PRE-TRAINED CONTEXTUAL EMBEDDING OF SOURCE CODE

Anonymous authors
Paper under double-blind review

ABSTRACT

The source code of a program not only serves as a formal description of an executable task, but it also serves to communicate developer intent in a human-readable form. To facilitate this, developers use meaningful identifier names and natural-language documentation. This makes it possible to successfully apply sequence-modeling approaches, shown to be effective in natural-language processing, to source code. A major advancement in natural-language understanding has been the use of pre-trained token embeddings; BERT and other works have further shown that pre-trained contextual embeddings can be extremely powerful and can be finetuned effectively for a variety of downstream supervised tasks. Inspired by these developments, we present the first attempt to replicate this success on source code. We curate a massive corpus of Python programs from GitHub to pre-train a BERT model, which we call *Code Understanding BERT* (CuBERT). We also pre-train Word2Vec embeddings on the same dataset. We create a benchmark of five classification tasks and compare finetuned CuBERT against sequence models trained with and without the Word2Vec embeddings. Our results show that CuBERT outperforms the baseline methods by a margin of 2.9–22%. We also show its superiority when finetuned with smaller datasets, and over fewer epochs.

1 INTRODUCTION

Modern software development places a high value on writing clean and readable code. This helps other developers understand the author's intent so that they can maintain and extend the code. Developers use meaningful identifier names and natural-language documentation to make this happen (Martin, 2008). As a result, source code contains substantial information that can be exploited by machine-learning algorithms. Sequence modeling on source code has been shown to be successful in a variety of software-engineering tasks, such as code completion (Hindle et al., 2012; Raychev et al., 2014), source code to pseudocode mapping (Oda et al., 2015), API-sequence prediction (Gu et al., 2016), program repair (Pu et al., 2016; Gupta et al., 2017), and natural language to code mapping (Iyer et al., 2018), among others.

The distributed vector representations of tokens, called token (or word) embeddings, are a crucial component of neural methods for sequence modeling. Learning useful embeddings in a supervised setting with limited data is often difficult. Therefore, many unsupervised learning approaches have been proposed to take advantage of large amounts of unlabeled data that are more readily available. This has resulted in ever more useful pre-trained token embeddings (Mikolov et al., 2013a; Pennington et al., 2014). However, the subtle differences in the meaning of a token in varying contexts are lost when each word is associated with a single representation. Recent techniques for learning contextual embeddings (McCann et al., 2017; Peters et al., 2018; Radford et al., 2018; 2019; Devlin et al., 2019; Yang et al., 2019) provide ways to compute representations of tokens based on their surrounding context, and have shown significant accuracy improvements in downstream tasks, even with only a small number of task-specific parameters.

Inspired by the success of pre-trained contextual embeddings for natural languages, we present the first attempt to apply the underlying techniques to source code. In particular, BERT (Devlin et al., 2019) produces a bidirectional Transformer encoder (Vaswani et al., 2017) by training it to predict values of masked tokens and whether two sentences follow each other in a natural discourse. The pre-trained model can be finetuned for downstream supervised tasks and has been shown to

produce state-of-the-art results on a number of NLP benchmarks. In this work, we derive contextual embedding of source code by training a BERT model on source code. We call our model CuBERT, short for *Code Understanding BERT*.

In order to achieve this, we curate a massive corpus of Python programs collected from GitHub. GitHub projects are known to contain a large amount of duplicate code. To avoid biasing the model to such duplicated code, we perform deduplication using the method of Allamanis (2018). The resulting corpus has 6.6M unique files with a total of 2 billion words. We also train Word2Vec embeddings (Mikolov et al., 2013a;b), namely, continuous bag-of-words (CBOW) and Skipgram embeddings, on the same corpus. For evaluating CuBERT, we create a benchmark of five classification tasks, ranging from classification of source code according to presence or absense of certain classes of bugs, to mismatch between a function's natural language description and its body, to predicting the right kind of exception to catch for a given code fragment. These tasks are motivated by prior work in this space, but unfortunately, the associated datasets come from different languages and varied sources. We want to ensure that there is no overlap between pre-training and finetuning datasets, and that all of the tasks are defined on Python code. We therefore create new datasets for the five tasks after carefully separating the pre-training and finetuning corpora.

We finetune CuBERT on each of the tasks and compare the results with multi-layered bidirectional LSTM (Hochreiter & Schmidhuber, 1997) models. We train the LSTM models from scratch and also using pre-trainined Word2Vec embeddings. Our results show that CuBERT consistently outperforms these baseline models by 2.9–22% across the tasks. We perform a number of additional studies by varying the sampling strategies used for training Word2Vec models, by varying program lengths, and by comparing against Transformer models trained from scratch. In addition, we also show that CuBERT can be finetuned effectively using only 33% of the task-specific labeled data and with only 2 epochs, and that it attains results competitive to the baseline models trained with the full datasets and much larger number of epochs. The contributions of this paper are as follows:

- We present the first attempt at pre-training a BERT contextual embedding of source code.
- We show the efficacy of the pre-trained contextual embedding on five classification tasks. Our results show that the finetuned models outperform the baseline LSTM models supported by Word2Vec embeddings, and Transformers trained from scratch. Further, the finetuning works well even for smaller datasets and fewer training epochs.
- We plan to make the models and datasets publicly available for use by others.

2 Related Work

Given the abundance of natural-language text, and the relative difficulty of obtaining labeled data, much effort has been devoted to using large corpora to learn about language in an unsupervised fashion, before trying to focus on tasks with small labeled training datasets. Word2Vec (Mikolov et al., 2013a;b) computed word embeddings based on word co-occurrence and proximity, but the same embedding is used regardless of the context. The continued advances in word embeddings (Pennington et al., 2014) led to publicly released pre-trained embeddings, used in a variety of tasks.

To deal with varying word context, contextual word embeddings were developed (McCann et al., 2017; Peters et al., 2018; Radford et al., 2018; 2019), in which an embedding is learned for the *context* of a word in a particular sentence, namely the sequence of words preceding it and possibly following it. BERT (Devlin et al., 2019) improved natural-language pre-training by using a denoising autoencoder. Instead of learning a language model, which is inherently sequential, BERT optimizes for predicting a noised word within a sentence. Such prediction instances are generated by choosing a word position and either keeping it unchanged, removing the word, or replacing the word with a random wrong word. It also pre-trains with the objective of predicting whether two sentences can be next to each other. These pre-training objectives, along with the use of a Transformer-based architecture, gave BERT an accuracy boost in a number of NLP tasks over the state-of-the-art. BERT has been improved upon in various ways, including modifying training objectives, utilizing ensembles, combining attention with autoregression (Yang et al., 2019), and expanding pre-training corpora and time (Liu et al., 2019). However, the main architecture of BERT seems to hold up as the state-of-the-art, as of this writing.

In the space of programming languages, attempts have been made to learn embeddings in the context of specific software-engineering tasks. These include embeddings of variable and method identifiers using local and global context (Allamanis et al., 2015), abstract syntax trees or ASTs (Mou et al., 2016), paths in ASTs (Alon et al., 2019), memory heap graphs (Li et al., 2016), and ASTs enriched with data flow information (Allamanis et al., 2018). These approaches require analyzing source code beyond simple tokenization, and using these methods for pre-training would pass on the burden of program analysis to downstream tasks as well. In this work, we derive a pre-trained contextual embedding of tokenized source code without explicitly modeling source-code-specific information, and show that the resulting embedding can be effectively finetuned for downstream tasks.

3 Experimental Setup

3.1 Code Corpus for Finetuning Tasks

We use the ETH Py150 corpus (Raychev et al., 2016) to generate datasets for the finetuning tasks. The ETH Py150 corpus consists of 150K Python files from GitHub, and is partitioned into a training split (100K files) and a test split (50K files). We held out 10K files from the training split as a validation split. We deduplicated the dataset in the fashion of Allamanis (2018), resulting in a slightly smaller dataset of 85K, 9.5K, and 47K files in train, validation, and test, respectively.

3.2 The GitHub Python Pre-Training Code Corpus

We used the public GitHub repository hosted on Google's BigQuery platform (the `github_repos` dataset under BigQuery's public-data project, `bigquery-public-data`). We extracted all files ending in `.py`, under open-source, redistributable licenses, removed symbolic links, and retained only files reported to be in the `refs/heads/master` branch. This resulted in about 16.1M files.

To avoid duplication between pre-training and finetuning data, we removed files that had high similarity to the files in the ETH Py150 dataset, using the method of Allamanis (2018). This brought the dataset to 13.5M files. We then further deduplicated the remaining files, by clustering them into equivalence classes holding similar files according to the same similarity metric, and keeping only one exemplar per equivalence class. This helps avoid biasing the pre-trained embedding. Finally, we removed files that could not be tokenized. In the end, we were left with 6.6M Python files containing over 2 billion words. This is our Python pre-training code corpus.

3.3 Source Code Modeling

We first tokenize a Python program using the standard Python tokenizer (the `tokenize` package). We leave language keywords intact and produce special tokens for syntactic elements that have either no string representation (e.g., `DEDENT` tokens, which occur when a nested program scope concludes), or ambiguous interpretation (e.g., new line characters inside string literals, at the logical end of a Python statement, or in the middle of a Python statement result in distinct special tokens). We split identifiers according to common heuristic rules (e.g., snake or Camel case). Finally, we split string literals using heuristic rules, on whitespace characters, and on special characters. We limit all thus produced tokens to a maximum length of 15 characters. We call this the *program vocabulary*. Our Python pre-training code corpus contained 10.2M unique tokens, including 12 reserved tokens.

We greedily compress the program vocabulary into a *subword vocabulary* (Schuster & Nakajima, 2012) using the `SubwordTextEncoder` from the Tensor2Tensor project (Vaswani et al., 2018), resulting in slightly over 50K tokens. All words in the program vocabulary can be losslessly encoded using one or more of the subword tokens.

We encode programs first into program tokens, as described above, and then encode those tokens one by one in the subword vocabulary. The objective of this encoding scheme is to preserve syntactically meaningful boundaries of tokens. For example, the identifier "`snake_case`" could be encoded as "`sna ke _ ca se`", preserving the snake case split of its characters, even if the subtoken "`e_c`" were very popular in the corpus; the latter encoding might result in a smaller representation but would lose the intent of the programmer in using a snake-case identifier. Similarly, "`i=0`" may be very frequent in the corpus, but we still force it to be encoded as separate tokens `i`, `=`, and `0`,

ensuring that we preserve the distinction between operators and operands. Both the BERT model and the Word2Vec embeddings are built on the subword vocabulary.

3.4 FINETUNING TASKS

To evaluate CuBERT, we design five finetuning tasks. These are motivated by prior work, but unfortunately, the associated datasets come from different languages and varied sources. We want the tasks to be on Python code, and for accurate results, we ensure that there is no overlap between pre-training and finetuning datasets. We therefore create the five tasks on the ETH Py150 corpus (see Section 3.1). As discussed in Section 3.2, we ensure that there is no duplication between this and the pre-training corpus. We hope that our datasets for these tasks will be useful to others as well. The finetuning tasks are described below.

Variable Misuse Allamanis et al. (2018) observed that developers may mistakenly use an incorrect variable in the place of a correct one. These mistakes may occur when developers copy-paste similar code but forget to rename all occurrences of variables from the original fragment, or when there are similar variable names in contexts that can be confused with each other. These can be subtle errors that remain undetected during compilation. The task by Allamanis et al. (2018) is to predict a correct variable name at a location within a function and was devised on C# programs. We take the classification version restated by Vasic et al. (2019), wherein, given a function, the task is to predict whether there is a variable misuse at some location in the function, without specifying a particular location to consider. In this setting, the classifier has to consider all variables and their usages to make the decision. In order to create negative (buggy) examples, we replace a variable use at some location with another variable that is defined within the function.

Wrong Binary Operator Pradel & Sen (2018) proposed the task of detecting whether a binary operator in a given expression is correct. They use features extracted from limited surrounding context. We use the entire function with the goal of detecting whether any binary operator in the function is incorrect. The negative examples are created by randomly replacing some binary operator with another type-compatible operator.

Swapped Operand Pradel & Sen (2018) propose the wrong binary operand task where a variable or constant is used incorrectly in an expression, but that task is quite similar to the variable misuse task we already use. We therefore define another class of operand errors where the operands of non-commutative binary operators are swapped. The operands can be arbitrary subexpressions, and are not restricted to be just variables or constants. To simplify example generation, we restrict examples for this task to those in which the binary operator and its operands all fit within a single line.

Function-Docstring Mismatch Developers are encouraged to write descriptive docstrings to explain the functionality and usage of functions. Barone & Sennrich (2017) have created a parallel corpus of functions and docstrings for machine translation. We similarly prepare a sentence-pair classification problem where the function and its docstring form two distinct sentences. The positive examples come from the correct function-docstring pairs. We create negative examples by replacing correct docstrings with docstrings of other functions, randomly chosen from the dataset. For this task, the existing docstring is removed from the function body.

Exception Type While it is possible to write generic exception handlers (e.g., "`except Exception`" in Python), it is considered a good coding practice to catch and handle the precise exceptions that can be raised by a code fragment. We identified the 20 most common exception types from the GitHub dataset, excluding the catch-all `Exception`. Given a function with an `except` clause for one of these exception types, we replace the exception with a special "hole" token. The task is the multi-class classification problem of predicting the original exception type.

Table 1 lists the sizes of the resulting benchmark datasets extracted from the (deduplicated) ETH Py150 corpus. The Exception Type task contains fewer examples than the other tasks, since examples for this task only come from functions that catch one of the chosen 20 exception types.

	Train	Validation	Test
Variable Misuse	796020	8192 (86810)	429854
Wrong Binary Operator	537244	8192 (59112)	293872
Swapped Operand	276116	8192 (30818)	152248
Function-Docstring	391049	8192 (44029)	213269
Exception Type	21694	2459 (2459)	12036

Table 1: Benchmark finetuning datasets. Note that for validation, we have subsampled the original datasets (in parentheses) down to 8192 examples, except for exception classification, which only had 2459 validation examples, all of which are included.

3.5 BERT FOR SOURCE CODE

The BERT model (Devlin et al., 2019) consists of a multi-layered Transformer encoder. It is trained with two tasks: (1) to predict the correct tokens in a fraction of all positions, some of which have been replaced with incorrect tokens or the special `[MASK]` token (the Masked Language Model task) and (2) to predict whether the two sentences separated by the special `[SEP]` token follow each other in some natural discourse (the Next Sentence Prediction task). Thus, each example consists of one (for MLM) or two (for NSP) *sentences*, where a sentence is the concatenation of contiguous lines from the source corpus, sized to fit the target example length. To ensure that every sentence is treated in multiple instances of both MLM and NSP, BERT by default duplicates the corpus 10 times, and generates independently derived examples from each duplicate. With 50% probability, the second example sentence comes from a random document (for NSP). With 15% probability, a token is chosen for an MLM prediction (up to 20 per example), and from those chosen, 80% are masked, 10% are left undisturbed, and 10% are replaced with a random token.

CUBERT is similarly formulated, but a CUBERT sentence is a logical code line, as defined by the Python standard. Intuitively, a logical code line is the shortest sequence of consecutive lines that may constitute a legal statement, e.g., it has correctly matching parentheses. We count example lengths by counting the subword tokens of both sentences (see Section 3.3).

We train the BERT Large model, consisting of 24 layers with 16 attention heads and hidden size of 1024 units. Sentences are created by parsing our pre-training dataset. Task-specific classifiers pass the embedding of a special start-of-example `[CLS]` token through feedforward and softmax layers.

3.6 BASELINES

3.6.1 WORD2VEC

We train Word2Vec models using the same pre-training corpus as the BERT model. To maintain parity, we generate the dataset for Word2Vec using the same pipeline as BERT but by disabling masking and generation of negative examples for NSP. The dataset is generated without any duplication. We train both CBOW and Skipgram models using GenSim (Řehůřek & Sojka, 2010). To deal with the large vocabulary, we use negative sampling and hierarchical softmax (Mikolov et al., 2013a;b) to train the two versions. In all, we obtain four Word2Vec embeddings.

3.6.2 BIDIRECTIONAL LSTM AND TRANSFORMER

In order to obtain context-sensitive encodings of input sequences for the finetuning tasks, we use multi-layered bidirectional BiLSTMs (Hochreiter & Schmidhuber, 1997) (BiLSTMs). These are initialized with the pre-trained Word2Vec embeddings. Additionally, to further evaluate whether LSTMs alone are sufficient without pre-training, we try initializing the BiLSTM with an embedding matrix that is trained from scratch. We also trained Transformer models (Vaswani et al., 2017) for our finetuning tasks. We used BERT's own Transformer implementation, to ensure comparability of results.

4 EXPERIMENTAL RESULTS

4.1 TRAINING DETAILS

As stated above, CuBERT's dataset generation duplicates the corpus 10 times, whereas Word2Vec is trained without duplication. To compensate for this difference, we trained Word2Vec for 10 epochs and CuBERT for 1 epoch. We pre-train CuBERT with the default configuration of the BERT Large model. For sequences of length 128, 256 and 512, we use batch sizes of 8192, 4096 and 2048 respectively. For Word2Vec, when training with negative samples, we choose 10 negative samples. The embedding sizes for all the pre-trained models are set at 1024.

For the baseline BiLSTM models, we did extensive experimentation on the Variable Misuse task by varying the number of layers (1–3) and the number of hidden units (128, 256, 512). We also tried LSTM output dropout probability (0.1, 0.5), optimizers (Adam (Kingma & Ba, 2014) and AdaGrad (Duchi et al., 2011)), and learning rates (1e-3, 1e-4, 1e-5). The most promising combination was a 3-layered BiLSTM with 512 hidden units per layer, LSTM output dropout probability of 0.1 and Adam optimizer with learning rate of 1e-3. We use this set of parameters for all the tasks except the Exception Type task. Due to the much smaller dataset size of the latter (Table 1), we did a separate search and chose a single-layer BiLSTM with 256 hidden units. We used the batch size of 8192 for the larger tasks and 64 for the Exception Type task.

For the baseline Transformer models, we originally attempted to train a Transformer model of the same configuration as CuBERT. However, the size of our training dataset seemed too small to train that large a Transformer. Instead, we performed a hyperparameter search over transformer layers (1–6), hidden units (128, 256, 512), learning rates (5e-5, 1e-4, 5e-4, 1e-3) and batch sizes (64, 256, 1024, 2048, 4096, 8192) on the Variable Misuse task. The best architecture (4 layers, 512 hidden units, 16 attention heads, learning rate of 5e-4, batch size of 4096) is used for all the tasks except the Exception Type task. A separate experimentation for the smaller Exception Type dataset resulted in the best configuration of 3 layers, 512 hidden units, 16 attention heads, learning rate of 5e-5, and batch size of 2048.

4.2 RESEARCH QUESTIONS

We set out to answer the following research questions. We will address each with our results.

1. Do contextual embeddings help with source-code analysis tasks, when pre-trained on an unlabeled code corpus? We compare CuBERT to BiLSTM models with and without pre-trained Word2Vec embeddings (Section 4.3).
2. Does finetuning actually help, or is the Transformer model behind CuBERT the main power behind the approach? We compare finetuned CuBERT models to Transformer-based models trained from scratch (Section 4.4).
3. How does the performance of CuBERT on our tasks scale with the amount of available labeled training data? We compare the performance of finetuned CuBERT models when finetuning with one third, two thirds, or the full training dataset for each task (Section 4.5).
4. How does example length affect the benefits of CuBERT? We compare finetuning performance for different example lengths (Section 4.6).

Except for Section 4.6, all the results are presented for sequences of length 512. We give examples for each of our tasks in the Appendix and include visualizations of attention weights for them.

4.3 CONTEXTUAL VS. WORD EMBEDDINGS

The purpose of this analysis is to understand how much pre-trained contextual embeddings help, compared to word embeddings. For each finetuning task, we trained BiLSTM models starting with each of our baseline Word2Vec embeddings, namely, continuous bag of words (CBOW) and Skipgram trained with negative sampling or hierarchical softmax. In all the models, the Word2Vec embeddings can be refined during training. Within the first 100 epochs, the performance of the BiLSTM models stopped improving. The best model weights per task were selected by finding the

	Setting		Misuse	Operator	Operand	Docstring	Exception
BiLSTM (100 epochs)	From scratch		76.05%	82.00%	87.77%	78.43%	40.37%
	CBOW	ns	**77.66**%	**84.42**%	88.66%	**89.13**%	48.85%
		hs	77.01%	84.11%	**89.69**%	86.74%	46.73%
	Skipgram	ns	71.58%	83.06%	87.67%	84.69%	48.54%
		hs	77.21%	83.06%	89.01%	82.56%	**49.68**%
CuBERT	2 epochs		90.09%	85.15%	88.67%	95.81%	52.38%
	10 epochs		92.73%	88.43%	88.67%	95.81%	62.55%
	20 epochs		**94.61**%	**90.24**%	**92.56**%	**96.85**%	**71.74**%
Transformer	(100 epochs)		79.37%	78.66%	86.21%	91.10%	48.60%

Table 2: Test accuracies of finetuned CuBERT against BiLSTM (with and without Word2Vec embeddings) and Transformer trained from scratch. "ns" and "hs" respectively refer to negative sampling and hierarchical softmax settings used for training CBOW and Skipgram models. "From scratch" refers to training with freshly initialized token embeddings, that is, without pre-trained Word2Vec embeddings.

minimum validation loss on the corresponding dataset (Table 1) over the first 100 epochs. On the CuBERT side, we finetuned the pre-trained model for 20 epochs, with similar model selection.

The resulting test-split accuracies are shown in Table 2. CuBERT consistently outperforms BiLSTM (with the best task-wise Word2Vec configuration) on all tasks, by a margin of 2.9–22%. Thus, the pre-trained contextual embedding provides superior results even with a smaller budget of 20 epochs, compared to the 100 epochs used for BiLSTMs. The Exception Type classification task is an interesting case since it has an order of magnitude less training data than the other tasks (see Table 1). The difference between the performance of BiLSTM and CuBERT is the highest for this task. Thus, finetuning is of much value for tasks with limited labeled training data.

We analyzed the performance of CuBERT with the reduced finetuning budget of only 2 and 10 epochs (see Table 2). Except for the Operand task, CuBERT outperforms BiLSTM within 2 finetuning epochs. On the Operand task, the performance difference between CuBERT with 2 or 10 finetuning epochs and BiLSTM is about 1%. For the rest of the tasks, CuBERT with only 2 finetuning epochs outperforms BiLSTM (with the best task-wise Word2Vec configuration) by a margin of 0.7–12%. This shows that CuBERT can reach accuracies that are comparable to or better than those of BiLSTMs trained with Word2Vec embeddings within only a few epochs.

We also trained the BiLSTM models from scratch, that is, without using the Word2Vec embeddings. The results are shown in the first row of Table 2. Compared to those, the use of Word2Vec embeddings performs better by a margin of 1.5–10.5%. Though no single Word2Vec configuration is the best, CBOW trained with negative sampling gives the most consistent results overall.

4.4 Is Transformer All You Need?

One may wonder if CuBERT's promising results derive more from using a Transformer-based model for its classification tasks, and less from the actual, unsupervised pre-training. Here we compare our results to a Transformer-based model trained from scratch, i.e., without the benefit of a pre-trained embedding. All the models were trained for 100 epochs during which their performance stopped improving. We selected the best model per task using least validation loss. As seen from the last row of Table 2, the performance of CuBERT is substantially higher than the Transformer models trained from scratch. We therefore conclude that pre-training is crucial to CuBERT's success.

4.5 The Effects of Little Supervision

The big draw of unsupervised pre-training followed by finetuning is that some tasks have small labeled datasets. We study here how CuBERT fares when the size of its training split is reduced. We sampled uniformly the training split of ETH Py150 down to $2/3$rds and $1/3$rd of its original size, and produced training datasets for each task from each sub-split. We then finetuned the pre-trained

Best of # Epochs	Train Fraction	Misuse	Operator	Operand	Docstring	Exception
2	100%	90.09%	85.15%	88.67%	95.81%	52.38%
	66%	89.52%	83.26%	88.66%	95.17%	34.70%
	33%	88.64%	82.28%	87.45%	95.29%	26.87%
10	100%	92.73%	88.43%	88.67%	95.81%	62.55%
	66%	92.06%	87.06%	90.39%	95.64%	64.59%
	33%	91.23%	84.44%	87.45%	95.48%	54.22%
20	100%	94.61%	90.24%	92.56%	96.85%	71.74%
	66%	94.19%	89.36%	92.01%	96.17%	70.11%
	33%	93.54%	87.67%	91.30%	96.37%	67.72%

Table 3: Effects of reducing training-split size on finetuning performance.

Length	Misuse	Operator	Operand	Docstring	Exception
128	85.89%	77.92%	77.17%	97.10%	55.95%
256	92.69%	86.52%	87.26%	97.08%	65.38%
512	94.61%	90.24%	92.56%	96.85%	71.74%

Table 4: Best out of 20 epochs of finetuning, for three example lengths.

CuBERT model with each of the 3 different training splits. Validation and testing were done with the same original datasets. Table 3 shows the results.

The Function Docstring task seems robust to the reduction of the training dataset, both early and late in the finetuning process (that is, within 2 vs. 20 epochs), whereas the Exception Classification task is heavily impacted by the dataset reduction, given that it has relatively few training examples to begin with. Interestingly enough, for some tasks, even finetuning for only 2 epochs and only using a third of the training data outperforms the baselines. For example, for both Variable Misuse and Function Docstring, CuBERT at 2 epochs and $1/3$rd training data outperforms the BiLSTM with Word2Vec and the Transformer baselines.

4.6 The Effects of Reducing Context

Context size is especially useful in code tasks, given that some relevant information may lie many "sentences" away from its locus of interest. Here we study how reducing the context length (i.e., the length of the examples used to pre-train and finetune) affects performance. We produce data with shorter example lengths by following the standard BERT mechanism. Table 4 shows the results.

Although context seems to be important to most tasks, the Function Docstring task seems to improve with reduced context. This may be because the task primarily depends on comparison between the docstring and the function signature, and including more context dilutes the model's focus.

For comparison, we also evaluated the BiLSTM model on sequences of length 128 and 256 for the Variable Misuse task. We obtained accuracies of 71.34% and 73.63% respectively, which are lower than the best BiLSTM accuracy on sequence length 512 and also lower than the accuracies of CuBERT for the corresponding lengths (see Table 4).

5 Conclusions

We present the first attempt at pre-trained contextual embedding of source code by training a BERT model, called CuBERT, which we finetuned on five tasks and compared against BiLSTM with Word2Vec embeddings and Transformer models. CuBERT outperformed the baseline models consistently. We evaluated CuBERT with less data and fewer epochs, highlighting the benefits of pre-training on a massive, unsupervised code corpus. We see this as a promising step towards source-code understanding, and plan to explore its utility on other programming languages and tasks.

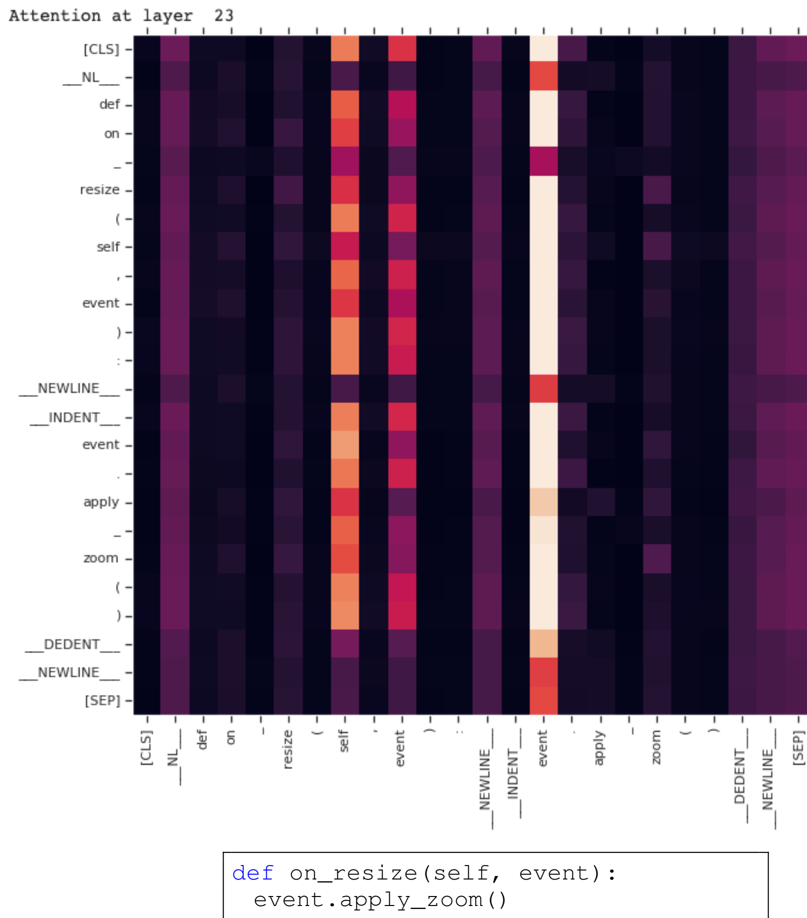

Figure 1: Variable Misuse Example. In the code snippet, ‘`event.apply_zoom`’ should actually be ‘`self.apply_zoom`’. The CuBERT variable-misuse model correctly predicts that the code has an error. As seen from the attention map, the query tokens are attending to the second occurrence of the ‘`event`’ token in the snippet, which corresponds to the incorrect variable usage.

A Appendix

In this section, we provide sample code snippets used to test the different classification tasks. Further, Figures 1–5 show visualizations of the attention matrix of the last layer of the finetuned CuBERT model (Coenen et al., 2019) for the code snippets. In the visualization, the Y-axis shows the query tokens and X-axis shows the tokens being attended to. The attention weight between a pair of tokens is the maximum of the weights assigned by the multi-head attention mechanism. The color changes from dark to light as weight changes from 0 to 1.

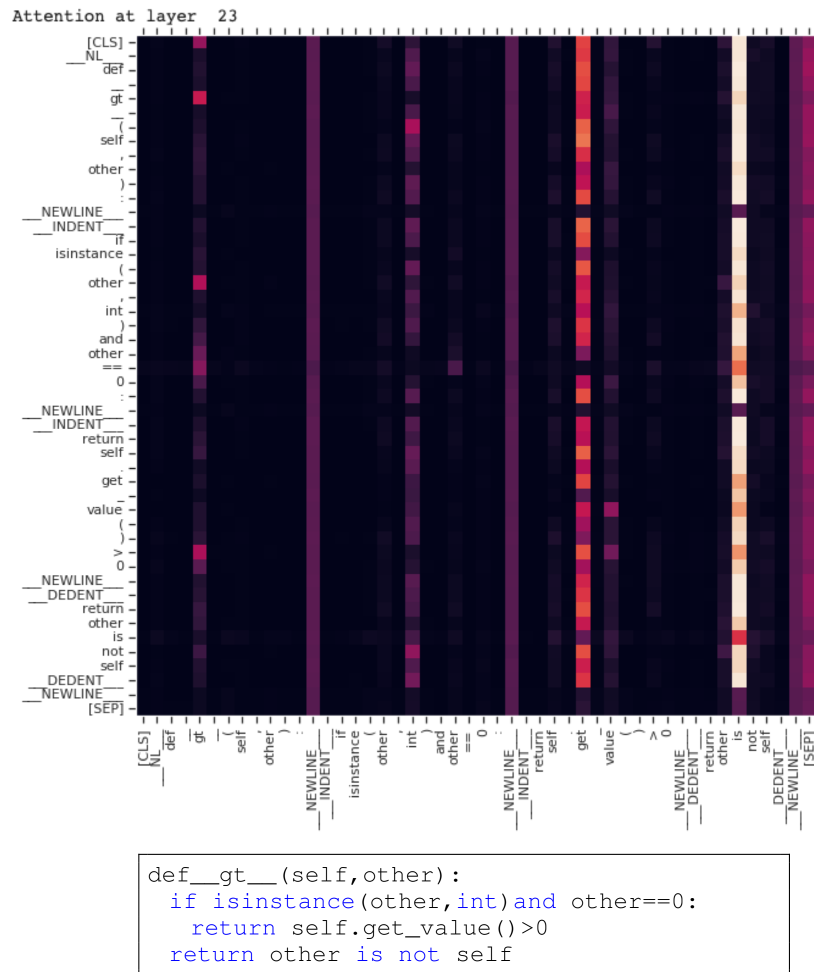

Figure 2: Wrong Operator Example. In this code snippet, ‘`other is not self`’ should actually be ‘`other < self`’. The CuBERT wrong-binary-operator model correctly predicts that the code snippet has an error. As seen from the attention map, the query tokens are all attending to the incorrect operator ‘`is`’.

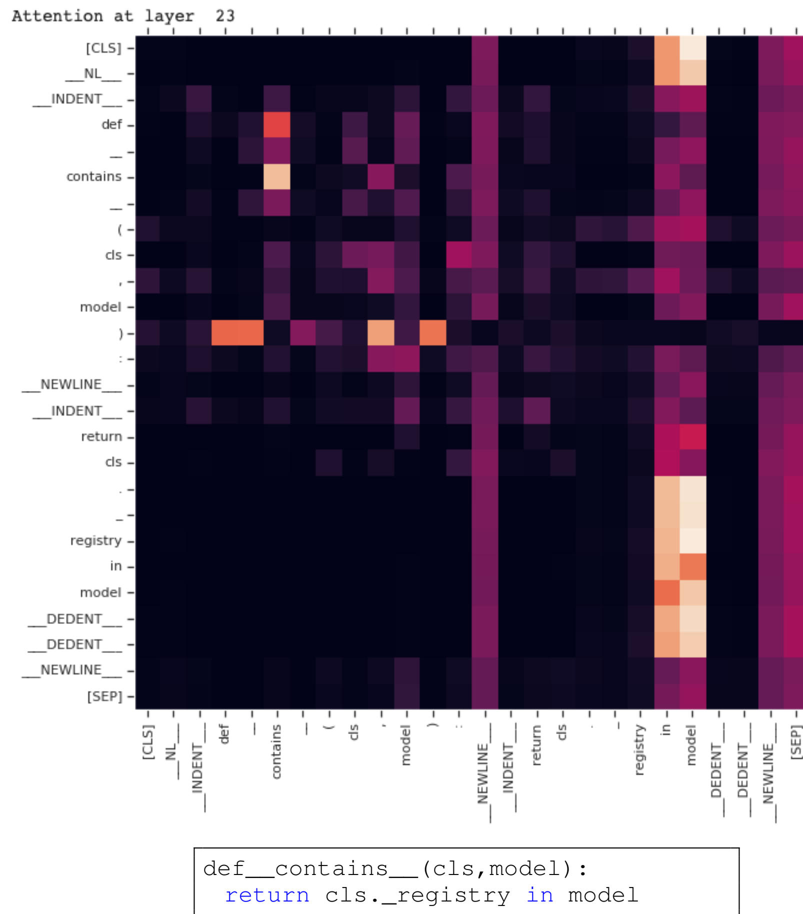

Figure 3: Swapped Operand Example. In this code snippet, the return statement should be ‘`model in cls._registry`’. The swapped-operand model correctly predicts that the code snippet has an error. The query tokens are paying substantial attention to ‘`in`’ and the second occurrence of ‘`model`’ in the snippet.

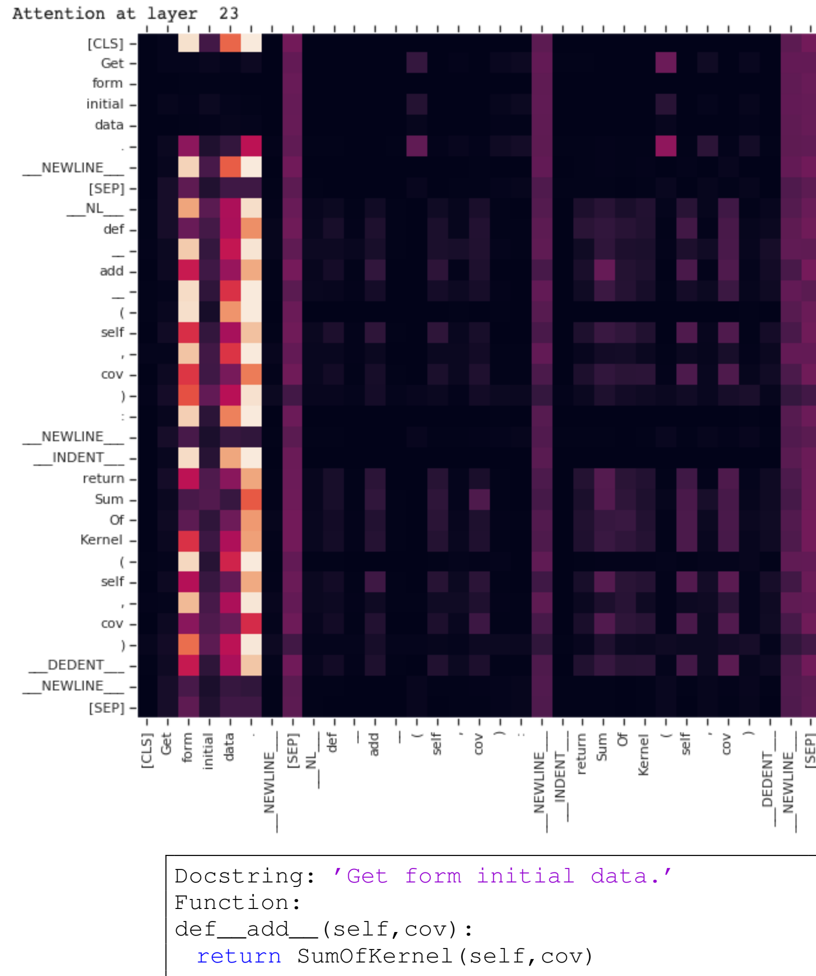

Figure 4: Function Docstring Example. The CuBERT function-docstring model correctly predicts that the docstring is wrong for this code snippet. Note that most of the query tokens are attending to the tokens in the docstring.

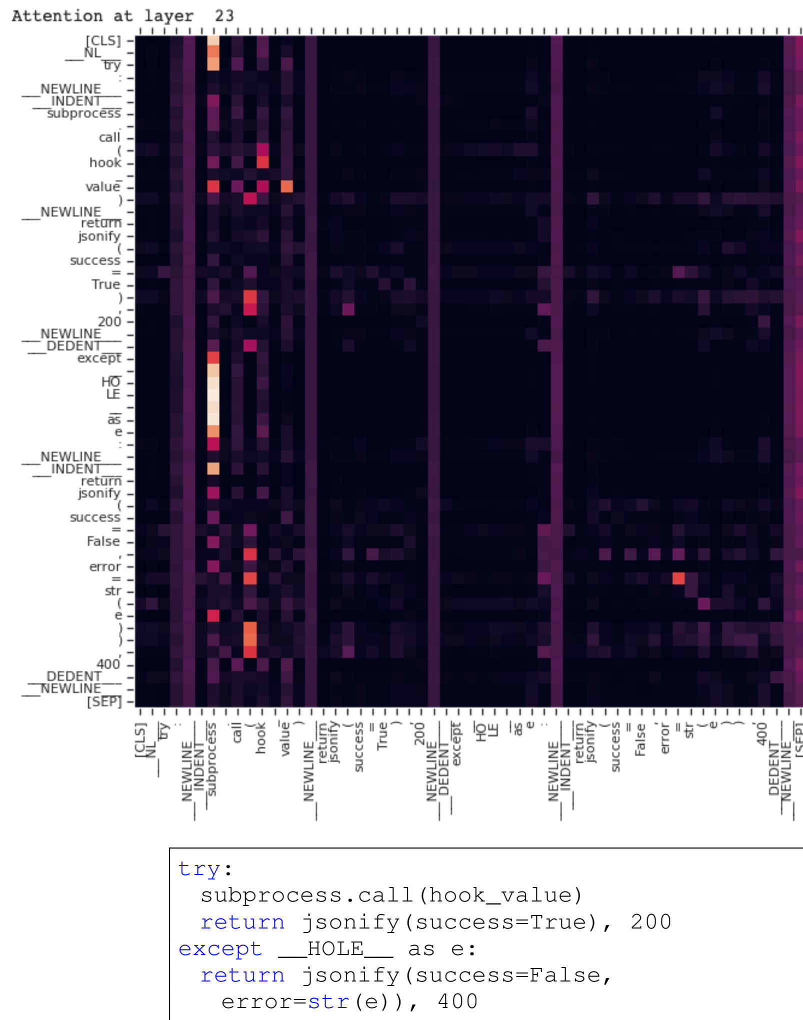

Figure 5: Exception Classification Example. For this code snippet, the CuBERT exception-classification model correctly predicts '__HOLE__' as 'OSError'. The model's attention matrix also shows that '__HOLE__' is attending to 'subprocess', which is indicative of an OS-related error.
