NEURAL MODULE NETWORKS FOR REASONING OVER TEXT

Anonymous authors
Paper under double-blind review

ABSTRACT

Answering compositional questions that require multiple steps of reasoning against text is challenging, especially when they involve discrete, symbolic operations. Neural module networks (NMNs) learn to parse such questions as executable programs composed of learnable modules, performing well on synthetic visual QA domains. However, we find that it is challenging to learn these models for non-synthetic questions on open-domain text, where a model needs to deal with the diversity of natural language and perform a broader range of reasoning. We extend NMNs by: (a) introducing modules that reason over a paragraph of text, performing symbolic reasoning (such as arithmetic, sorting, counting) over numbers and dates in a probabilistic and differentiable manner; and (b) proposing an unsupervised auxiliary loss to help extract arguments associated with the events in text. Additionally, we show that a limited amount of heuristically-obtained question program and intermediate module output supervision provides sufficient inductive bias for accurate learning. Our proposed model significantly outperforms state-of-the-art models on a subset of the DROP dataset that poses a variety of reasoning challenges that are covered by our modules.

1 INTRODUCTION

Being formalism-free and close to an end-user task, QA is increasingly becoming a proxy for gauging a model’s natural language understanding capability (He et al., 2015; Talmor et al., 2018). Recent models have performed well on certain QA datasets, sometimes rivaling humans (Zhang et al., 2019), but it has become increasingly clear that they primarily exploit surface level lexical cues (Jia & Liang, 2017; Feng et al., 2018) and compositional QA still remains a challenge. Answering complex compositional questions against text is challenging since it requires a comprehensive understanding of both the question semantics and the text against which the question needs to be answered. Consider the question in Figure 1; a model needs to understand the compositional reasoning structure of the questions, perform accurate information extraction from the passage (eg. extract lengths, kickers, etc. for the field goals and touchdowns), and perform symbolic reasoning (eg. counting, sorting, etc.).

Semantic parsing techniques, which map natural language utterances to executable programs, have been used for compositional question understanding for a long time (Zelle & Mooney, 1996; Zettlemoyer & Collins, 2005; Liang et al., 2011), but have been limited to answering questions against structured and semi-structured knowledge sources. Neural module networks (NMNs; Andreas et al., 2016) extend semantic parsers by making the program executor a learned function composed of neural network modules. These modules are designed to perform basic reasoning tasks and can be composed to perform complex reasoning over unstructured knowledge.

NMNs perform well on synthetic visual question answering (VQA) domains such as CLEVR (Johnson et al., 2017) and it is appealing to apply them to answer questions over text due to their interpretable, modular, and inherently compositional nature. We find, however, that it is non-trivial to extend NMNs for answering non-synthetic questions against open-domain text, where a model needs to deal with the ambiguity and variability of real-world text while performing a diverse range of reasoning. Jointly learning the parser and executor using only QA supervision is also extremely challenging ( §2.2).

Our contributions are two-fold: Firstly, we extend NMNs to answer compositional questions against a paragraph of text as context. We introduce neural modules to perform reasoning over text using distributed representations, and perform symbolic reasoning, such as arithmetic, sorting, comparisons,
Under review as a conference paper at ICLR 2020

Figure 1: Model Overview: Given a question, our model parses it into a program composed of neural modules. This program is executed against the context to compute the final answer. The modules operate over soft attention values (on the question, passage, numbers, and dates). For example, \texttt{filter} takes as input attention over the question \texttt{(in the second quarter)} and filters the output of the \texttt{find} module by producing an attention mask over tokens that belong to the \texttt{second quarter}.

and counting (§3). The modules we define are probabilistic and differentiable, which lets us maintain uncertainty about intermediate decisions and train the entire model via end-to-end differentiability.

Secondly, we show that the challenges arising in learning from end-task QA supervision can be alleviated with an auxiliary loss over the intermediate latent decisions of the model. Specifically, we introduce an unsupervised objective that provides an inductive bias to perform accurate information extraction from the context (§4.1). Additionally, we show that providing heuristically-obtained supervision for question programs and outputs for intermediate modules in a program (§4.2) for a small subset of the training data (5–10%) is sufficient for accurate learning.

We experiment on 21,800 questions from the recently proposed DROP dataset (Dua et al., 2019) that are heuristically chosen based on their first n-gram such that they are covered by our designed modules. This is a significantly-sized subset that poses a wide variety of reasoning challenges and allows for controlled development and testing of models. We show that our model, which has interpretable intermediate outputs by design, significantly outperforms state-of-the-art black box models on this dataset. We conclude with a discussion of the challenges of pushing NMNs to the entire DROP dataset, where some questions require reasoning that is hard to design modules for.

2 Neural Module Networks

Consider the question “Who kicked the longest field goal in the second quarter?” in Figure 1. Multiple reasoning steps are needed to answer such a question: find all instances of “field goal” in the paragraph, select the ones “in the second quarter”, find their lengths, compute the “longest” of them, and then find “who kicked” it. We would like to develop machine reading models that are capable of understanding the context and the compositional semantics of such complex questions in order to provide the correct answer, ideally while also explaining the reasoning that led to that answer.

Neural module networks (NMN) capture this intuition naturally, which makes them a good fit to solve reasoning problems like these. A NMN would parse such a question into an executable program, such as \texttt{relocate(find-max-num(filter(find())))}, whose execution against the given paragraph yields the correct answer. These programs capture the abstract compositional reasoning structure required to answer the question correctly and are composed of learnable modules designed to solve sufficiently independent reasoning tasks. For example, the \texttt{find} module should ground the question span “field goal” to its various occurrences in the paragraph; the module \texttt{find-max-num} should output the span amongst its input that is associated with the largest length; and finally, the \texttt{relocate} module should find “who kicked” the field goal corresponding to its input span.

2.1 Components of a NMN for Text

Modules. To perform natural language and symbolic reasoning over different types of information, such as text, numbers, and dates, we define a diverse set of differentiable modules to operate over these different data types. We describe these modules and the data types in [3].
Contextual Token Representations. Our model represents the question \( q \) as \( Q \in \mathbb{R}^{n \times d} \) and the context paragraph \( p \) as \( P \in \mathbb{R}^{m \times d} \) using contextualized token embeddings. These are outputs of either the same bidirectional-GRU or a pre-trained BERT (Devlin et al., 2019) model. Here \( n \) and \( m \) are the number of tokens in the question and the paragraph, respectively. Appendix A.1 contains details about how these contextual embeddings are produced.

Question Parser. We use an encoder-decoder model with attention to map the question into an executable program. Similar to N2NMN (Hu et al., 2017), at each timestep of decoding, the attention that the parser puts on the question is available as a side argument to the module produced at that timestep during execution. This lets the modules have access to question information without making hard decisions about which question words to put into the program.

In our model, the data types of the inputs and output of modules automatically induce a type-constrained grammar which lends itself to top-down grammar-constrained decoding as performed by Krishnamurthy et al. (2017). This ensures that the decoder always produces well-typed programs. For example, if a module \( f_1 \) inputs a number, and \( f_2 \) outputs a date, then \( f_1(f_2) \) is invalid and would not be explored while decoding. The output of the decoder is a linearized abstract syntax tree (in an in-order traversal). See A.2 for details.

Learning. We define our model probabilistically, i.e., for any given program \( z \), we can compute the likelihood of the gold-answer \( p(y^*|z) \). Combined with the likelihood of the program under the question-parser model \( p(z|q) \), we can maximize the marginal likelihood of the answer by enumerating all possible programs: \( J = \sum_z p(y^*|z)p(z|q) \). Since the space of all programs is intractable, we run beam search to enumerate top-K programs and maximize the approximate marginal-likelihood.

2.2 Learning Challenges in NMN for Text

As mentioned above, the question parser and the program executor both contain learnable parameters. Each of them is challenging to learn in its own right and joint training further exacerbates the situation.

Question Parser. Our model needs to parse free-form real-world questions into the correct program structure and identify its arguments (e.g. "who kicked", "field goal", etc.). This is challenging since the questions are not generated from a small fixed grammar (unlike CLEVR), involve lexical variability, and have no program supervision. Additionally, many incorrect programs can yield the same correct answer thus training the question parser to highly score incorrect interpretations.

Program Executor. The output of each intermediate module in the program is a latent decision by the model since the only feedback available is for the final output of the program. The absence of any direct feedback to the intermediate modules complicates learning since the errors of one module would be passed on to the next. Differentiable modules that propagate uncertainties in intermediate decisions help here, such as attention on pixels in CLEVR, but do not fully solve the learning challenges.

Joint Learning. Jointly training the parser and executor increases the latent choices available to the model by many folds while the only supervision available is the gold answer. Additionally, joint learning is challenging as prediction errors from one component lead to incorrect training of the other. E.g., if the parser predicts the program \( \text{relocate(find())} \) for the question in Fig. 1, then the associated modules would be incorrectly trained to predict the gold answer. On the next iteration, incorrect program execution would provide the wrong feedback to the question parser and lead to its incorrect training, and learning fails.

3 Modules for Reasoning over Text

Modules are designed to perform basic independent reasoning tasks and form the basis of the compositional reasoning that the model is capable of. We identify a set of tasks that need to be performed to support diverse enough reasoning capabilities over text, numbers, and dates, and define modules accordingly. Since the module parameters will be learned jointly with the rest of the model, we would like the modules to maintain uncertainties about their decisions and propagate them through the decision making layers via end-to-end differentiability. One of the main contributions of our work is introducing differentiable modules that perform reasoning over text and symbols in a probabilistic manner. Table 3 gives an overview of representative modules and 3.2 describes them in detail.
whose

The output is an

The modules operate over the following data types. Each data type represents its underlying value as a normalized distribution over the relevant support.

- **Question (Q) and Paragraph (P) attentions**: soft subsets of relevant tokens in the text.
- **Number (N) and Date (D)**: soft subset of unique numbers and dates from the passage.
- **Count Number (C)**: count value as a distribution over the supported count values (0 − 9).
- **Time Delta (TD)**: a value amongst all possible unique differences between dates in the paragraph. In this work, we consider differences in terms of years.
- **Span (S)**: span-type answers as two probability values (start/end) for each paragraph token.

### 3.1 Data Types

The modules operate over the following data types. Each data type represents its underlying value as a normalized distribution over the relevant support.

### 3.2 Neural Modules for Question Answering

The question and paragraph contextualized embeddings (Q and P) are available as global variables to all modules in the program. The question attention computed by the decoder during the timestep the module was produced is also available to the module as a side argument, as described in §2.1.

**find(\(Q\)) \rightarrow P**  This module is used to ground attended question tokens to similar tokens in the paragraph (e.g., “field goal” in Figure 1). We use a question-to-paragraph attention matrix \(A \in \mathbb{R}^{n \times m}\) whose \(i\)-th row is the distribution of similarity over the paragraph tokens for the \(i\)-th question token. The output is an expected paragraph attention; a weighted-sum of the rows of \(A\), weighed by the input question attention, \(P = \sum_i Q_i \cdot A_i \in \mathbb{R}^m\). \(A\) is computed by normalizing (using softmax) the rows of a question-to-paragraph similarity matrix \(S \in \mathbb{R}^{n \times m}\). Here \(S_{ij}\) is the similarity between the contextual embeddings of the \(i\)-th question token and the \(j\)-th paragraph token computed as, \(S_{ij} = w^T_{\text{filter}}[Q_i \odot P_j]\), where \(w_{\text{filter}} \in \mathbb{R}^{3d}\) is a learnable parameter vector of this module, \([\cdot]\) denotes the concatenation operation, and \(\odot\) is elementwise multiplication.

**filter(\(Q, P\)) \rightarrow P**  This module masks the input paragraph attention conditioned on the question, selecting a subset of the attended paragraph (e.g., selecting fields goals “in the second quarter” in Fig. 1). We compute a locally-normalized paragraph-token mask \(M \in \mathbb{R}^m\) where \(M_j\) is the masking score for the \(j\)-th paragraph token computed as \(M_j = \sigma(w^T_{\text{filter}}[Q_j \odot P_j])\). Here \(Q = \sum_i Q_i \in \mathbb{R}^d\), is a weighted sum of question-token embeddings, \(w_{\text{filter}}^T \in \mathbb{R}^{3d}\) is a learnable parameter vector, and \(\sigma\) is the sigmoid non-linearity function. The output is a normalized masked input paragraph attention, \(P_{\text{filtered}} = \text{normalize}(M \odot P)\).

**relocate(\(Q, P\)) \rightarrow P**  This module re-attends to the paragraph based on the question and is used to find the arguments for paragraph spans (e.g., shifting the attention from “field goals” to “who kicked” them). We first compute a paragraph-to-paragraph attention matrix \(R \in \mathbb{R}^{m \times m}\) based on the question, as \(R_{ij} = w_{\text{relocate}}^T[Q_i \odot P_j]\), where \(Q = \sum_i Q_i \in \mathbb{R}^d\), and \(w_{\text{relocate}} \in \mathbb{R}^{3d}\) is a learnable parameter vector. Each row of \(R\) is also normalized using the

\[w_{\text{filter}}^T = \text{normalize}(M \odot P)\].
softmax operation. The output attention is a weighted sum of the rows $R$ weighted by the input paragraph attention, $P_{\text{relocated}} = \sum_i P_i \cdot R_i$.

**find-num** ($P$) → $N$ This module finds a number distribution associated with the input paragraph attention. We use a paragraph token-to-number-token attention map $A_{\text{num}} \in \mathbb{R}^{m \times N_{\text{token}}}$ whose $i$-th row is probability distribution over number-containing tokens for the $i$-th paragraph token. We first compute a token-to-number similarity matrix $S_{\text{num}} \in \mathbb{R}^{m \times N_{\text{token}}}$ as, $S_{\text{num}}_{i,j} = P_i^T \cdot W_{\text{num}} \cdot P_{n_j}$, where $n_j$ is the index of the $j$-th number token and $W_{\text{num}} \in \mathbb{R}^{d \times d}$ is a learnable parameter. $A_{\text{num}}^i = \text{softmax}(S_{\text{num}}^i)$. We compute an expected distribution over the number tokens $T = \sum_i P_i \cdot A_{\text{num}}^i$, and aggregate the probabilities for number-tokens with the same value to compute the output distribution $N$. For example, if the values of the number-tokens are $[2, 3, 4]$ and $T = [0.1, 0.4, 0.3, 0.2]$, the output will be a distribution over $\{2, 3, 4\}$ with $N = [0.5, 0.3, 0.2]$.

**count** ($P$) → $C$ This module is used to count the number of attended paragraph spans. The idea is to learn a module that detects contiguous spans of attention values and counts each as one. For example, if an attention vector is $[0, 0, 0.3, 0.3, 0, 0.4]$, the count module should produce an output of 2. The module first scales the attention using the values $[1, 2, 5, 10]$ to convert it into a matrix $P_{\text{scaled}} \in \mathbb{R}^{m \times 4}$. A bidirectional-GRU then represents each token attention as a hidden vector $h_t$. A single-layer feed-forward network maps this representation to a soft 0/1 score to indicate the presence of a span surrounding it. These scores are summed to compute a count value, $c_v = \sum \sigma(FF(\text{countGRU}(P_{\text{scaled}}))) \in \mathbb{R}$. We hypothesize that the output count value is normally distributed with $c_v$ as mean, and a constant variance $v = 0.5$, and compute a categorical distribution over the supported count values, as $p(c) \propto \exp((-c-c_v)^2/2v^2)$ for $c \in [0, 9]$. Pretraining this module by generating synthetic data of attention and count values helps (see A.4).

**compare-num-lt** ($P_1$, $P_2$) → $P$ This module performs a soft less-than operation between two passage distributions. For example, to find the city with fewer people, cityA or cityB, the module would output a linear combination of the two input attentions weighted by which city was associated with a lower number. This module internally calls the find-num module to get a number distribution for each of the input paragraph attentions, $N_1$ and $N_2$. It then computes two soft boolean values, $p(N_1 < N_2)$ and $p(N_2 < N_1)$, and outputs a weighted sum of the input paragraph attentions. The boolean values are computed by marginalizing the relevant joint probabilities:

$$p(N_1 < N_2) = \sum_i \sum_j \mathbb{1}_{N_1 < N_2} N_1^i N_2^j \quad p(N_2 < N_1) = \sum_i \sum_j \mathbb{1}_{N_2 < N_1} N_2^i N_1^j$$

The final output is, $P_{\text{out}} = p(N_1 < N_2) \cdot P_1 + p(N_2 < N_1) \cdot P_2$. When the predicted number distributions are peaky, $p(N_1 < N_2)$ or $p(N_2 < N_1)$ is close to 1, and the output is either $P_1$ or $P_2$.

We similarly include the comparison modules compare-num-gt, compare-date-lt, and compare-date-gt, defined in an essentially identical manner, but for greater-than and for dates.

**time-diff** ($P_1$, $P_2$) → $TD$ The module outputs the difference between the dates associated with the two paragraph attentions as a distribution over all possible difference values. The module internally calls the find-date module to get a date distribution for the two paragraph attentions, $D_1$ and $D_2$. The probability of the difference being $t_d$ is computed by marginalizing over the joint probability for the dates that yield this value, as $p(t_d) = \sum_{i,j} \mathbb{1}_{(d_i - d_j = t_d)} D_1^i D_2^j$.

**find-max-num** ($P$), **find-min-num** ($P$) → $P$ Given a passage attention attending to multiple spans, this module outputs an attention for the span associated with the largest (or smallest) number. We first compute an expected number token distribution $T$ using find-num, then use this to compute the expected probability that each number token is the one with the maximum value, $T_{\text{max}} \in \mathbb{R}^{N_{\text{token}}}$ (explained below). We then re-distribute this distribution back to the original passage tokens associated with those numbers. The contribution from the $i$-th paragraph token to the $j$-th number token, $T_{ij}$, was $P_i \cdot A_{\text{num}}_{ij}$. To compute the new attention value for token $i$, we re-weight this contribution based on the ratio $T_{ij} / T_i$ and marginalize across the number tokens to get the new token attention value: $P_i = \sum_j T_{ij} / T_i \cdot P_i \cdot A_{\text{num}}_{ij}$. 

Under review as a conference paper at ICLR 2020
We provide heuristically-obtained noisy supervision for the output of the
find-num module. For questions like “how many yards was the longest/shortest
touchdown?”, we identify all instances of the token “touchdown” in the
paragraph and assume the closest number to it should be the shortest
goal instead of all in goals. We supervise this as a multi-hot vector $N^*$ and use
an auxiliary loss, similar to question-attention loss, against the output distribution $N$ of find-num. We follow the same procedure for a few other question
types involving dates and numbers; see A.7 for details.

4 Auxiliary Supervision

As mentioned in §4.2 jointly learning the parameters of the parser and the modules using only
end-task QA supervision is extremely challenging. To overcome issues in learning, (a) we introduce
an unsupervised auxiliary loss to provide an inductive bias to the execution of find-num, find-date,
and relocate modules (4.1); and (b) provide heuristically-obtained supervision for question
program and intermediate module output (4.2) for a subset of questions (5–10%).

4.1 Unsupervised Auxiliary Loss for IE

The find-num, find-date, and relocate modules perform information extraction by finding
relevant arguments for entities and events mentioned in the context. In our initial experiments we
found that these modules would often spuriously predict a high attention score for output tokens that
appear far away from their corresponding inputs. We introduce an auxiliary objective to induce the
idea that the arguments of a mention should appear near it. For any token, the objective increases the
sum of the attention probabilities for output tokens that appear within a window $W = 10$, letting
the model distribute the mass within that window however it likes. The objective for the find-num is

$$H_{loss}^n = - \sum_{i=1}^{m} \log \left( \sum_{j=0}^{N_{dom}} \mathbb{1}_{n_j \in [i \pm W]} A_{num}^{ij} \right)$$

We compute a similar loss for the date-attention map $A_{date} (H_{loss}^d)$ and the relocate-map $R (H_{loss}^r)$. The final auxiliary loss is $H_{loss} = H_{loss}^n + H_{loss}^d + H_{loss}^r$.

4.2 Question Parse and Intermediate Module Output Supervision

Question Parse Supervision. Learning to parse questions in a noisy feedback
environment is very challenging. For example, even though the questions in CLEVR
are programmatically generated, Hu et al. (2017) needed to pre-train their parser using external
supervision for all questions. For DROP, we have no such external supervision. In order to
bootstrap the parser, we analyze some questions manually and come up with a few heuristic
patterns to get program and corresponding question attention supervision (for modules that require it)
for a subset of the training data (10% of the questions; see A.6). For example, for program find-num(find-max-num(find())), we provide supervision for question tokens to attend to when predicting the find module.

Intermediate Module Output Supervision. Consider the question, “how many yards was
the shortest goal?”. The model only gets feedback for how long the shortest goal is, but not for other
goals. Such feedback biases the model in predicting incorrect values for intermediate modules (only
the shortest goal instead of all in find-num) which in turn hurts model generalization.

We provide heuristically-obtained noisy supervision for the output of the find-num and
find-date modules for a subset of the questions (5%) for which we also provide question program
supervision. For questions like “how many yards was the longest/shortest touchdown?”, we identify
all instances of the token “touchdown” in the paragraph and assume the closest number to it should be
an output of the find-num module. We supervise this as a multi-hot vector $N^*$ and use an auxiliary
loss, similar to question-attention loss, against the output distribution $N$ of find-num. We follow
the same procedure for a few other question types involving dates and numbers; see A.7 for details.
5 Experiments

5.1 Dataset

We perform experiments on a portion of the recently released DROP dataset (Dua et al., 2019), which to the best of our knowledge is the only dataset that requires the kind of compositional and symbolic reasoning that our model aims to solve. Our model possesses diverse but limited reasoning capability; hence, we try to automatically extract questions in the scope of our model based on their first n-gram. These n-grams were selected by performing manual analysis on a small set of questions. The dataset we construct contains 20,000 questions for training/validation, and 1800 questions for testing (25% of DROP). Since the DROP test set is hidden, this test set is extracted from the validation data. Though this is a subset of the full DROP dataset it is still a significantly-sized dataset that allows drawing meaningful conclusions. We will make the subset and splits available publicly.

Based on the manual analysis we classify these questions into different categories, which are:
- **Date-Compare** e.g. What happened last, commission being granted to Robert or death of his cousin?
- **Date-Difference** e.g. How many years after his attempted assassination was James II coronated?
- **Number-Compare** e.g. Were there more of cultivators or main agricultural labourers in Sweden?
- **Extract-Number** e.g. How many yards was Kasay’s shortest field goal during the second half?
- **Count** e.g. How many touchdowns did the Vikings score in the first half?
- **Extract-Argument** e.g. Who threw the longest touchdown pass in the first quarter?

**Auxiliary Supervision** Out of the 20,000 training questions, we provide question program supervision for 10% (2000), and intermediate module output supervision for 5% (1000) of training questions. We use curriculum learning (Bengio et al., 2009) where the model is trained only on heuristically-supervised non-count questions for the first 5 epochs.

5.2 Results

We compare to publicly available best performing models: NAQANet (Dua et al., 2019), NABERT+ (Kinley & Lin, 2019), TAG-NABERT+ (Avia Efrat & Shoham, 2019), and MTMSN (Hu et al., 2019), all trained on the same data as our model. We implement our model using AllenNLP (Gardner et al., 2018) (code available at https://anon.ymo.us). The hyperparameters used for our model are described in the appendix. All results are reported as an average of 4 model runs.

**Overall.** Table 2a compares our model’s performance to state-of-the-art models on our full test set. Our model achieves an F1 score of 73.1 (w/ GRU) and significantly outperforms NAQANet (62.1 F1). Using BERT representations, our model’s performance increases to 77.4 F1 and outperforms SoTA models that use BERT representations, such as MTMSN (76.5 F1). This shows the efficacy of our proposed model in understanding complex compositional questions and performing multi-step reasoning over natural language text. Additionally, this shows that structured models still benefit when used over representations from large pretrained-LMs, such as BERT.

**Performance by Question Type.** Table 2b shows the performance for different question types as identified by our heuristic labeling. Our model outperforms MTMSN on majority of question types but struggles with counting questions; it outperforms MTMSN on only some of the runs. Even after
Under review as a conference paper at ICLR 2020

(a) **Effect of Auxiliary Supervision:** The auxiliary loss contributes significantly to the performance, whereas module output supervision has little effect. *(Training diverges without $H_{loss}$ for the BERT-based model.)*

(b) **Performance with less training data:** Our model performs significantly better than the baseline with less training data, showing the efficacy of explicitly modeling compositionality.

![Figure 2: Effect of auxiliary losses and the size of training data on model performance.](image)

Effect of Auxiliary Supervision.

Effect of Additional Supervision. Figure 2a shows that the unsupervised auxiliary objective significantly improves model performance (from 57.3 to 73.1 F1). The model using BERT diverges while training without the auxiliary objective. Additionally, the intermediate module output supervision has slight positive effect on the model performance.

Effect of Training Data Size. Figure 2b shows that our model significantly outperforms MTMSN when training using less data, especially using 10-25% of the available supervision. This shows that explicitly modeling compositionality improves model generalization.

6 **Related Work**

Semantic parsing techniques have been used for a long time for compositional question understanding. Approaches have used labeled logical-forms (Zelle & Mooney, 1996; Zettlemoyer & Collins, 2005), or weak QA supervision (Clarke et al., 2010; Berant et al., 2013; Reddy et al., 2014) to learn parsers to answer questions against structured knowledge bases. These have also been extended for QA using symbolic reasoning against semi-structured tables (Pasupat & Liang, 2015; Krishnamurthy et al., 2017; Neelakantan et al., 2016). Recently, BERT-based models for DROP have been proposed (Hu et al., 2019; Andor et al., 2019; Kinley & Lin, 2019), but all these models essentially perform a multiclass classification over pre-defined programs. Our model on the other hand provides an interpretable, compositional parse of the question and exposes its intermediate reasoning steps.

For combining learned execution modules with semantic parsing, many variations to NMNs have been proposed: NMN (Andreas et al., 2016) use a PCFG parser to parse the question and only learn module parameters. N2NMNs (Hu et al., 2017) simultaneously learn to parse and execute but require pre-training the parser. Gupta & Lewis (2018) propose a NMN model for QA against knowledge graphs and learn execution for semantic operators from QA supervision alone. Recent works (Gupta & Lewis, 2018; Mao et al., 2019) also use domain-knowledge to alleviate issues in learning by using curriculum learning to train the executor first on simple questions for which parsing is not an issue. All these approaches perform reasoning on synthetic domains, while our model is applied to natural language. Concurrently, Jiang & Bansal (2019) apply NMN to HotpotQA (Yang et al., 2018) but their model comprises of only 3 modules and is not capable of performing symbolic reasoning.

7 **Conclusion**

We show how to use neural module networks to answer compositional questions requiring symbolic reasoning against natural language text. We define probabilistic modules that propagate uncertainty
about symbolic reasoning operations in a way that is end-to-end differentiable. Additionally, we show that injecting inductive bias using unsupervised auxiliary losses significantly helps learning.

While we have demonstrated marked success in broadening the scope of neural modules and applying them to open-domain text, it remains a significant challenge to extend these models to the full range of reasoning required even just for the DROP dataset. For example, it is unclear how to design modules for questions that require aggregation across entity mentions (e.g. “Which kicker scored the most field goals?”), solving top-K (e.g. “Which race was second-most prevalent in Huntington Beach?”), or require IE for implicit arguments (e.g. “How many points did the packers fall behind during the game?” requires extracting points scored by the other team). NMNs provide interpretability, compositionality, and improved generalizability, but at the cost of restricted expressivity as compared to more black box models. Future research is necessary to continue bridging these reasoning gaps.

Our model represents the question \( q \) as \( Q \in \mathbb{R}^{n \times d} \) and paragraph \( p \) as \( P \in \mathbb{R}^{m \times d} \) using contextualized token embeddings. These embeddings are either produced using a multi-layer GRU network that is trained from scratch, or a pre-trained BERT model that is fine-tuned during training.

**GRU:** We use a 2-layer, 64-dimensional \( (d = 128, \text{effectively}) \), bi-directional GRU. The same GRU is used for both, the question and the paragraph. The token embeddings input to the contextual encoder are a concatenation of 100-d pre-trained GloVe embeddings, and 200-d embeddings output from a CNN over the token’s characters. The CNN uses filters of size=5 and character embeddings of 64-d. The pre-trained glove embeddings are fixed, but the character embeddings and the parameters for the CNN are jointly learned with the rest of the model.

**BERT:** The input to the BERT model is the concatenation of the question and paragraph in the following format: [CLS] Question [SEP] Context [SEP]. The question and context tokens input to the BERT model are sub-words extracted by using BERT’s tokenizer. We separate the question and context representation from the output of BERT as \( Q \) and \( P \), respectively. We use ‘bert-base-uncased’ model for all out experiments.
A.2 Question Parser Decoder

The decoder for question parsing is a single-layer, 100-dimensional, LSTM. For each module, we use a 100-dimensional embedding to present it as an action in the decoder’s input/output vocabulary. The attention is computed as a dot-product between the decoder hidden-state and the encoders hidden states which is normalized using the softmax operation.

As the memory-state for the zero-eth time-step in the decoder, we use the last hidden-state of the question encoder GRU, or the [CLS] embedding for the BERT-based model.

We use a beam-size of 4 for the approximate maximum marginal likelihood objective. Optimization is performed using the Adam algorithm with a learning rate of 0.001 or using BERT’s optimizer with a learning rate of $1e^{-5}$.

A.3 Number and Date Parsing

We pre-process the paragraphs to extract the numbers and dates in them. For numbers, we use a simple strategy where all tokens in the paragraph that can be parsed as a number are extracted. For example, 200 in “200 women”. The total number of number-tokens in the paragraph is denoted by $N_{tokens}$. We do not normalize numbers based on their units and leave it for future work.

To extract dates from the paragraph, we run the spaCy-NER\(^2\) and collect all “DATE” mentions. To normalize the date mentions we use an off-the-shelf date-parser\(^3\). For example, a date mention “19th November, 1961” would be normalized to $(19, 11, 1961)$ (day, month, year). The total number of date-tokens is denoted by $D_{tokens}$

A.4 Pre-training Count Module

As mentioned in the paper, training the count module is challenging and found that pre-training the parameters of the count module helps.

To re-iterate, the module gets as input a paragraph attention $P \in \mathbb{R}^m$. The module first scales the attention using the values $[1, 2, 5, 10]$ to convert it into a matrix $P_{\text{scaled}} \in \mathbb{R}^{m \times 4}$. A bidirectional-GRU then represents each token attention as a hidden vector $h_t$. A single-layer feed-forward network maps this representation to a soft 0/1 score to indicate the presence of a span surrounding it. These scores are summed to compute a count value, $c_v$.

$$\text{count scores} = \sigma\left(FF(\text{countGRU}(P_{\text{scaled}}))\right) \in \mathbb{R}^m$$

$$c_v = \sum \text{count scores} \in \mathbb{R}$$

We generate synthetic data to pre-train this module; each instance is a normalized-attention vector $x = \mathbb{R}^m$ and a count value $y \in [0, 9]$. This is generated by sampling $m$ uniformly between 200 − 600, then sampling a count value $y$ uniformly in $[0, 9]$. We then sample $y$ span-lengths between 5 − 15 and also sample $y$ non-overlapping span-positions in the attention vector $x$. For all these $y$ spans in $x$, we put a value of 1.0 and zeros everywhere else. We then add 0-mean, 0.01-variance gaussian noise to all elements in $x$ and normalize to make the normalized attention vector that can be input to the count module.

We train the parameters of the count module using these generated instances using $L_2$-loss between the true count value and the predicted $c_v$.

The countGRU in the count module (spanGRU – span module) is a 2-layer, bi-directional GRU with input-dim = 4 and output-dim = 20. The final feed-forward comprises of a single-layer to map the output of the countGRU into a scalar score.

**A.5 SPAN Module**

The \texttt{span} module is implemented similar to the \texttt{count} module. The input paragraph attention is first scaled using $[1, 2, 5, 10]$, then a bidirectional-GRU represents each attention as a hidden vector, and a single-layer feed-forward network maps this to 2 scores, for span start and end. A softmax operation on these scores gives the output probabilities.

**A.6 Auxiliary Question Parse Supervision**

For questions with parse supervision $z^*$, we decouple the marginal likelihood into two maximum likelihood objectives, $p(z^*|q)$ and $p(y^*|z^*)$. We also add a loss for the decoder to attend to the tokens in the question attention supervision when predicting the relevant modules. The question attention supervision is provided as a multi-hot vector $\alpha^* \in \{0, 1\}^n$. The loss against the predicted attention vector $\alpha$ is, $Q_{loss} = -\sum_{i=1}^n \alpha^*_i \log \alpha_i$. Since the predicted attention is a normalized distribution, the objective increases the sum of log-probabilities of the tokens in the supervision.

The following patterns are used to extract the question parse supervision for the training data:

1. \textit{what happened first SPAN1 or SPAN2?}  
   \texttt{span(compare-date-lt(find(), find()))}: with \texttt{find} attentions on SPAN1 and SPAN2, respectively. Use \texttt{compare-date-gt}, if \texttt{second} instead of \texttt{first}.

2. \textit{were there fewer SPAN1 or SPAN2?}  
   \texttt{span(compare-num-lt(find(), find()))}: with \texttt{find} attentions on SPAN1 and SPAN2, respectively. Use \texttt{compare-num-gt}, if \texttt{more} instead of \texttt{fewer}.

3. \textit{how many yards was the longest \{touchdown / field goal\}?}  
   \texttt{find-num(find-max-num(find()))}: with \texttt{find} attention on \texttt{touchdown / field goal}. For \texttt{shortest}, the \texttt{find-min-num} module is used.

4. \textit{how many yards was the longest \{touchdown / field goal\} SPAN?}  
   \texttt{find-num(find-max-num(filter(find()))): with \texttt{find} attention on \texttt{touchdown / field goal} and \texttt{filter} attention on all SPAN tokens.

5. \textit{how many \{field goals, touchdowns, passes\} were scored SPAN?}  
   \texttt{count(filter(find()))}: with \texttt{find} attention on \texttt{field goals, touchdowns, passes} and \texttt{filter} attention on SPAN.

6. \textit{who \{kicked, caught, threw, scored\} SPAN?}  
   \texttt{span(relocate(filter(find()))): with \texttt{relocate} attention on \texttt{kicked, caught, threw, scored}, \texttt{find} attention on \texttt{touchdown / field goal}, and \texttt{filter} attention on all other tokens in the SPAN.

**A.7 Heuristic Intermediate Module Output Supervision**

As mentioned in Section 4.3, we heuristically find supervision for the output of the \texttt{find-num} and \texttt{find-date} module for a subset of questions that already contain question program supervision. These are as follows:

1. \textit{how many yards was the longest/shortest \{touchdown, field goal\}?}  
   We find all instances of touchdown/field goal in the passage and assume that the number appearing closest should be an output of the \texttt{find-num} module.

2. \textit{what happened first EVENT1 or EVENT2?}  
   Similar to above, we perform fuzzy matching to find the instance of EVENT1 and EVENT2 in the paragraph and assume that the closest dates should be the output of the two \texttt{find-date} module calls made by the \texttt{compare-date-lt} module in the gold program.

3. \textit{were there fewer SPAN1 or SPAN2?}  
   This is exactly the same as previous for \texttt{find-num} module calls by \texttt{compare-num-lt}.
