Ensembles of models often yield improvements in system performance. These ensemble approaches have also been empirically shown to yield robust measures of uncertainty, and are capable of distinguishing between different forms of uncertainty. However, ensembles come at a computational and memory cost which may be prohibitive for many applications. There has been significant work done on the distillation of an ensemble into a single model. Such approaches decrease computational cost and allow a single model to achieve an accuracy comparable to that of an ensemble. However, information about the diversity of the ensemble, which can yield estimates of different forms of uncertainty, is lost. This work considers the novel task of Ensemble Distribution Distillation (EnD$^2$) — distilling the distribution of the predictions from an ensemble, rather than just the average prediction, into a single model. EnD$^2$ enables a single model to retain both the improved classification performance of ensemble distillation as well as information about the diversity of the ensemble, which is useful for uncertainty estimation. A solution for EnD$^2$ based on Prior Networks, a class of models which allow a single neural network to explicitly model a distribution over output distributions, is proposed in this work. The properties of EnD$^2$ are investigated on both an artificial dataset, and on the CIFAR-10, CIFAR-100 and TinyImageNet datasets, where it is shown that EnD$^2$ can approach the classification performance of an ensemble, and outperforms both standard DNNs and Ensemble Distillation on the tasks of misclassification and out-of-distribution input detection.

1 Introduction

Neural Networks (NNs) have emerged as the state-of-the-art approach to a variety of machine learning tasks (LeCun et al., 2015) in domains such as computer vision (Girshick, 2015; Simonyan & Zisserman, 2015; Villegas et al., 2017), natural language processing (Mikolov et al., 2013b; 2010), speech recognition (Hinton et al., 2012; Hannun et al., 2014) and bio-informatics (Caruana et al., 2015; Alipanahi et al., 2015). Despite impressive supervised learning performance, NNs tend to make over-confident predictions (Lakshminarayanan et al., 2017) and, until recently, have been unable to provide measures of uncertainty in their predictions. As NNs are increasingly being applied to safety-critical tasks such as medical diagnosis (De Fauw et al., 2018), biometric identification (Schroff et al., 2015) and self driving cars, estimating uncertainty in model’s predictions is crucial, as it enables the safety of an AI system (Amodei et al., 2016) to be improved by acting on the predictions in an informed manner.

Ensembles of NNs are known to yield increased accuracy over a single model (Murphy, 2012), allow useful measures of uncertainty to be derived (Lakshminarayanan et al., 2017), and also provide defense against adversarial attacks (Smith & Gal, 2018). There is both a range of Bayesian Monte-Carlo approaches (Gal & Ghahramani, 2016; Welling & Teh, 2011; Garipov et al., 2018; Maddox et al., 2019), as well as non-Bayesian approaches, such as random-initialization (Lakshminarayanan et al., 2017) and bagging (Murphy, 2012; Osband et al., 2016), to generating ensembles. Crucially, ensemble approaches allow total uncertainty in predictions to be decomposed into knowledge uncertainty and data uncertainty. Data uncertainty is the irreducible uncertainty in predictions which arises due to the complexity, multi-modality and noise in the data. Knowledge uncertainty, also known as epistemic uncertainty (Gal, 2016) or distributional uncertainty (Malinin & Gales, 2018), is uncertainty due to a lack of understanding or knowledge on the part of the model regarding the current input for which the model is making a prediction. In other words, this form of uncertainty arises when the test input $x^*$
comes from a different distribution than the one that generated the training data. Mismatch between
the test and training distributions is also known as a dataset shift (Quinonero-Candela, 2009), and is a
situation which often arises for real world problems. Distinguishing between sources of uncertainty is
important, as in certain machine learning applications it may be necessary to know not only whether
the model is uncertain, but also why. For instance, in active learning, additional training data should
be collected from regions with high knowledge uncertainty, but not data uncertainty.

A fundamental limitation of ensembles is that the computational cost of training and inference can be
many times greater than that of a single model. One solution is to distill an ensemble of models into a
single model to yield the mean predictions of the ensemble (Hinton et al., 2015; Korattikara Balan
et al., 2015). However, this collapses an ensemble of conditional distributions over classes into a
single point-estimate conditional distribution over classes. As a result, information about the diversity
of the ensemble is lost. This prevents measures of knowledge uncertainty, such as mutual information
(Malinin & Gales, 2018; Depeweg et al., 2017), from being estimated.

In this work, we investigate the explicit modelling of the distribution over the ensemble predictions,
rather than just the mean, with a single model. This problem — referred to as Ensemble Distribution
Distillation (EnD^2) — yields a method that preserves both the distributional information and improved
classification performance of an ensemble within a single neural network model. It is important to
highlight that Ensemble Distribution Distillation is a novel task which, to our knowledge, has not
been previously investigated. Here, the goal is to extract as much information as possible from an
ensemble of models and retain it within a single, possibly simpler, model. As an initial solution to
this problem, this paper makes use of a recently introduced class of models, known as Prior Networks
(Malinin & Gales, 2018, 2019), which explicitly model a conditional distribution over categorical
distributions by parameterizing a Dirichlet distribution. Within the context of EnD^2 this effectively
allows a single model to emulate the complete ensemble.

The contributions of this work are as follows. Firstly, we define the task of Ensemble Distribution
Distillation (EnD^3) as a new challenge for machine learning research. Secondly, we propose and
evaluate a solution to this problem using Prior Networks. EnD^2 is initially investigated on artificial
data, which allows the behaviour of the models to be visualized. It is shown that distribution-
distilled models are able to distinguish between data uncertainty and knowledge uncertainty. Finally,
EnD^2 is evaluated on CIFAR-10, CIFAR-100 and TinyImageNet datasets, where it is shown that
EnD^2 yields models which approach the classification performance of the original ensemble and
outperform standard DNNs and regular Ensemble Distillation (EnD) models on the tasks of identifying
misclassifications and out-of-distribution (OOD) samples.

2 Ensembles

In this work, a Bayesian viewpoint on ensembles is adopted, as it provides a particularly elegant probabilistic framework, which allows knowledge uncertainty to be linked to Bayesian model uncertainty. However, it is also possible to construct ensembles using a range of non-Bayesian approaches. For example, it is possible to explicitly construct an ensemble of M models by training on the same data with different random seeds (Lakshminarayanan et al., 2017) and/or different model architectures. Alternatively, it is possible to generate ensembles via Bootstrap methods (Murphy, 2012, Osband et al., 2016) in which each model is trained on a re-sampled version of the training data. The essence of Bayesian methods is to treat the model parameters \( \theta \) as random variables and place a prior distribution \( p(\theta) \) over them to compute a posterior distribution \( p(\theta|D) \) via Bayes’ rule:

\[
p(\theta|D) = \frac{p(D|\theta)p(\theta)}{p(D)} \propto p(D|\theta)p(\theta)
\]

Here, model uncertainty is captured in the posterior distribution \( p(\theta|D) \). Consider an ensemble of models \( \{P(y|x^*, \theta^{(m)})\}_{m=1}^{M} \) sampled from the posterior:

\[
\{P(y|x^*, \theta^{(m)})\}_{m=1}^{M} \rightarrow \{P(y|\pi^{(m)})\}_{m=1}^{M}, \quad \pi^{(m)} = f(x^*; \theta^{(m)}), \quad \theta^{(m)} \sim p(\theta|D)
\]

where \( \pi \) are the parameters of a categorical distribution \( \{P(y = \omega_1), \cdots, P(y = \omega_K)\} \). The expected predictive distribution for a test input \( x^* \) is obtained by taking the expectation with respect to the model posterior:

\[
P(y|x^*, D) = \mathbb{E}_{p(\theta|D)}[P(y|x^*, \theta)]
\]
Each of the models $P(y|x^*, \theta^{(m)})$ yields a different estimate of data uncertainty. Uncertainty in predictions due to model uncertainty is expressed as the level of spread, or ‘disagreement’, of an ensemble sampled from the posterior. The aim is to craft a posterior $p(\theta|D)$, via an appropriate choice of prior $p(\theta)$, which yields an ensemble that exhibits the set of behaviours described in figure 1. Specifically, for an in-domain test input $x^*$, the ensemble should produce a consistent set of predictions with little spread, as described in figure 1a and figure 1b. In other words, the models should agree in their estimates of data uncertainty. On the other hand, for inputs which are different from the training data, the models in the ensemble should ‘disagree’ and produce a diverse set of predictions, as shown in figure 1c. Ideally, the models should yield increasingly diverse predictions as input $x^*$ moves further away from the training data. If an input is completely unlike the training data, then the level of disagreement should be significant. Hence, the measures of model uncertainty will capture knowledge uncertainty given an appropriate choice of prior.

Given an ensemble $\{P(y|x^*, \theta^{(m)})\}_{m=1}^{M}$ which exhibits the desired set of behaviours, the entropy of the expected distribution $P(y|x^*, D)$ can be used as a measure of total uncertainty in the prediction. Uncertainty in predictions due to knowledge uncertainty can be assessed via measures of the spread, or ‘disagreement’, of the ensemble such as Mutual Information:

$$I[y, \theta|x^*, D] = \mathcal{H}[E_{p(\theta|D)}[P(y|x^*, \theta)]] - E_{p(\theta|D)}[\mathcal{H}[P(y|x^*, \theta)]]$$

This formulation of mutual information allows the total uncertainty to be decomposed into knowledge uncertainty and expected data uncertainty. The entropy of the expected distribution, or total uncertainty, will be high whenever the model is uncertain - both in regions of severe class overlap and out-of-domain. However, the difference of the entropy of the expected posterior and the expected entropy of the posterior will be non-zero only if the models disagree. For example, in regions of class overlap, each member of the ensemble will yield a high entropy posterior (figure 1d) - the entropy of the expected and the expected entropy will be similar and mutual information will be low. In this situation total uncertainty is dominated by data uncertainty. On the other hand, for out-of-domain inputs the ensemble yields diverse posterior distributions over classes such that the expected posterior over classes is near uniform (figure 1c), while the expected entropy may be much lower. In this region of input space the models’ understanding of data is low and, therefore, knowledge uncertainty is high.

3 ENSemble DISTRIBUTION Distillation

Previous work [Hinton et al., 2015; Korattikara Balan et al., 2015; Wong & Gales, 2017; Wang et al., 2018] has investigated distilling a single large network into a smaller one and an ensemble of networks into a single neural network. In general, distillation is done by minimizing the KL-divergence between the model and the expected predictive distribution of an ensemble:

$$\mathcal{L}(\theta_{\text{end}}, D_{\text{ens}}) = -E_{p(x)}\left[\text{KL}[E_{p(\theta|D)}[P(y|x; \theta)] \parallel P(y|x; \theta_{\text{end}})]\right]$$

This approach essentially aims to train a single model that captures the mean of an ensemble, allowing the model to achieve a higher classification performance at a far lower computational cost. However, the limitation of this approach with regards to uncertainty estimation is that the information about the diversity of the ensemble is lost. As a result, it is no longer possible to decompose total uncertainty into knowledge uncertainty and data uncertainty via mutual information as in equation 4. In this work
we propose the task of Ensemble Distribution Distillation, where the goal is to capture not only the mean of the ensemble, but also its diversity. In this section, we outline an initial solution to this task.

An ensemble of models can be viewed as a set of samples from an implicit distribution of output distributions:

$$\{ P(y|x^*, \theta^{(m)}) \}_{m=1}^{M} \rightarrow \{ P(y|\pi^{(m)}) \}_{m=1}^{M}, \quad \pi^{(m)} \sim p(\pi|x^*, D)$$

(6)

Recently, a new class of models was proposed, called Prior Networks (Malinin & Gales, 2018; 2019), which explicitly parameterize a conditional distribution over output distributions $p(\pi|x^*, \theta)$ using a single neural network. Thus, a Prior Network is able to effectively emulate an ensemble, and therefore yield the same measures of uncertainty. A Prior Network $p(\pi|x^*, \hat{\theta})$ models a distribution over categorical output distributions by parameterizing the Dirichlet distribution.

$$p(\pi|x; \hat{\theta}) = \text{Dir}(\pi|\hat{\alpha}), \quad \hat{\alpha} = f(x; \hat{\theta})$$

(7)

The distribution is parameterized by its concentration parameters $\alpha$, which can be obtained by placing an exponential function at the output of a Prior Network: $\hat{\alpha}_c = e^{z_c}$, where $z$ are the logits predicted by the model. While a Prior Network could, in general, parameterize arbitrary distributions over categorical distributions, the Dirichlet is chosen due to its tractable analytic properties, which allow closed form expressions for all measures of uncertainty to be obtained. However, it is important to note that the Dirichlet distribution may be too limited to fully capture the behaviour of an ensemble and other distributions may need to be considered.

In this work we consider how an ensemble, which is a set of samples from an implicit distribution over distributions, can be distribution distilled into an explicit distribution over distributions modelled using a single Prior Network model, ie: $\{ P(y|x; \theta^{(m)}) \}_{m=1}^{M} \rightarrow p(\pi|x; \hat{\theta})$.

This is accomplished in several steps. Firstly, a transfer dataset $D_{\text{ens}} = \{ x_i, \pi_i^{(1:M)} \}_{i=1}^{N} = \hat{p}(x, \pi)$ is composed of the inputs $x_i$ from the original training set $D = \{ x_i, y_i \}_{i=1}^{N}$ and the categorical distributions $\{ \pi_i^{(1:M)} \}_{i=1}^{N}$ derived from the ensemble for each input. Secondly, given this transfer set, the model $p(\pi|x; \theta)$ is trained by minimizing the negative log-likelihood of each categorical distribution $\pi_i^{(m)}$:

$$\mathcal{L}(\theta, D_{\text{ens}}) = -E_{p(x)}[E_{p(\pi|x)}[\ln p(\pi|x; \theta)]]$$

(8)

Thus, Ensemble Distribution Distillation with Prior Networks is a straightforward application of maximum-likelihood estimation to Prior Network models. Given a distribution-distilled Prior Network, the predictive distribution is given by the expected categorical distribution under the Dirichlet prior:

$$P(y|x^*, \hat{\theta}) = E_{p(\pi|x^*, \hat{\theta})}[P(y|\pi)] = \hat{\pi}$$

(9)

Separable measures of uncertainty can be obtained by considering the mutual information between the prediction $y$ and the parameters of $\pi$ of the categorical:

$$\frac{\mathcal{M}I[y, \pi|x^*, \hat{\theta}]}{\text{Knowledge Uncertainty}} = \frac{\mathcal{H}[E_{p(\pi|x^*, \hat{\theta})}[P(y|\pi)]]}{\text{Total Uncertainty}} - \frac{E_{p(\pi|x^*, \hat{\theta})}[\mathcal{H}[P(y|\pi)]]}{\text{Expected Data Uncertainty}}$$

(10)

Similar to equation [4], this expression allows total uncertainty, given by the entropy of the expected distribution, to be decomposed into data uncertainty and knowledge uncertainty. If Ensemble Distribution Distillation is completely successful, then the measures of uncertainty derivable from a distribution-distilled Prior Network should be identical to those derived from the original ensemble.

### 3.1 Temperature Annealing

Minimization of the negative log-likelihood of the model on the transfer dataset $D_{\text{ens}} = \{ x_i, \pi_i^{(1:M)} \}_{i=1}^{N}$ is equivalent to minimization of the KL-divergence between the model and the empirical distribution $\hat{p}(x, \pi)$. On training data, this distribution is often 'sharp' at one of the corners of the simplex. At the same time, the Dirichlet distribution predicted by the model has its mode near the center of the simplex with little support at the corners at initialization. Thus, the common support between the model and the target empirical distribution is limited. Optimization of the KL-divergence...
between distributions with limited non-zero common support is particularly difficult. To alleviate this issue, and improve convergence, the proposed solution is to use temperature to ‘heat up’ both distributions and increase common support by moving the modes of both distributions closer together. The empirical distribution is ‘heated up’ by raising the temperature $T$ of the softmax of each model in the ensemble in the same way as in (Hinton et al., 2015). This moves the predictions of the ensemble closer to the center of the simplex and decreases their diversity, making it better modelled by a sharp Dirichlet distribution. The output distribution of the EnD$^2$ model $p(\pi|\mathbf{x}; \mathbf{\theta})$ is heated up by raising the temperature of the concentration parameters: $\hat{\alpha}_c = e^{z_c}/T$, making support more uniform across the simplex. An annealing schedule is used to re-emphasize the diversity of the empirical distribution and return it to its ‘natural’ state by lowering the temperature down to 1 as training progresses.

4 Experiments on Artificial Data

The current section investigates Ensemble Distribution Distillation (EnD$^2$) on an artificial dataset shown in figure 2. This dataset consists of three spiral arms extending from the center with both increasing noise and distance between the arms. Each arm corresponds to a single class. This dataset is chosen such that it is not linearly separable and requires a powerful model to correctly model the decision boundaries, and also such that there are definite regions of class overlap.

In the following set of experiments, an ensemble of 100 neural networks is constructed by training neural networks from 100 different random initializations. A smaller (sub) ensemble of only 10 neural networks is also considered. The models are trained on 3000 data-points sampled from the spiral dataset, with 1000 examples per class. The classification performance of EnD$^2$ is compared to the performance of individual neural networks, the overall ensemble and regular Ensemble Distillation (EnD). The results are presented in table 1.

Table 1: Classification Performance (% Error) on $D_{test}$ of size 1000, trained on $D_{trn}$ of size 1000 with 3 spiral classes. Dataset sizes given as number of examples per class.

<td>12.47</td>
</tr>
</tbody>
</table>

The results show that an ensemble of 10 models has a clear performance gain compared to the mean performance of the individual models. An ensemble of 100 models has a smaller performance gain over an ensemble of only 10 models. Ensemble Distillation (EnD) is able to recover the classification performance of both an ensemble of 10 and 100 models with only very minor degradation in performance. Finally, Ensemble Distribution Distillation is also able to recover most of the performance gain of an ensemble, but with a slightly larger degradation. This is likely due to forcing a single model to learn not only the mean, but also the distribution around it, which likely requires more capacity from the network. The measures of uncertainty derived from an ensemble of 100 models and from Ensemble Distribution Distillation are presented in figures 3a-c and figures 3d-f, respectively. The results show that EnD$^2$ successfully captures data uncertainty and also correctly decomposes total uncertainty into knowledge uncertainty and data uncertainty. However, it fails to appropriately
capture knowledge uncertainty further away from the training region, as there are obvious dark holes in figure (g), where the model yields low knowledge uncertainty far from the region of training data.

In order to overcome these issues, a thick ring of inputs far from the training data was sampled as depicted in figure (b). The predictions of the ensemble were obtained for these input points and used as additional auxiliary training data $D_{aux}$. Table 2 shows how using the auxiliary training data affects the performance of the Ensemble Distillation and Ensemble Distribution Distillation. There is a minor drop in performance of both distillation approaches. However, the overall level of performance is not compromised and is still higher than the average performance of each individual DNN model.

The behaviour of measures of uncertainty derived from Ensemble Distribution Distillation with auxiliary training data ($\text{EnD}^2_{aux}$) is shown in figures (g)-(i). These results show that successful Ensemble Distribution Distillation of the out-of-distribution behaviour of an ensemble based purely on observations of the in-domain behaviour is challenging and may require the use additional training data. This is compounded by the fact that the diversity of an ensemble on training data that the model has seen is typically smaller than on a heldout test-set.

5 Experiments on Image Data

Having confirmed the properties of EnD\(^2\) on an artificial dataset, we now investigate Ensemble Distribution Distillation on the CIFAR-10 (C10), CIFAR-100 (C100) and TinyImageNet (TIM) (Krizhevsky, 2009; CS231N, 2017) datasets. Similarly to section 4, an ensemble of a 100 models is constructed by training NNs on C10/100/TIM data from different random initializations. The transfer dataset is constructed from C10/100/TIM inputs and ensemble logits to allow for temperature annealing during training, which we found to be essential to getting EnD\(^2\) to train well. In addition, we also consider Ensemble Distillation and Ensemble Distribution Distillation on a transfer set that contains both the original C10/C100/TIM training data and auxiliary (AUX) data taken from the other dataset\(^1\) termed EnD\(^{+}\)AUX and EnD\(^2\)AUX, respectively. It is important to note that the auxiliary data has been treated in the same way as main data during construction of the transfer set and distillation. This offers an advantage over traditional Prior Network training (Malinin & Gales, 2018, 2019), where the knowledge of which examples are in-domain and out-of-distribution is required a-priori. For Ensemble Distribution Distillation, models can be distribution-distilled using any (potentially unlabeled) auxiliary data on which ensemble predictions can be obtained. Note that in these experiments we explicitly chose to use the simpler VGG-16 (Simonyan & Zisserman, 2015) architecture rather than more modern architectures like ResNet (He et al., 2016) as the goal of this work is to analyze the properties of Ensemble Distribution Distillation in a clean and simple configuration. The datasets and training configurations for all models are detailed in appendix A.

Firstly, we investigate the ability of a single model to retain the ensemble’s classification and prediction-rejection (misclassification detection) performance after either Ensemble Distillation (EnD) or Ensemble Distribution Distillation (EnD\(^2\)), with results presented in table 3 in terms of error rate and prediction rejection ratio (PRR), respectively. A higher PRR indicates that the model is able to better detect and reject incorrect predictions based on measures of uncertainty. This metric is detailed in appendix B. Additional analysis of test-set negative log-likelihood and calibration can be found in appendix D.

Table 3 shows that both EnD and EnD\(^2\) are able to retain both the improved classification and prediction-rejection performance of the ensemble relative to individual models trained with maximum likelihood on all datasets, both with and without auxiliary training data. Note, that on C100 and TIM, EnD\(^2\) yields better classification performance than EnD. Furthermore, EnD\(^2\) also either consistently outperforms or matches EnD in terms of PRR on all datasets, both with and without auxiliary training data. This suggests that EnD\(^2\) is able to yield benefits on top of standard Ensemble Distillation due to retaining information about the diversity of the ensemble.

Ensemble Distribution Distillation was also investigated on the task of out-of-domain (OOD) input detection (Hendrycks & Gimpel, 2016), where measures of uncertainty are used to classify inputs as either ID or OOD. The ID examples are the test set of C100/TIM, and the test OOD examples are chosen to be the test sets of LSUN (Yu et al., 2015), C100 or TIM, such that the test OOD data is never seen by the model during training.

Table 4 shows that, the measures of uncertainty derived from the ensemble outperform those from a single neural network. Curiously, standard ensemble distillation (EnD) clearly fails to capture those gains, both with and without auxiliary training data. The difference in OOD detection performance

\footnote{\textsuperscript{1}The auxiliary training data for CIFAR-10 is CIFAR-100, and CIFAR-10 for CIFAR-100/TinyImageNet.}
between EnD and the ensemble is greater on C100 than on C10 and TIM. Furthermore, EnD often performs worse than the individuals models. At the same time, Ensemble Distribution Distillation is generally able to reproduce the OOD detection performance of the ensemble. When auxiliary training data is used, EnD$^2$ is able to perform on par with the ensemble, indicating that it has successfully learned how the distribution of the ensemble behaves on unfamiliar data. These results further suggest that EnD$^2$ is able to preserve information about the diversity of an ensemble, unlike standard EnD, and this information is important to good OOD detection performance.

Curiously, the ensemble sometimes displays better OOD detection performance using measures of total uncertainty. At the same time, EnD$^2$, especially with auxiliary training data, tends to have better OOD detection performance using measures of knowledge uncertainty. This may be due to the use of a Dirichlet output distribution, which may not be able to fully capture the details of the ensemble’s behaviour. Furthermore, as EnD$^2$ is (implicitly) trained by minimizing the forward KL-divergence, which is zero-avoiding (Murphy, 2012), it is likely that the distribution learned by the model is ‘wider’ than the empirical distribution. This effect is explored in more detail in appendix C.

6 CONCLUSION

Ensemble Distillation approaches have become popular, as they allow a single model to achieve classification performance comparable to that of an ensemble at a lower computational cost. This work proposes the novel task Ensemble Distribution Distillation (EnD$^2$) — distilling an ensemble into a single model, such that it exhibits both the improved classification performance of the ensemble and retains information about its diversity. An approach to EnD$^2$ based on using Prior Network models is considered in this work. Experiments described in sections 4 and 5 show that on both artificial data and image classification tasks it is possible to distribution distill an ensemble into a single model such that it retains the classification performance of the ensemble. Furthermore, measures of uncertainty provided by EnD$^2$ match the behaviour of an ensemble of models on artificial data, and the model is able to differentiate between different types of uncertainty. However, this required obtaining auxiliary training data on which the ensemble is more diverse in order to allow the distribution-distilled model to learn appropriate out-of-domain behaviour. On image classification tasks measures of uncertainty derived from EnD$^2$ allow the model to outperform both single NNs and EnD models on the tasks of misclassification and out-of-distribution input detection. These results are promising, and show that Ensemble Distribution Distillation enables a single model to capture more useful properties of an ensemble than standard Ensemble Distillation. Future work should further investigate properties of temperature annealing, investigate ways to enhance the diversity of an ensemble, consider different sources of ensembles and model architectures, and examine more flexible output distributions.

All models considered in this work were implemented in Pytorch \cite{Paszke2017} using a variant of the VGG16 \cite{Simonyan2015} architecture for image classification. DNN and EnD models were trained using the negative log-likelihood loss of the labels and the mean ensemble predictions respectively. EnD$^2$ models were trained using the negative log-likelihood of the ensemble’s output categorical distributions. All models were trained using the Adam \cite{Kingma2015} optimizer, with a 1-cycle learning rate policy and dropout regularization. For all ensembles, models were trained using different random seed initialization, and using different seeds for shuffling the data. In addition, data augmentation was applied via random left-right flips, random shifts up to $\pm 4$ pixels and random rotations by up to $\pm 15$ degrees. Tables e6 details the training configurations for all models.

Table 6: Training Configurations. $\eta_0$ is the initial learning rate, $T_0$ is the initial temperature and ‘Annealing’ refers to whether a temperature annealing schedule was used. The batch size for all models was 128. Dropout rate is quoted in terms of probability of not dropping out a unit.

</table>

Temperature of 2.5 was used for Ensemble Distillation as recommended in \cite{Hinton2015}, and was found to yield the best classification performance out of \{1, 2, 5, 10\}. Temperature annealing resulted in worse classification performance for Ensemble Distillation, and hence was not used in the experiments. Equivalently, for Ensemble Distribution Distillation, we found that an initial temperature of 10 performed best out of \{5, 10, 20\}. Furthermore, batch normalisation was used for both Ensemble Distillation and Ensemble Distribution Distillation.

To create the transfer set $D_{aux}$, ensembles were evaluated on the unaugmented CIFAR-10 and CIFAR-100 training examples. During distillation (both EnD and EnD$^2$), models were trained on the augmented examples with the ensemble predictions on the corresponding unaugmented inputs.
APPENDIX B ASSESSING MISCLASSIFICATION DETECTION PERFORMANCE

In this work measures of uncertainty are used for two practical applications of uncertainty - misclassification detection and out-of-distribution sample detection. Both can be seen as an outlier detection task based on measures of uncertainty, where misclassifications are one form of outlier and out-of-distribution inputs are another form of outlier. These tasks can be formulated as threshold-based binary classification \cite{HendrycksG16}. Here, a detector \( I_T(x) \) assigns the label 1 (uncertain prediction) if an uncertainty measure \( \mathcal{H}(x) \) is above a threshold \( T \), and label 0 (confident prediction) otherwise. This uncertainty measure can be any of the measures discussed in sections 2 and 3.

\[
I_T(x) = \begin{cases} 1, & \mathcal{H}(x) > T \\ 0, & \mathcal{H}(x) \leq T \end{cases}
\tag{11}
\]

Given a set of true positive examples \( D_p = \{x_p^{(i)}\}_{i=1}^{N_p} \) and a set of true negative examples \( D_n = \{x_n^{(j)}\}_{j=1}^{N_n} \) the performance of such a detection scheme can be evaluated at a particular threshold value \( T \) using the true positive rate \( t_p(T) \) and the false positive rate \( f_p(T) \):

\[
t_p(T) = \frac{1}{N_p} \sum_{i=1}^{N_p} I_T(x_p^{(i)}) \quad f_p(T) = \frac{1}{N_n} \sum_{j=1}^{N_n} I_T(x_n^{(j)})
\tag{12}
\]

The range of trade-offs between the true positive and the false positive rates can be visualized using a Receiver-Operating-Characteristic (ROC) and the quality of the possible trade-offs can be summarized using the area under the ROC curve (AUROC) \cite{Murphy12}. If there are significantly more negatives than positives, however, this measure will over-estimate the performance of the model and yield a high AUROC value \cite{Murphy12}. In this situation it is better to calculate the precision and recall of this detection scheme at every threshold value and plot them against each other on a Precision-Recall (PR) curve \cite{Murphy12}. The recall \( R(T) \) is equal to the true positive rate \( t_p(T) \), while precision measures the number of true positives among all samples labelled as positive:

\[
P(T) = \frac{\sum_{i=1}^{N_p} I_T(x_p^{(i)})}{\sum_{i=1}^{N_p} I_T(x_p^{(i)}) + \sum_{j=1}^{N_n} I_T(x_n^{(j)})} \quad R(T) = \frac{1}{N_p} \sum_{i=1}^{N_p} I_T(x_p^{(i)})
\tag{13}
\]

The quality of the trade-offs can again be summarized via the area under the PR curve (AUPR). For both the ROC and the PR curves an ideal detection scheme will achieve an AUC of 100%. A completely random detection scheme will have an AUROC of 50% and the AUPR will be the ratio of the number of positive examples to the total size of the dataset (positive and negative) \cite{Murphy12}. Thus, the recall is given by the error rate of the classifier. This makes it difficult to compare different models with different base error rates, as AUPR can increase both due to better misclassification detection and worse error rates.

In this work we propose an alternative to using AUPR to assess misclassification detection performance. Consider the task of misclassification detection - ideally we would like to detect all of the inputs which the model has misclassified based on a measure of uncertainty. Then, the model can either choose to not provide any prediction for these inputs, or they can be passed over or ‘rejected’ to an oracle (ie: human) to obtain the correct prediction. The latter process can be visualized using a rejection curve depicted in figure 4, where the predictions of the model are replaced with predictions provided by an oracle in some particular order based on estimates of uncertainty. If the estimates of uncertainty are ‘useless’, then, in expectation, the rejection curve would be a straight line from base error rate to the lower right corner. However, if the estimates of uncertainty are ‘perfect’ and always bigger for a misclassification than for a correct classification, then they would produce the ‘oracle’ rejection curve. The ‘oracle’ curve will go down linearly to 0% classification error at the percentage of rejected examples equal to the number of misclassifications. A rejection curve produced by estimates of uncertainty which are not perfect, but still informative, will sit between the ‘random’ and ‘oracle’ curves.

The quality of the rejection curve can be assessed by considering the ratio of the area between the ‘uncertainty’ and ‘random’ curves \( AR_{uns} \) (orange in figure 4) and the area between the ‘oracle’ and ‘random’ curves \( AR_{orc} \) (blue in figure 4). This yields the rejection area ratio \( RR \):

\[
RR = \frac{AR_{uns}}{AR_{orc}}
\tag{14}
\]
A rejection area ratio of 1.0 indicates optimal rejection, a ratio of 0.0 indicates ‘random’ rejection. A negative rejection ratio indicates that the estimates of uncertainty are ‘perverse’ - they are higher for accurate predictions than for misclassifications. An important property of this performance metric is that it is independent of classification performance, unlike AUPR, and thus it is possible to compare models with different base error rates.

APPENDIX C  APPROPRIATENESS OF DIRICHLET DISTRIBUTION

Throughout this work, a Prior Network that parametrizes a Dirichlet was used for distribution-distilling ensembles of models. However, the output distributions of an ensemble for the same input are not necessarily Dirichlet-distributed, especially in regions where the ensemble is diverse. Thus, in this appendix we investigate how well a model which parameterized a Dirichlet distribution is able to capture the exact behaviour of an ensemble of models, both in-domain and out-of-distribution.

To check how well EnD\textsuperscript{2} captures the ensemble distribution, two histograms showing the example count with a given uncertainty for the CIFAR-10 ensemble and EnD\textsuperscript{2}\textsubscript{+AUX} are shown in figure 5.

The first image shows the uncertainty histogram for ID data, and the second for test OOD data (a concatenation of LSUN and TIM). On in-domain data, EnD\textsuperscript{2} is seemingly able to emulate the uncertainty metrics of the ensemble well. Despite EnD\textsuperscript{2} performing very well on the out-of-domain detection task, there is a noticeable mismatch between the ensemble and EnD\textsuperscript{2} in the uncertainty metrics they provide. This is expected, as on in-domain examples the samples from the ensemble will be highly concentrated around the mean. This behaviour can be adequately modelled by a Dirichlet. On out-of-domain data, however, the samples from the ensemble might be diverse in a way
that’s different from a Dirichlet distribution. For instance, the distribution could be multimodal or crescent-shaped. Thus, as a consequence of this, combined with forward KL-divergence between the model and the empirical distribution of the ensemble being zero-avoiding, the model yields an output distribution which is typically more diverse than the original ensemble. It is possible that the ensemble could be better modelled by a different output distribution, such as a mixture of Dirichlet distributions or a Logistic-normal distribution. However, this does not seem to adversely impact OOD detection performance as measures of uncertainty for ID and OOD data are further spread apart and the rank ordering of ID and OOD data is either maintained or improved, which is supported by results from section 5.

**APPENDIX D  NEGATIVE LOG-LIKELIHOOD AND CALIBRATION**

In this work, measures of uncertainty derived from ensembles, EnD and EnD$^2$ models were assessed on threshold-based outlier detection tasks, such as misclassification detection/rejection and out-of-distribution input detection. These tasks assess measures of uncertainty on a per-prediction basis on a downstream application. However, it is also possible to assess measures of uncertainty on a per-dataset basis by considering metrics like the test-set negative log-likelihood (NLL) and calibration (Maddox et al., 2019). However, as these metrics are removed from downstream applications, they are not considered in the main paper and instead provided in this appendix. Nevertheless, it is known that ensembles yield improvements in calibration and test-set negative log-likelihood (Lakshminarayanan et al., 2017), and it is therefore interesting to assess whether EnD and EnD$^2$ models retain those improvements.

Table 7 shows the results for negative log-likelihood and calibration. Both Ensemble Distillation and Ensemble Distribution Distillation seem to give similarly minor gains in NLL over a single model. However, EnD seems to have marginally better NLL performance, while EnD$^2$ tends to yield better calibration performance. There are seemingly limited gains in ECE and NLL when using auxiliary data during distillation for EnD$^2$, and sometimes even a degradation in NLL and ECE. This may be due to a Dirichlet output distribution attempting to capture non-Dirichlet-distributed ensemble predictions on the auxiliary data. Furthermore, metrics like ECE and NLL are evaluated on in-domain data, which would explain the lack of improvement from distilling ensemble behaviour on auxiliary data.

Table 7: Mean test-set negative log-likelihood (NLL) and expected calibration error (ECE) on C10/C100/TIM across three models ±2σ.
