, we analyzed the agent training performance and found that, for the HalfCheetah environment, the Q-functions of soft actor-critic policies were often less prone to becoming degenerate when using REx penalty coefficients $\beta \in \{5, 10\}$. This is demonstrated in Fig. 2. We present two hypotheses regarding the source of the Q-function instability, and why environment models trained with REx may be yielding improvements.

Degenerate Predictions: From the evaluation returns shown in Figure 2b, we know that the reward models can make degenerate predictions, which could lead to instability in Q-function training. However, the returns shown were obtained over 1000 step episodes, whereas in policy training roll-outs of 5-10 steps were typically used. The learned reward models would therefore need to



(a) Average Q-Values

(b) Evaluation Returns

Figure 2: Environment models trained using larger REx penalty coefficients were observed to be more robust to the Q-function being learned as part of SAC policy training becoming degenerate. This is demonstrated by the relative stability of the average Q-values. When evaluating policies against the learned environment model being used to train them, we observe extreme episode returns for those models trained with no or low REx penalty coefficients. Results reported for Mixed HalfCheetah multi-demonstrator dataset, with MOPO penalty coefficient $\lambda = 0$ and roll-out length of $h = 5$.

make degenerate predictions within 5-10 steps to negatively impact Q-function learning. We have observed cases of this occurring (see Appendix E), however it does not appear to be a necessary condition for Q-function instability to occur. Note, rather than the issue lying solely with the reward model, it is likely that errors in the dynamics models will also be contributing by leading the agent into unnatural states. Further analysis of the trajectories produced in the learned environment is necessary.

Environment Model Complexity: The environment model may be less well-behaved and more complex than the real environment. For instance, a small change in the current state could have a large and unpredictable impact on the predicted next state. If we assume the neural network used has sufficient capacity and is provided with sufficient data to capture the real environment, the function approximation component of the classic deadly triad (Sutton & Barto, 2018) would theoretically not be an issue. However, the environment model state representation may fail to capture all quirks in the environment model, resulting in function approximation continuing to be problematic. That is: function approximation is not an issue if we can perfectly approximate the function, and perhaps the actor and critic can manage to do that on the real environment but struggle to do the same for the learned environment model.

4.4 Increased Exploration During Policy Training

In addition to improving the stability of policy training, we hypothesise that the improved domain generalization performance of environment models trained with REx may enable increased exploration of the state-action space, leading to the identification of more optimal policies. To evaluate the extent of exploration during policy training, we used PCA to project transition records into two-dimensions, such that they could be visualised. Initial experiments indicate this technique may hold promise (see Appendix F.2), however further work is necessary to ensure observed differences cannot simply be explained by the fraction of the original data's variance captured by the projection.

5 Conclusions

In this paper, we have highlighted and exploited the opportunity to take advantage of knowledge that static datasets have been collected from multiple demonstrators, which we believe to be the most natural setting. We presented a practical algorithm for Domain-Invariant Model-based Offline RL (DIMORL), and have illustrated that this method may increase the stability of policy learning, enable greater exploration, and yield more optimal policies in many settings. Further experimentation and analysis is needed to validate our findings, and to fully take advantage of the algorithm's potential.

A DIMORL IMPLEMENTATION DETAILS

The MOPO algorithm (Yu et al., 2020) and codebase[2] was used as the basis for DIMORL. Our modified version is outlined in Algorithm 1. We trained environment models $p_{\theta,\phi}(s_{t+1}, r_t|s_t, a_t)$ against multi-demonstrator datasets $\mathcal{D}_{\mathcal{E}} = \bigcup_{e=1}^{M} \mathcal{D}_e$, where the outputs of the models parameterise a Gaussian distribution with diagonal covariance matrix: $\mathcal{N}(s_{t+1}, r_t; \mu_\theta^i(s,a), \Sigma_\phi^i(s,a))$.

Individual negative log-likelihood values, $\mathcal{R}_{nll}^e$, are calculated for each demonstrator's data, $\mathcal{D}_e$. These are then used to calculate the MOPO V-REx loss given by Equation 2, where β is the REx penalty coefficient. $\mathcal{R}_{wr}$ is an ℓ_2 weight regularisation penalty, and $\mathcal{R}_{vb}$ is a loss term relating to the learning of variance bounds. Chua et al. (2018) highlight that outside of the training distribution the predicted variance can assume arbitrary values, and can both collapse to zero or explode to infinity (in contrast to models like GPs where variance values are better behaved). Chua et al. (2018) found that bounding the output variance such that it cannot exceed the range seen in the training data was beneficial, and so include the $\mathcal{R}_{vb}$ penalty.

$$\mathcal{R}_{MOPO\ V\text{-}REx} = \sum_{e=1}^{M} [\mathcal{R}_{nll}^e] + \beta \cdot \text{Var}\left(\mathcal{R}_{nll}^1, \mathcal{R}_{nll}^2, \ldots, \mathcal{R}_{nll}^M\right) + \mathcal{R}_{wr} + \mathcal{R}_{vb} \tag{2}$$

Algorithm 1 DIMORL - an extension of MOPO(Yu et al., 2020) to include REx in environment model training

Require: : MOPO reward penalty coefficient λ, roll-out length h, roll-out batch size b, REx penalty coefficient β

Train on batch data $\mathcal{D}_{\text{env}}$ an ensemble of N probabilistic dynamics models $\{p_{\theta,\phi}(s_{t+1}, r_t|s_t, a_t) = \mathcal{N}(\mu_\theta^i(s,a), \Sigma_\phi^i(s,a))\}_{i=1}^N$ with REx penalty coefficient β
Initialise policy π^{off} and empty replay buffer $\mathcal{D}_{\text{model}} \leftarrow \varnothing$
for epoch $1, 2, \ldots$ **do**
  for $1, 2, \ldots, b$ (in parallel) **do**
    Sample state s_1 from $\mathcal{D}_{\text{env}}$ for the initialisation of the roll-out
    for $j = 1, 2, \ldots, h$ **do**
      Sample an action $a_j \sim \pi(s_j)$
      Randomly pick dynamics $\hat{T}$ from $\{\hat{T}^i\}_{i=1}^N$ and sample $s_{j+1}, r_j \sim \hat{T}(s_j, a_j)$
      Compute $\tilde{r_j} = r_j - \lambda \max_{i=1}^N ||\Sigma_\phi^i(s_j, a_j)||_{\text{F}}$
      Add sample $(s_j, a_j, \tilde{r}_j, s_{j+1})$ to $\mathcal{D}_{\text{model}}$
  Drawing samples from $\mathcal{D}_{\text{env}} \bigcup \mathcal{D}_{\text{model}}$, use SAC to update π^{off}

Environment model training was split into two phases:

1. **ERM:** No REx penalty is used (i.e., $\beta = 0$) until the original MOPO termination condition is reached: the loss on a held-out evaluation dataset does not decrease by more than 1 % for any model in the ensemble for five consecutive epochs Yu et al. (2020).
2. **REx:** Training was then allowed to continue for the same number of epochs completed in the ERM phase, with the REx penalty coefficient now set to a user defined value. We investigated REx penalty coefficients $\beta \in \{0, 5, 10, 20\}$ in our work.

B SAC DEMONSTRATORS AND MULTI-DEMONSTRATOR DATASETS

To proxy for real-world demonstrators (whether humans, or pre-existing control policies), we trained a selection of demonstrator policies, π^e, using online RL algorithms and the OpenAI Gym MuJoCo Hopper, HalfCheetah and Walker2d environments. The sole purpose of these policies was to generate individual demonstrator datasets, $\mathcal{D}_e$, for use in training environment models. To increase data diversity, additional demonstrator datasets are created using a random policy, $\pi^{\mathcal{N}}$. Each

Walker2d	1	4139	4312
Walker2d	2	4134	5430
Walker2d	3	4795	-

Table 2: Two implementations (Softlearning (Haarnoja et al., 2018a;b) and D3RLPY Seno & Imai (2021)) of the online soft actor-critic (SAC) algorithm (Haarnoja et al., 2018a;b) were used to create pseudo-demonstrators by taking snapshots of the policy being learned. As would be expected, the return of the policy generally increases with the amount of training.

dataset comprises N_e transition tuples of the form: (s^e, a^e, s'^e, r^e, e). The unique demonstrator identifier e is used during the training of dynamics models with Risk Extrapolation (REx) to identify individual domains. The identifier is simply a number, and provides no information about the demonstrator. Independently sampled evaluation datasets are also created for each demonstrator. Collections of M individual datasets are combined to produce multi-demonstrator datasets: $\mathcal{D}_{\mathcal{E}} = \{(s_i^e, a_i^e, s_i'^e, r_i^e, e)_{i=1}^{N_e}\}_{e=1}^{M}$.

As a proxy for real-world demonstrators, a selection of soft actor-critic (SAC) (Haarnoja et al., 2018a;b) policies were trained online. To increase the diversity of the demonstrators, we used two different implementations of the SAC algorithm: **Softlearning**, the official SAC implementation (Haarnoja et al., 2018a;b); and **D3RLPY**, which implements a version of SAC with delayed policy updates (Seno & Imai, 2021). Policies were trained using the default hyperparameters provided in their respective repositories. As shown in Table 2, snapshots of each policy were taken at regular intervals during training to emulate demonstrators with varying degrees of skill.

We selected subsets of five pseudo-demonstrators for each MuJoCo environment to produce three multi-demonstrator datasets: Novice, Mixed, and Experienced. As their names indicate, the Novice and Mixed datasets comprised transition records generated using pseudo-demonstrators trained online for minimal and extended number of training steps respectively, while Mixed uses a combination of each. Table 3 shows the individual pseudo-demonstrator policies used to create the datasets. Each policy contributed 20,000 transition records, and so each multi-demonstrator dataset consists of a total of 100,000 records.

C Environment Model OOD Performance

Figure 3 shows the average and worst-case OOD log-likelihoods and mean-squared errors (MSEs) obtained for all MuJoCo environments and multi-demonstrator datasets. Across all environments and multi-demonstrator datasets, environment models trained using REx achieved improved average and worst-case log-likelihoods. The results were more mixed for the MSE values–small increases in MSE were sometimes observed, as can be seen for the Walker2d experienced dataset in Figure 3f.

Environment	Policy Identifier	Multi-Demonstrator Dataset								
		Novice			Mixed			Experienced		
		Type	**Steps**	**Return**	**Type**	**Steps**	**Return**	**Type**	**Steps**	**Return**

Walker2D	5	D3	0.2	**1587**	D3	2	**5430**	D3	2	**5430**

Table 3: Individual demonstrator policies the comprise the Novice, Mixed and Experienced multi-demonstrator datasets, including the return of the policy. Each individual demonstrator contributed 20,000 transition records. *Rand* denotes a random policy, *SL* a policy trained using the Softlearning library, and *D3* a policy trained using the D3RLPY library.

The discrepancy likely arises given it was the variance of log-likelihoods across training domains that was minimised during model training. Future experiments could evaluate the impact of updating the training procedure to minimise the variance of the training MSEs, or both the log-likelihoods and MSEs simultaneously.

Increasing the REx penalty coefficient leads to higher log-likelihood values in the majority of cases. One exception is the peak in worst-case performance that all Hopper multi-demonstrator datasets exhibit when $\beta = 10$. This indicates that the REx penalty coefficient is still a hyperparameter that needs to be appropriately tuned.

C.1 Correlation between Environment Model OOD Performance and Policy Returns

As demonstrated by Figure 4, no correlation is observed between the average OOD log-likelihood of environment models and the average evaluation return of policies trained using them. It should, however, be noted that the distribution of roll-out starting locations differs across the experiments, which will have had an influence on the observed results.

D Offline Training Results

D.1 ID Roll-out Starting Locations

The results of experiments run against multi-demonstrator datasets generated using the HalfCheetah, Hopper and Walker2d environments are shown in Table 4, Table 5 and Table 6 respectively. In all of these experiments, during policy training, roll-out starting locations were drawn from the same dataset used to train the environment model.

As noted in the main text, across all environments, a policy trained offline with DIMORL obtained a higher average return for the Novice multi-demonstrator dataset than any of the individual demonstrators that were used to generate the dataset. The same consistency was not observed for the Mixed or Experienced datasets. This reaffirms the importance of action diversity in offline model-based methods, whereas model-free techniques are potentially better suited to datasets collected from less-diverse, more experienced demonstrators Yu et al. (2020).

We also note the lack of consistency regarding the optimal MOPO penalty coefficient. Yu et al. (2021) highlight the poor calibration between MOPO penalty and actual model error, which is likely responsible for the inconsistency observed.

Dataset	Roll-out Length	MOPO Pen. Coeff, λ	REx Penalty Coefficient, β

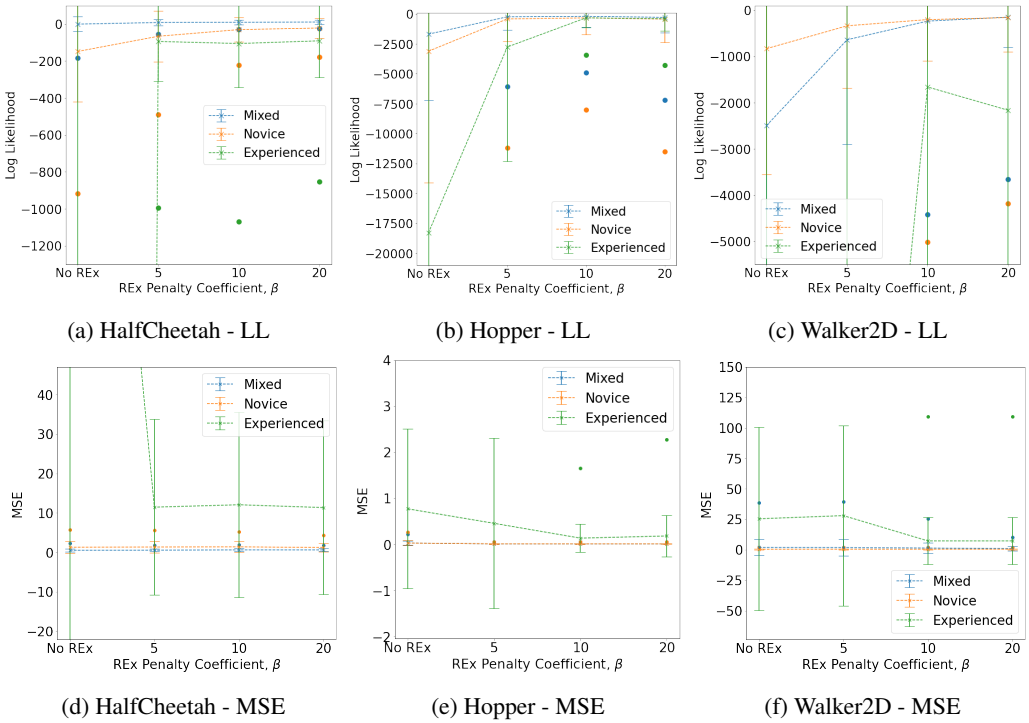
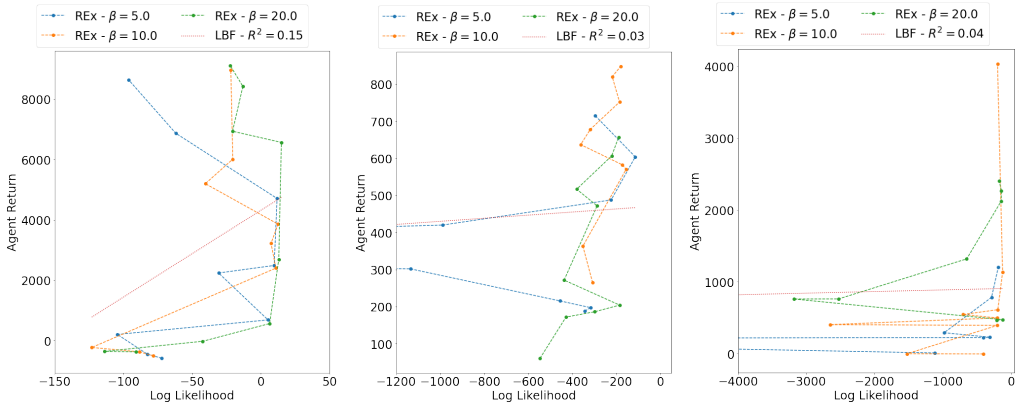
Table 5: Average and standard deviation, over three random seeds, of the evaluation returns for policies learned using dynamics models trained against multi-demonstrator datasets generated from the Hopper environment. The overall highest return for each multi-demonstrator dataset has been bolded. If a value has a number in brackets next to it then only this number of agents completed 1 million steps of training. If there is no value then none of the agents completed 1 million steps of training.



(a) HalfCheetah - LL (b) Hopper - LL (c) Walker2D - LL

(d) HalfCheetah - MSE (e) Hopper - MSE (f) Walker2D - MSE

Figure 3: Environment models trained with REx typically achieve improved average and worst-case out-of-distribution performance, both in terms of log-likelihood (LL) and mean-squared error (MSE).



(a) HalfCheetah (b) Hopper (c) Walker2D

Figure 4: No correlation is observed between the average OOD log-likelihood of environment models and the average evaluation return of policies trained using them. The results shown are for a roll-out length of 5. A line of best fit (LBF) is shown, along with the corresponding R^2 value.

D.2 OOD Roll-out Starting Locations

We refer to roll-out starting locations as being OOD if they are sampled from any dataset other than the one used to train the environment model that is used in policy training. The results of experiments run against multi-demonstrator datasets generated using the HalfCheetah and Hopper environments are shown in Table 7 and Table 8 respectively. roll-out starting locations for these experiments were drawn from the following datasets:

Dataset	Roll-out Length	MOPO Pen. Coeff, λ	REx Penalty Coefficient, β			
			0	**5**	**10**	**20**
Novice	5	0	263 ± 203	412 ± 263	501 ± 89	1068 ± 849

Table 7: Average and standard deviation, over three random seeds, of the evaluation returns for policies learned using dynamics models trained against multi-demonstrator datasets generated from the HalfCheetah environment. During offline policy training with the SAC algorithm, roll-out starting locations were sampled from the indicated dataset. If a value has a number in brackets next to it then only this number of agents completed 0.5 million steps of training. If there is no value then none of the agents completed 0.5 million steps of training.

1. **RAND:** Transitions were generated by taking random actions in the environment.

2. **D4RL-MR:** The D4RL medium-replay datasets for each of the environments (Fu et al., 2020).

Experiments were not run for environment models trained on the HalfCheetah Experienced multi-demonstrator dataset given that (when using MOPO penalty coefficient $\lambda = 0$) no policies were learned when drawing starting locations from the same dataset used to train the models. If policies cannot be learned using in-distribution starting locations, then we do not expect to be able to learn them using OOD starting locations. We are yet to run similar experiments for the Walker2D multi-demonstrator datasets, but we anticipate similar results to those seen for the HalfCheetah and Walker2D datasets (i.e., an inability to learn a policy). Additionally, experiments are still to be run for MOPO penalty coefficients $\lambda > 0$.

Env. Model Train. Dataset	Roll-out Start. Loc. Dataset	Roll-out Length	REx Penalty Coefficient, β 0	5	10	20

Table 8: Average and standard deviation, over three random seeds, of the evaluation returns for policies learned using dynamics models trained against multi-demonstrator datasets generated from the Hopper environment. During offline policy training with the SAC algorithm, roll-out starting locations were sampled from the indicated dataset. If a value has a number in brackets next to it then only this number of agents completed 1 million steps of training. If there is no value then none of the agents completed 1 million steps of training.

E Degenerate Reward Predictions

Figure 5 demonstrates that abnormally large reward predictions can occur within the first 10 steps of episodes generated using environment models trained without REx. Out of the 60 episodes shown in Figure 5, six contained reward predictions with an absolute value exceeding one million. If these episodes are excluded then the largest absolute reward prediction was 12.29. No episodes generated absolute reward predictions greater than 12.29 in the first 5 steps, while 2 episodes did within the first 10 steps. Note that our aim in this experiment was merely to show the possibility of abnormally large reward predictions in the early stages of episodes, not prove that the problem is common/widespread.

F Additional Experiments

F.1 Noisy Roll-out Starting Locations

To further assess the potential benefits of environment models trained with REx, we analysed the impact of adding noise to the roll-out starting locations used during offline policy training. Note that the environment models were trained on the original multi-demonstrator datasets (which have no noise), and starting locations were still sampled from the same dataset used to train the environment models. The only change was that noise with standard deviation $\sigma \in \{0.00, 0.01, 0.05, 0.10\}$ was added to the dataset before starting locations were sampled from it. Figure 6 shows that environment models trained with REx yielded policies with higher average returns across all noise levels for both the HalfCheetah and Hopper environments. For the Walker2D environment, environment models trained with REx penalty coefficients $\beta \in \{10, 20\}$ yielded policies with higher returns. For both HalfCheetah and Hopper environments, the highest policy evaluation return was obtained when $\sigma = 0.01$–suggesting that a small amount of noise was beneficial. We hypothesise that the distribution of noisy starting locations is more diverse, enabling greater exploration. In the case of the Hopper environment, it was the environment model trained without REx that obtained the highest average return for $\sigma = 0.01$, whereas the returns for the equivalent HalfCheetah and Walker2D environment models decreased significantly. This may be thanks to the greater simplicity of the Hopper environment.

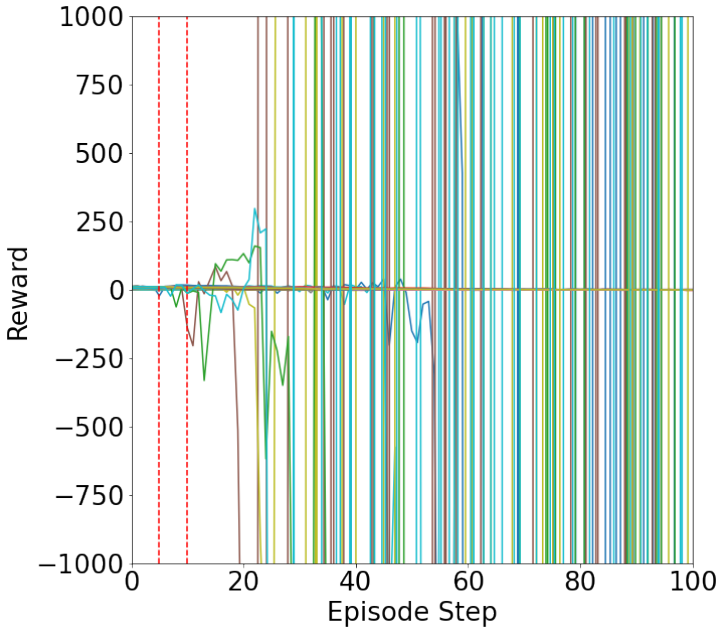

Figure 5: Abnormally large reward predictions can be made within the first 10 steps of an episode. Six different starting locations were randomly sampled from the HalfCheetah Mixed multi-demonstrator dataset. Ten episodes of 1000 steps were then generated from each starting location, using an environment model trained on the HalfCheetah Mixed multi-demonstrator dataset and a policy trained using the same environment model ($\beta = 0, \lambda = 0, h = 10$). For each episode, the rewards at each step over the first 100 steps are shown. The dashed vertical red lines denote the 5 and 10 step marks.

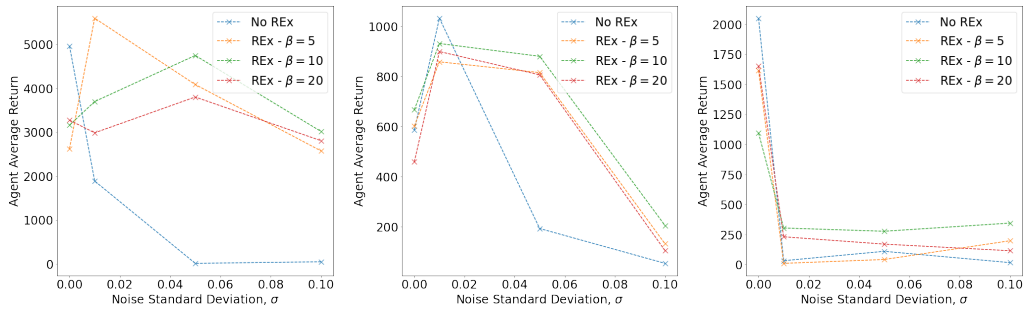

(a) HalfCheetah, $h = 5$ (b) Hopper, $h = 5$ (c) Walker2D, $h = 10$

Figure 6: No correlation is observed between the average OOD log-likelihood of environment models and the average evaluation return of policies trained using them. The results shown are for a roll-out length of 5. A line of best fit (LBF) is shown, along with the corresponding R^2 value.

F.2 Analysis of Training Exploration using PCA

In an attempt to determine whether environment models trained with REx supported increased exploration of the state-action space during policy training, we investigated the use of PCA to project transition records into two-dimensions, such that they could be visualised. For experiments using the Gym MuJoCo HalfCheetah environment, we sampled 100,000 transition records from the model pool every 100,000 training steps, excluding the zeroth and final training steps. Figure 7 shows the projections for a set of six policy training experiments, using the Mixed dataset and $\beta \in \{0, 10\}$. The projection matrix was trained on the complete collection of sampled transition records for the six experiments. Note that, unlike all other experiments in this paper, the environment models used in these experiments received one additional epoch of training prior to being used to learn a policy. This is the default behaviour of the MOPO codebase when utilising pre-trained environment models (Yu et al., 2020). The average return for the experiments that did not use an environment model trained with REx was -420 ± 50, while for the REx experiments it was 8128 ± 1053. The projected records appear to indicate that increased exploration of the state-action space took place when using an environment model trained with REx. It is important to recognise, however, that the projections for REx experiments have higher explained variance, which may partially or fully explain the observed difference. The results will of course be sensitive to the datasets used to learn the projection matrix. We believe that further investigation of this method is warranted.

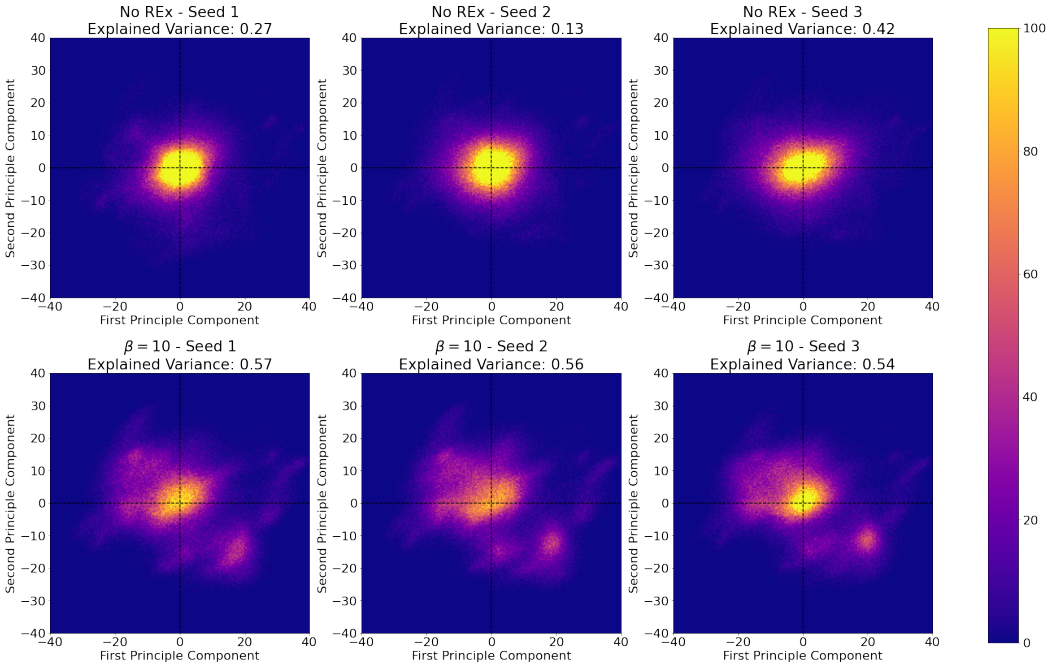

Figure 7: A 2D projection of state-action pairs sampled from the model pool during policy training appears to indicate that increased exploration of the space took place when using an environment model trained with REx ($\beta = 10$). It is important to recognise, however, that the projections for REx experiments have higher explained variance, which may partially or fully explain the observed difference. The projection matrix was trained on the complete collection of sampled transition records for the six experiments shown. MOPO penalty coefficient $\lambda = 5$ and roll-out length $h = 10$ were used.
