Paper under double-blind review

ABSTRACT

Previous work showed empirically that large neural networks can be significantly reduced in size while preserving their accuracy. Model compression became a central research topic, as it is crucial for deployment of neural networks on devices with limited computational and memory resources. The majority of the compression methods are based on heuristics and offer no worst-case guarantees on the trade-off between the compression rate and the approximation error for an arbitrarily new sample.

We propose the first efficient, data-independent neural pruning algorithm with a provable trade-off between its compression rate and the approximation error for any future test sample. Our method is based on the coresets framework, which finds a small weighted subset of points that provably approximates the original inputs. Specifically, we approximate the output of a layer of neurons by a coreset of neurons in the previous layer and discard the rest. We apply this framework in a layer-by-layer fashion from the top to the bottom. Unlike previous works, our coreset is data independent, meaning that it provably guarantees the accuracy of the function for any input $x \in \mathbb{R}^d$, including an adversarial one. We demonstrate the effectiveness of our method on popular network architectures. In particular, our coresets yield 90% compression of the LeNet-300-100 architecture on MNIST while improving the accuracy.

1 INTRODUCTION

Neural networks today are the most popular and effective instrument of machine learning with numerous applications in different domains. Since Krizhevsky et al. (2012) used a model with 60M parameters to win the ImageNet competition in 2012, network architectures have been growing wider and deeper. The vast overparametrization of neural networks offers better convergence (Allen-Zhu et al., 2019) and better generalization (Neyshabur et al., 2018). The downside of the overparametrization is its high memory and computational costs, which limit the use of these networks to high performance computational platforms. Fortunately, it was observed that a trained network could be reduced to smaller sizes without much accuracy loss. Following this observation, many approaches to compress existing models have been proposed (see Gale et al. (2019) for a recent review on network sparsification, and Mozer & Smolensky (1989); Srivastava et al. (2014); Yu et al. (2018); He et al. (2017) for neural pruning).

Although a variety of model compression heuristics have been successfully applied to different neural network models, such as Jacob et al. (2018); Han et al. (2015); Alvarez & Salzmann (2017), these approaches generally lack strong provable guarantees on the **trade-off between the compression rate and the approximation error**. The absence of worst-case performance analysis can potentially be a glaring problem depending on the application. Moreover, data-dependent methods for model compression (e.g., Mozer & Smolensky (1989); Srivastava et al. (2014); Hu et al. (2016); Yu et al. (2018); Baykal et al. (2018)) rely on the statistics presented in a data set. Hence, these methods are vulnerable to adversarial attacks (Szegedy et al., 2014), which design inputs that do not follow these statistics.

Ideally, a network compression framework should 1) provide provable guarantees on the trade-off between the compression rate and the approximation error, 2) be data independent, 3) provide high compression rate, and 4) be computationally efficient. To address these goals, we propose

an efficient framework with provable guarantees for neural pruning, which is based on the existing theory of coresets such as (Braverman et al., 2016). Coresets decrease massive inputs to smaller instances while maintaining a good provable approximation of the original set with respect to a given function. Our main idea is to treat neurons of a neural network as inputs in a coreset framework. Specifically, we reduce the number of neurons in layer i by constructing a coreset of neurons in this layer that provably approximates the output of neurons in layer $i + 1$ and discarding the rest. The coreset algorithm provides us with the choice of neurons in layer i and with the new weights connecting these neurons to layer $i + 1$. The coreset algorithm is applied layer-wise from the top to the bottom of the network.

The size of the coreset, and consequently the number of remaining neurons in layer i , is provably related to the approximation error of the output of layer $i + 1$. Thus, we can theoretically derive the trade-off between the compression rate and the approximation error of the network. The coreset approximation of neurons provably holds for *any input*; thus our compression is data-independent.

Similar to our approach, Baykal et al. (2018) used coresets for model compression. However, their coresets are data-dependent; therefore, they cannot guarantee robustness over inputs. Moreover, they construct coresets of weights, while our approach constructs coresets of neurons. Neural pruning reduces the size of the weight tensors, while keeping the network dense. Hence the implementation of the pruned network requires no additional effort. Implementing networks with sparse weights (which is the result of weight pruning) is harder and in many cases does not result in actual computational savings.

Our empirical results on LeNet-300-100 for MNIST (LeCun et al., 1998) and VGG-16 (Simonyan & Zisserman, 2014) for CIFAR-10 (Krizhevsky, 2009) demonstrate that our framework based on coresets of neurons outperforms sampling-based coresets by improving compression without sacrificing the accuracy. Finally, our construction is very fast, it took about 112 sec. to compress the dense layers in the VGG-16 network using the platform specified in the experimental section.

Our Contributions: We propose an efficient, data-independent neural pruning algorithm with a provable trade-off between the compression rate and the output approximation error. This is the first framework to perform neural pruning via coresets. Table 1 compares model compression approaches according to the stated criteria and shows that our framework is the only one that checks all the boxes. We provide theoretical compression rates for some of the most popular neural activation functions summarized in Table 2.

2 RELATED WORK

2.1 CORESETS

Our compression algorithm is based on a data summarization approach known as coresets. Over the past decade, coreset constructions have been recognized for high achievements in data reduction in a variety of applications, including k -means, SVD, regression, low-rank approximation, PageRank, convex hull, and SVM; see details in Phillips (2016). Many of the non-deterministic coreset based methods rely on the sensitivity framework, in which elements of the input are sampled according to their sensitivity (Langberg & Schulman, 2010; Braverman et al., 2016; Tolochinsky & Feldman, 2018), which is used as a measure of their importance. The sampled elements are usually reweighted afterwards.

2.2 MODEL COMPRESSION

State-of-the-art neural networks are often overparameterized, which causes a significant redundancy of weights. To reduce both computation time and memory requirements of trained networks, many approaches aim at removing this redundancy by model compression.

Weight Pruning: Weight pruning was considered as far back as 1990 (LeCun et al., 1990), but has recently seen more study (Lebedev & Lempitsky, 2016; Dong et al., 2017). One of the most popular approaches is pruning via sparsity. Sparsity can be enforced by L_1 regularization to push weights towards zero during training (Hu et al., 2016). However, it was observed (Han et al., 2015) that after fine-tuning of the pruned network, L_2 regularized network outperformed L_1 , as there is no benefit to pushing values towards zero compared to pruning unimportant (small weight) connections.

The approach in Denton et al. (2014) exploits the linearity of the neural network by finding a low-rank approximation of the weights and keeping the accuracy within 1% of the uncompressed model. Jacob et al. (2018) performs quantization of the neural network’s weights and suggests a new training procedure to preserve the model accuracy after the quantization.

These methods showed high compression rates, e.g., the compression rate of AlexNet can reach 35x with the combination of pruning, quantization, and Huffman coding (Han et al., 2016). Nevertheless, strong provable worst-case analysis is noticeably absent for most weight pruning methods.

Neural pruning: Weight pruning leads to an irregular network structure, which needs a special treatment to deal with sparse representations, making it hard to achieve actual computational savings. On the other hand, neural pruning (Hu et al., 2016) and filter pruning in CNNs (e.g. Zhuang et al. (2018); Li et al. (2017); Liu et al. (2017) simply reduce the size of the tensors.

The method in Hu et al. (2016) first identifies weak neurons by analyzing their activations on a large validation dataset. Then those weak neurons are pruned and the network is retrained. The processes are repeated several times. Zhuang et al. (2018) introduces channel pruning based on the contribution to the discriminative power. These methods are data-dependent; thus they cannot provide guarantees of approximation error for any future input.

Li et al. (2017) measures the importance of channels by calculating the sum of absolute values of weights. Other channel pruning methods either impose channel-wise sparsity in training, followed by pruning channels with small scaling factors, and fine-tuning (e.g. Liu et al. (2017)) or perform channel pruning by minimizing the reconstruction error of feature maps between the pruned and pre-trained model (e.g., He et al. (2017).) These methods lack provable guarantees on the trade-offs between their accuracy and compression.

Coreset-Based Model Compression Similar to our work, the approach in Baykal et al. (2018) uses coresets for model compression. However, they construct coresets of weights, while we construct coresets of neurons. Their approach computes the importance of each weight, which is termed sensitivity, using a subset from the validation set. The coreset is chosen for the specific distribution (of data) so consequently, the compressed model is data-dependent. In our construction, the input of the neural network is assumed to be an arbitrary vector in \mathbb{R}^d and the sensitivity of a neuron is computed for every input in \mathbb{R}^d . This means that we create a data-independent coreset; its size is independent of the properties of the specific data at hand, and the compression provably approximates any future test sample.

Dubey et al. (2018) builds upon k-means coresets by adding a sparsity constraint. The weighting of the filters in the coreset is obtained based on their activation magnitudes over the training set. The compression pipeline also includes a pre-processing step that follows a simple heuristic that eliminates filters based on the mean of their activation norms over the training set. This construction is obviously data-dependent and it uses coresets as an alternative mechanism for low-rank approximation of filters.

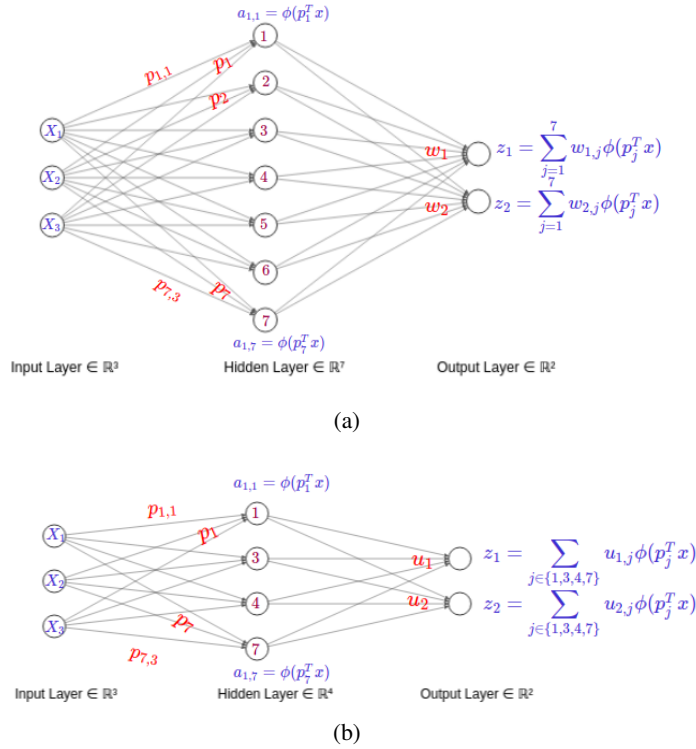

Figure 1: Illustration of our neuron coreset construction on a toy example: (a) a full network, (b) the compressed network. Both neurons in the second layer in (b) choose the same coreset comprising neurons $\{1, 2, 3, 7\}$ from layer 1, but with different weights. The compressed network has pruned neurons $\{2, 5, 6\}$ from layer 1.

3 METHOD

We propose an algorithm for compressing layer i and we apply it to all layers from the top to the bottom of the network. We first give an intuitive description of the algorithm. We then formalize it and provide a theoretical analysis of the proposed construction.

3.1 DATA-INDEPENDENT CORESET FOR NEURAL PRUNING

Let $a_j^i = \phi(p_j^T x)$ be the j th neuron in layer i , in which p_j denotes its weights, and x denotes an arbitrary input in \mathbb{R}^d (see Figure 1, top). We first consider a single neuron in layer $i + 1$. The linear part of this neuron is $z = \sum_{j=1}^{|P|} w(p_j) \phi(p_j^T x)$. We would like to approximate z by $\tilde{z} = \sum_{l \in J^*} u(p_l) \phi(p_l^T x)$ where $J^* \subset \{1, \dots, |P|\}$ is a small subset, and we want this approximation to be bounded by a multiplicative factor that holds for any $x \in \mathbb{R}^d$. Unfortunately, our result in Theorem 6 shows that this idealized goal is impossible. However, we show in Theorem 7 and Corollary 8 that we can construct a small coreset C , such that $\|z - \tilde{z}\| \leq \epsilon$ for any input $x \in \mathbb{R}^d$.

Algorithm 1 summarizes the coreset construction for a single neuron with an activation function ϕ , (our results for common neural activation functions are summarized in Table 2). Algorithm 2 and Corollary 9 show the construction of a single coreset with possibly different weights for all neurons in layer $i + 1$ (see Figure 1, bottom).

3.2 PRELIMINARIES

Definition 1 (weighted set). *Let $P \subseteq \mathbb{R}^d$ be set, and w be a function that maps every $p \in P$ to a weight $w(p) > 0$. The pair (P, w) is called a weighted set.*

Algorithm 1: CORESET(P, w, m, ϕ, β)

Input: A weighted set (P, w) ,
 an integer (sample size) $m \geq 1$,
 an (activation) function $\phi : \mathbb{R} \rightarrow [0, \infty)$,
 an upper bound $\beta > 0$.
Output: A weighted set (C, u) ; see Theorem 7 and Corollary 8.

```

1 for every  $p \in P$  do
2    $\text{pr}(p) := \frac{w(p)\phi(\beta \|p\|)}{\sum_{q \in P} w(q)\phi(\beta \|q\|)}$ 
3    $u(p) := 0$ 
4  $C \leftarrow \emptyset$ 
5 for  $m$  iterations do
6   Sample a point  $q$  from  $P$  such that  $p \in P$  is chosen with probability  $\text{pr}(p)$ .
7    $C := C \cup \{q\}$ 
8    $u(q) := u(q) + \frac{w(q)}{m \cdot \text{pr}(q)}$ 
9 return  $(C, u)$ 

```

A coreset in this paper is applied on a query space which consists of an input weighted set, an objective function, and a class of models (queries) as follows.

Definition 2 (Query space). *Let $P' = (P, w)$ be a weighted set called the input set. Let $X \subseteq \mathbb{R}^d$ be a set, and $f : P \times X \rightarrow [0, \infty)$ be a loss function. The tuple (P, w, X, f) is called a query space.*

Given a set of points P and a set of queries X , a coreset of P is a weighted set of points that provides a good approximation to P for any query $x \in X$. We state the definition of coresets with multiplicative guarantees below, though we shall also reference coresets with additive guarantees.

Definition 3 (ε -coreset, multiplicative guarantee). *Let (P, w, X, f) be a query space, and $\varepsilon \in (0, 1)$ be an error parameter. An ε -coreset of (P, w, X, f) is a weighted set (Q, u) such that for every $x \in X$*

$$\left| \sum_{p \in P} w(p)f(p, x) - \sum_{q \in Q} u(q)f(q, x) \right| \leq \varepsilon \sum_{p \in P} w(p)f(p, x)$$

The size of our coresets depends on two parameters: the complexity of the activation function which is defined below, and the sum of a supremum that is defined later. We now recall the well-known definition of VC dimension (Vapnik & Chervonenkis, 2015) using the variant from (Feldman & Langberg, 2011).

Definition 4 (VC-dimension (Feldman & Langberg, 2011)). *Let (P, w, X, f) be a query space. For every $x \in \mathbb{R}^d$, and $r \geq 0$ we define $\text{range}_{P, f}(x, r) := \{p \in P \mid f(p, x) \leq r\}$ and $\text{ranges}(P, X, f) := \{C \cap \text{range}_{P, f}(x, r) \mid C \subseteq P, x \in X, r \geq 0\}$. For a set ranges of subsets of \mathbb{R}^d , the VC-dimension of $(\mathbb{R}^d, \text{ranges})$ is the size $|C|$ of the largest subset $C \subseteq \mathbb{R}^d$ such that*

$$|\{C \cap \text{range} \mid \text{range} \in \text{ranges}\}| = 2^{|C|}.$$

The VC-dimension of the query space (P, X, f) is the VC-dimension of $(P, \text{ranges}(P, X, f))$.

The VC-dimension of all the query spaces that correspond to the activation functions in Table 2 is $O(d)$, as most of the other common activation functions (Anthony & Bartlett, 2009).

The following theorem bounds the size of the coreset for a given query space and explains how to construct it. Unlike previous papers such as (Feldman & Langberg, 2011), we consider additive error and not multiplicative error.

Theorem 5 (Braverman et al. (2016)). *Let d be the VC-dimension of a query space (P, w, X, f) . Suppose $s : P \rightarrow [0, \infty)$ such that $s(p) \geq w(p) \sup_{x \in X} f(p, x)$. Let $t = \sum_{p \in P} s(p)$, and $\epsilon, \delta \in$*

(0, 1). Let $c \geq 1$ be a sufficiently large constant that can be determined from the proof, and let C be a sample (multi-set) of

$$m \geq \frac{ct}{\epsilon^2} \left(d \log t + \log \left(\frac{1}{\delta} \right) \right)$$

i.i.d. points from P , where for every $p \in P$ and $q \in C$ we have $\text{pr}(p = q) = s(p)/t$. Then, with probability at least $1 - \delta$,

$$\forall x \in X : \left| \sum_{p \in P} w(p) f(p, x) - \sum_{q \in C} \frac{w(q)}{m \text{pr}(q)} \cdot f(q, x) \right| \leq \epsilon.$$

Algorithm 2: CORESET PER LAYER($P, w_1, \dots, w_k, m, \phi, \beta$)

Input: Weighted sets $(P, w_1), \dots, (P, w_k)$,
an integer (sample size) $m \geq 1$,
an (activation) function $\phi : \mathbb{R} \rightarrow [0, \infty)$,
an upper bound $\beta > 0$.

Output: A weighted set (C, u) ; see Theorem 7.

```

1 for every  $p \in P$  do
2    $\text{pr}(p) := \max_{i \in [k]} \frac{w_i(p) \phi(\beta \|p\|)}{\sum_{q \in P} w_i(q) \phi(\beta \|q\|)}$ 
3    $u(p) := 0$ 
4  $C \leftarrow \emptyset$ 
5 for  $m$  iterations do
6   Sample a point  $q$  from  $P$  such that  $p \in P$  is chosen with probability  $\text{pr}(p)$ .
7    $C := C \cup \{q\}$ 
8    $\forall i \in [k] : u_i(q) := u_i(q) + \frac{w_i(q)}{m \cdot \text{pr}(q)}$ 
9 return  $(C, u_1, \dots, u_k)$ 

```

3.3 MAIN THEORETICAL RESULTS

Most of the coresets provide a $(1 + \epsilon)$ -multiplicative factor approximation for every query that is applied on the input set. The bound on the coreset size is independent or at least sub-linear in the original number n of points, for any given input set. Unfortunately, the following theorem proves that it is impossible to compute small coresets for many common activation functions such as ReLU. This holds even if there are constraints on both the length of the input set and the test set of samples.

Theorem 6 (No coreset for multiplicative error). *Let $\phi : \mathbb{R} \rightarrow [0, \infty)$ such that $\phi(b) > 0$ if and only if $b > 0$. Let $\alpha, \beta > 0$, $\epsilon \in (0, 1)$ and $n \geq 1$ be an integer. Then there is a set $P \subseteq \mathbb{B}_\alpha$ of n points such that if a weighted set (C, u) satisfies $C \subseteq P$ and*

$$\forall x \in \mathbb{B}_\beta : \left| \sum_{p \in P} \phi(p^T x) - \sum_{q \in C} u(q) \phi(q^T x) \right| \leq \epsilon \sum_{p \in P} \phi(p^T x), \quad (1)$$

then $C = P$.

The proof of Theorem 6 is provided in Appendix A.1.

The following theorem motivates the usage of additive ϵ -error instead of multiplicative $(1 + \epsilon)$ error. Fortunately, in this case there is a bound on the coreset's size for appropriate sampling distributions.

Theorem 7. *Let $\alpha, \beta > 0$ and $(P, w, \mathbb{B}_\beta, f)$ be a query space of VC-dimension d such that $P \subseteq \mathbb{B}_\alpha$, the weights w are non-negative, $f(p, x) = \phi(p^T x)$ and $\phi : \mathbb{R} \rightarrow [0, \infty)$ is a non-decreasing function. Let $\epsilon, \delta \in (0, 1)$ and*

$$m \geq \frac{ct}{\epsilon^2} \left(d \log t + \log \left(\frac{1}{\delta} \right) \right)$$

where

$$t = \phi(\alpha\beta) \sum_{p \in P} w(p)$$

and c is a sufficiently large constant that can be determined from the proof.

Let (C, u) be the output of a call to `CORESET`(P, w, m, ϕ, β); see Algorithm 1. Then, $|C| \leq m$ and, with probability at least $1 - \delta$,

$$\left| \sum_{p \in P} w(p) \phi(p^T x) - \sum_{p \in C} u(p) \phi(p^T x) \right| \leq \epsilon.$$

The proof is provided in Appendix A.2.

As weights of a neural network can take positive and negative values, we generalize our result to include negative weights in the following corollary.

Corollary 8 (Coreset with negative weights). *Let $(P, w, \mathbb{B}_\beta, f)$ be a general query spaces, of VC-dimension $O(d)$ such that $f(p, x) = \phi(p^T x)$ for some non-decreasing $\phi : \mathbb{R} \rightarrow [0, \infty)$ and $P \subseteq \mathbb{B}_\alpha$. Let*

$$s(p) = \sup_{x \in X} |w(p)| \phi(p^T x)$$

for every $p \in P$. Let $c \geq 1$ be a sufficiently large constant that can be determined from the proof, $t = \sum_{p \in P} s(p)$, and

$$m \geq \frac{ct}{\epsilon^2} \left(d \log t + \log \left(\frac{1}{\delta} \right) \right).$$

Let (C, u_1, u_2) be the output of a call to `CORESET`(P, w, m, ϕ, β); see Algorithm 1. Then, $|C| \leq m$ and, with probability at least $1 - \delta$,

$$\forall x \in \mathbb{B}_\beta : \left| \sum_{p \in P} w(p) \phi(p^T x) - \sum_{p \in C} u(p) \phi(p^T x) \right| \leq \epsilon.$$

The proof of Corollary 8 is provided in Appendix A.3.

3.4 FROM CORESET PER NEURON TO CORESET PER LAYER

Applying Algorithm 1 to each neuron in a layer $i + 1$ could result in the situation that a neuron in layer i is selected to the coreset of some neurons in layer $i + 1$, but not to others. In this situation, it cannot be removed. To perform neuron pruning, every neuron in layer $i + 1$ should select the same neurons for its coreset, maybe with different weights. Thus, we wish to compute a single coreset for multiple weighted sets that are different only by their weight function. Each such a set represents a neuron in level $i + 1$, which includes k neurons. Algorithm 2 and Corollary 9 show how to compute a single coreset for multiple weighted sets. Figure 1 provides an illustration of the layer pruning on a toy example.

Corollary 9 (Coreset per Layer). *Let $(P, w_1, \mathbb{B}_\beta, f), \dots, (P, w_k, \mathbb{B}_\beta, f)$ be k query spaces, each of VC-dimension $O(d)$ such that $f(p, x) = \phi(p^T x)$ for some non-decreasing $\phi : \mathbb{R} \rightarrow [0, \infty)$ and $P \subseteq \mathbb{B}_\alpha$. Let*

$$s(p) = \max_{i \in [k]} \sup_{x \in X} w_i(p) \phi(p^T x)$$

for every $p \in P$. Let $c \geq 1$ be a sufficiently large constant that can be determined from the proof, $t = \sum_{p \in P} s(p)$

$$m \geq \frac{ct}{\epsilon^2} \left(d \log t + \log \left(\frac{1}{\delta} \right) \right).$$

Let (C, u_1, \dots, u_k) be the output of a call to `CORESET`($P, w_1, \dots, w_k, m, \phi, \beta$); see Algorithm 2. Then, $|C| \leq m$ and, with probability at least $1 - \delta$,

$$\forall i \in [k], x \in \mathbb{B}_\beta : \left| \sum_{p \in P} w_i(p) \phi(p^T x) - \sum_{p \in C} u_i(p) \phi(p^T x) \right| \leq \epsilon.$$

The proof follows directly from Theorem 5.

Activation Function	Definition
ReLU	$\max(x, 0)$
σ	$\frac{1}{1+e^{-x}}$
binary	$\begin{cases} 0 & \text{for } x < 0 \\ 1 & \text{for } x \geq 0 \end{cases}$
ζ	$\ln(1 + e^x)$
soft-clipping	$\frac{1}{\alpha} \log \frac{1+e^{\alpha x}}{1+e^{\alpha(x-1)}}$
Gaussian	e^{-x}

Table 2: Examples of activation functions ϕ for which we can construct a coresets of size $O(\frac{\alpha\beta}{\epsilon^2})$ that approximates $\frac{1}{|P|} \sum_{p \in P} \phi(p^T x)$ with ϵ -additive error.

4 EXPERIMENTS

We first test our neural pruning with coresets on two popular models: LeNet-300-100 on MNIST (LeCun et al., 1998), and VGG-16 (Simonyan & Zisserman, 2014) on CIFAR-10 (Krizhevsky, 2009). We then compare the compression rate of our coresets (Neuron Coreset) to the compression methods based on the following sampling schemes:

Baselines: uniform sampling, percentile (which deterministically retains the inputs with the highest norms), and Singular Value Decomposition (SVD);

Schemes for matrix sparsification: based on L1 and L2 norms and their combination (Drineas & Zouzias, 2011; Achlioptas et al., 2013; Kundu & Drineas, 2014);

Sensitivity sampling: CoreNet and CoreNet++ (Baykal et al., 2018).

In all experiments we used ReLU networks and we computed the average error of the tested algorithms after performing each test ten times. After applying neural pruning the remaining weights were fine-tuned. The experiments were implemented in PyTorch (Paszke et al., 2017) on a Linux Machine using an Intel Xeon, 32-core CPU with 3.2 GHz, 256 GB of RAM and Nvidia TitanX and Quadro M4000 GPUs¹.

4.1 COMPRESSING LENET AND VGG

LeNet-300-100 network comprises two fully connected hidden layers with 300 and 100 neurons correspondingly, trained on MNIST data set. Our coresets were able to prune roughly 90% of the parameters and our compression did not have any associated accuracy cost – in fact, it slightly improved the classification accuracy.

VGG-16 (Simonyan & Zisserman, 2014) includes 5 blocks comprising convolutional and pooling layers, followed by 3 dense layers – the first two with 4096 neurons and the last with 1000 neurons. The model was trained and tested on CIFAR-10. We applied our algorithm for neural pruning to the dense layers, which have the largest number parameters. Our experiment showed slight improvement in accuracy of classification while the number of parameters decreased by roughly 75%. We summarize our findings in Table 3.

4.2 CORESETS ON RELU

We analyze the empirical trade-off between the approximation error $\left| \sum_{p \in P} w(p) \phi(p^T x) - \sum_{p \in C} u(p) \phi(p^T x) \right|$ and the size of the coresets, constructed by Algorithm 1, in comparison to uniform sampling and to percentile, which deterministically retains the inputs with the highest norms (note that in percentile the points are not weighted). We run three tests, varying the distribution of weights, and using MNIST as an input. In the first and second

¹We will make our code available upon acceptance or on reviewers’ request.

Network	Error(%)	# Parameters	Compression Ratio
LeNet-300-100	2.16	267K	
LeNet-300-100 Pruned	2.03	26K	90%
VGG-16	8.95	1.4M	
VGG-16 Pruned	8.16	350K	75%

Table 3: Empirical evaluations of our coresets on existing architectures for MNIST and CIFAR-10. Note the improvement of accuracy in both cases!

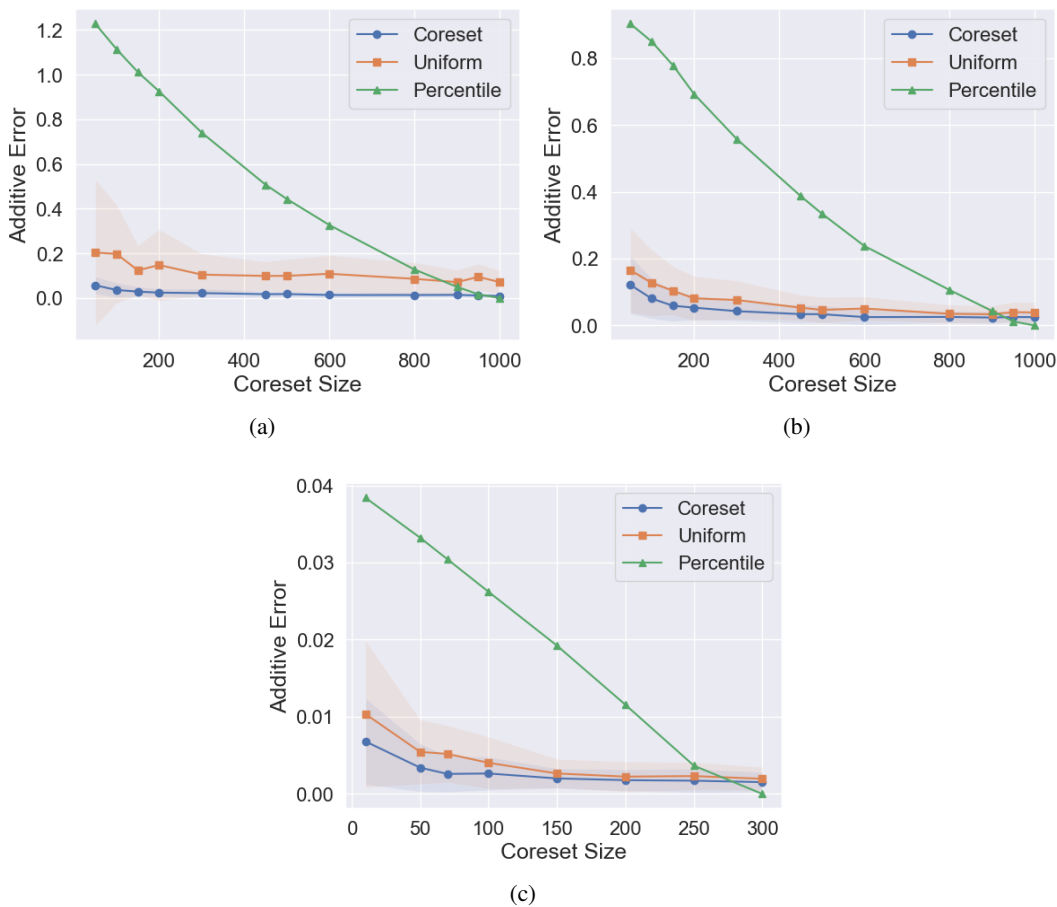

Figure 2: Approximation error of a single neuron on MNIST dataset across different coreset sizes. The weights of the points in (a) are drawn from the Gaussian distribution, in (b) from the Uniform distribution and in (c) we used the trained weights from LeNet-300-100. Our coreset, computed by Algorithm 1, outperforms other reduction methods.

tests (Figure 2, (a) and (b)) the weights are drawn from the Gaussian and Uniform distributions respectively. In the third test (Figure 2, (c)) we use the trained weights from Lenet-300-100. In all three tests, our coresets outperform the tested methods across all coreset sizes.

Comparison with Other Methods. We compare the average approximation error vs. compression rates of our neural pruning coreset with several other well-known algorithms (listed above). We run these tests on LeNet-200-105 architecture, trained and tested on MNIST, and we measure the

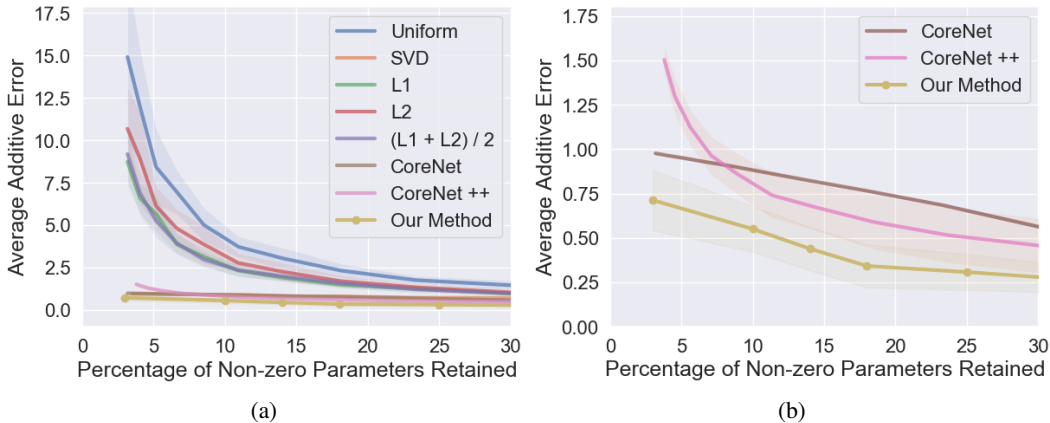

Figure 3: Average accuracy of various algorithms on LeNet-200-105 on MNIST dataset across different sparsity rates. Plot (a) shows the results of all tested methods. Plot (b) focuses on the three top methods. Our method, which constructs neural coresets by applying the Algorithm 2 in a layer-by-layer fashion, outperforms other coreset-based algorithms.

corresponding average approximation error as defined in (Baykal et al., 2018):

$$error_{\mathcal{P}_{test}} = \frac{1}{|\mathcal{P}_{test}|} \sum_{x \in \mathcal{P}_{test}} \|\phi_{\hat{\theta}}(x) - \phi_{\theta}(x)\|_1,$$

where $\phi_{\hat{\theta}}(x)$ and $\phi_{\theta}(x)$ are the outputs of the approximated and the original networks respectively. The results are summarized in Figure 3. As expected, all algorithms perform better with lower compression, but our algorithm outperforms the other methods, especially for high compression rates.

5 CONCLUSION

We proposed the first neural pruning algorithm with provable trade-offs between the compression rate and the approximation error for any future test sample. We base our compression algorithm on the coreset framework and construct coresets for most common activation functions. Our tests on ReLU networks show high compression rates with no accuracy loss, and our theory guarantees the worst case accuracy vs. compression trade-off for any future test sample, even an adversarial one. In this paper we focused on pruning neurons. In future work, we plan to extend the proposed framework to pruning filters in CNNs and to other architectures.

A APPENDIX

A.1 PROOF OF THEOREM 6

Consider the points on \mathbb{B}_α whose norm is α and last coordinate is $\alpha/2$. This is a $(d-1)$ -dimensional sphere S that is centered at $(0, \dots, 0, \alpha/2)$. For every point p on this sphere there is a hyperplane that passes through the origin and separates p from the rest of the points in S . Formally, there is an arbitrarily short vector x_p (which is orthogonal to this hyperplane) such that $x_p^T p > 0$, but $x_p^T q < 0$ for every $q \in S \setminus \{p\}$; see Fig. 4. By the definition of ϕ , we also have $\phi(x_p^T p) > 0$, but $\phi(x_p^T q) = 0$ for every $q \in S \setminus \{p\}$.

Figure 4: **(left)** Any point on a circle can be separated from the other points via a line. **(right)** The same holds for a circle which is the intersection of a d -dimensional sphere and a hyperplane; see Theorem 6.

Let P be an arbitrary set of n points in S , and $C \subset P$. Hence exists a point $p \in P \setminus C$. By the previous paragraph,

$$\begin{aligned} \left| \sum_{q \in P} \phi(x_p^T q) - \sum_{q \in C} u(q) \phi(x_p^T q) \right| &= |\phi(x_p^T p) - 0| = \phi(x_p^T p) \\ &= \sum_{q \in P} \phi(x_p^T q) > \epsilon \sum_{q \in P} \phi(x_p^T q). \end{aligned}$$

Therefore C does not satisfy equation 1 in Theorem 6.

A.2 PROOF OF THEOREM 7

We want to apply Algorithm 1, and to this end we need to prove a bound that is independent of x on the supremum s , the total supremum t , and the VC-dimension of the query space.

Bound on $f(p, x)$. Put $p \in P$ and $x \in \mathbb{B}_\beta$. Hence,

$$f(p, x) = \phi(p^T x) \leq \phi(\|p\| \|x\|) \quad (2)$$

$$\leq \phi(\|p\| \beta) \quad (3)$$

$$\leq \phi(\alpha\beta), \quad (4)$$

where equation 2 holds by the Cauchy-Schwarz inequality and since ϕ is non-decreasing, equation 3 holds since $x \in \mathbb{B}_\beta$, and equation 4 holds since $p \in \mathbb{B}_\alpha$.

Bound on the total sup t . Using our bound on $f(p, x)$,

$$t = \sum_{p \in P} s(p) = \sum_{p \in P} w(p) \phi(\|p\| \beta) \leq \phi(\alpha\beta) \sum_{p \in P} w(p),$$

where the last inequality is by equation 4.

Bound on the VC-dimension of the query space $(P, w, \mathbb{B}_\beta, f)$ is $O(d)$ as proved e.g. in Anthony & Bartlett (2009).

Putting all together. By applying Theorem 1 with $X = \mathbb{B}_\beta$, we obtain that, with probability at least $1 - \delta$,

$$\forall x \in \mathbb{B}_\beta : \left| \sum_{p \in P} w(p) f(p, x) - \sum_{q \in C} u(q) f(q, x) \right| \leq \epsilon.$$

Assume that the last equality indeed holds. Hence,

$$\forall x \in \mathbb{B}_\beta : \left| \sum_{p \in P} w(p) \phi(p^T x) - \sum_{q \in C} u(q) \phi(q^T x) \right| \leq \epsilon.$$

A.3 PROOF OF COROLLARY 8

Put $x \in \mathbb{B}_\beta$. Hence,

$$\left| \sum_{p \in P} w(p) \phi(p^T x) - \sum_{p \in C} u(p) \phi(p^T x) \right| \quad (5)$$

$$\leq \left| \sum_{\substack{p \in P \\ w(p) \geq 0}} w(p) \phi(p^T x) - \sum_{\substack{p \in C \\ u(p) \geq 0}} u(p) \phi(p^T x) \right| + \left| \sum_{\substack{p \in P \\ w(p) < 0}} w(p) \phi(p^T x) - \sum_{\substack{p \in C \\ u(p) < 0}} u(p) \phi(p^T x) \right| \quad (6)$$

$$\leq \left| \sum_{\substack{p \in P \\ w(p) \geq 0}} w(p) \phi(p^T x) - \sum_{\substack{p \in C \\ u(p) \geq 0}} u(p) \phi(p^T x) \right| + \left| \sum_{\substack{p \in P \\ w(p) < 0}} |w(p)| \phi(p^T x) - \sum_{\substack{p \in C \\ u(p) < 0}} |u(p)| \phi(p^T x) \right| \quad (7)$$

Equation 6 is obtained by separating each sum into points with positive and negative weights and applying Cauchy-Schwarz inequality. Next, we bound points with positive and negative weights separately using Theorem 7.
