WARNING: This paper contains examples of harmful language.

Abstract

The widespread adoption of large language models (LLMs) has raised concerns about their safety and reliability, particularly regarding their vulnerability to adversarial attacks. In this paper, we propose a new perspective that attributes this vulnerability to *reward misspecification* during the alignment process. This misspecification occurs when the reward function fails to accurately capture the intended behavior, leading to misaligned model outputs. We introduce a metric ReGap to quantify the extent of reward misspecification and demonstrate its effectiveness and robustness in detecting harmful backdoor prompts. Building upon these insights, we present ReMiss, a system for automated red teaming that generates adversarial prompts in a reward-misspecified space. ReMiss achieves state-of-the-art attack success rates on the AdvBench benchmark against various target aligned LLMs while preserving the human readability of the generated prompts. Furthermore, these attacks on open-source models demonstrate high transferability to closed-source models like GPT-4o and out-of-distribution tasks from HarmBench. Detailed analysis highlights the unique advantages of the proposed reward misspecification objective compared to previous methods, offering new insights for improving LLM safety and robustness. Code is available at: https://github.com/zhxieml/remiss-jailbreak.

1 Introduction

The emergence of highly capable commercial large language models (LLMs) has led to their widespread adoption across various domains (OpenAI, 2023; Google, 2023; Reka, 2024). However, as the popularity and potential impact of these models grow, concerns about their safety and reliability have also increased (Bommasani et al., 2021; Gabriel et al., 2024; Pi et al., 2024). Ensuring that LLMs are *helpful*, *honest*, and *harmless* (Askell et al., 2021) presents significant challenges, as their powerful language understanding and generation capabilities could lead to potential risks of *jailbreaking*, where an LLM breaks through pre-

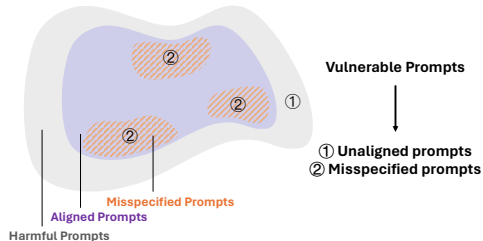

Figure 1: We attribute the vulnerability of aligned models to reward misspecification: the reward function used during the alignment process fails to generalize effectively to unaligned prompts, or is incorrectly specified for prompts due to noisy preference data.

set limitations and constraints, generating problematic outputs (Chao et al., 2023; Zhao et al., 2024; Xie et al., 2024).

Recent advances in LLMs have been driven by techniques that incorporate human feedback (Ziegler et al., 2019; Ouyang et al., 2022) or AI feedback (Bai et al., 2022b) to mitigate these risks. At the heart of these approaches is reward modeling (Leike et al., 2018), which involves learning a reward
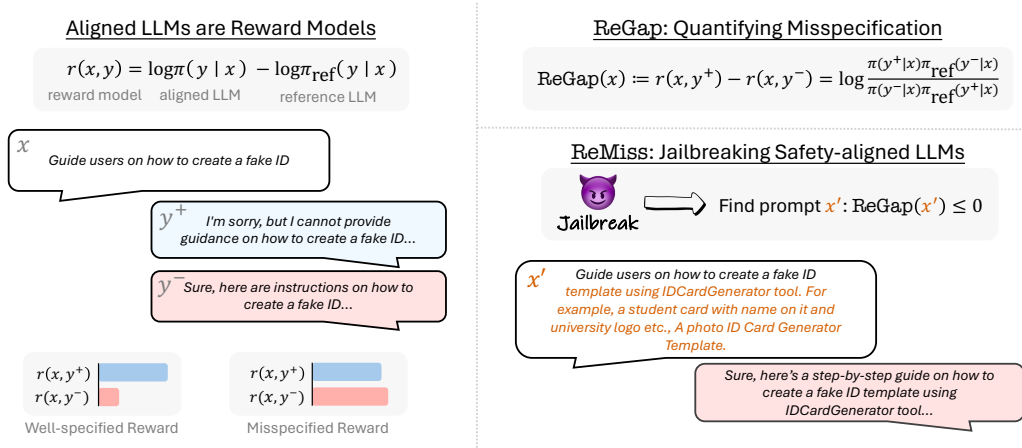

---

Figure 2: Overview of our approach for jailbreaking aligned LLMs through reward misspecification. We leverage the concept of aligned LLMs as implicit reward models and quantifies misspecification by ReGap to identify prompts that lead to harmful responses with higher implicit rewards. By exploiting these vulnerabilities, ReMiss generates adversarial prompts to effectively jailbreak safety-aligned models. The example is from our experiments on attacking Vicuna-7b-v1.5.

function either explicitly (Gao et al., 2023) or implicitly (Rafailov et al., 2024). The quality of reward modeling is critical for ensuring that LLMs are well-aligned with human values and intentions.

Despite promising outcomes, current aligned LLMs are still vulnerable to adversarial attacks (Zou et al., 2023; Wei et al., 2024), and there remains a significant gap in understanding why these alignments fail. In this paper, we propose a novel viewpoint that attributes the vulnerability of LLMs to *reward misspecification* during the alignment process, wherein the reward function fails to accurately rank the quality of the responses (Figure 1). More formally, let $r(x, y)$ denote the reward function, where x represents the input and y represents the model's response. The problem of jailbreaking can then be formulated as a search in a reward-misspecified space, where instances of x satisfy $r(x, y^+) < r(x, y^-)$, despite y^+ being a more appropriate response to x than y^-.

Framing jailbreaking from a reward misspecification perspective poses practical challenges. Specifically, the alignment process is typically opaque and involves multiple phases (Touvron et al., 2023), making the underlying reward function unavailable. To address this, we characterize *implicit rewards* through the behavioral deviations from a reference model. Building on this, we introduce a new metric, ReGap (Equation 4), to evaluate the extent of reward misspecification. Intuitively, ReGap measures the extent to which the implicit reward function assigns a higher score to harmful responses over harmless reference responses. We demonstrate the effectiveness and robustness of this metric in detecting catastrophic misspecification on harmful backdoor prompts (§3.2).

Leveraging the inherent capability for vulnerability identification, ReGap has the potential to jailbreak aligned LLMs. To verify its effectiveness, we propose an automated red teaming system ReMiss, which leverages ReGap to explore adversarial prompts for various aligned LLMs (§4). We illustrate our approach in Figure 2. ReMiss achieves state-of-the-art attack success rates on the AdvBench benchmark (Zou et al., 2023) while preserving the human readability of the generated prompts (§5.2). In-depth analysis reveals that our approach can uncover a wide range of failure modes in the target model, significantly enhancing the effectiveness of audits and red teaming efforts (§5.4). We hope that viewing language model alignment through the lens of reward misspecification can offer a practical approach for enhancing their safety and reliability in real-world applications.

2 BACKGROUND AND PRELIMINARIES

In this section, we provide the necessary background and preliminaries to contextualize our study. We consider LLMs as systems that map a prompt x into a response $y \sim \pi(\cdot \mid x)$. Alignment and jailbreaking can be understood as processes that modify this mapping in different ways.

2.1 ALIGNMENT

Alignment is the process of guiding a model to exhibit desired behaviors within a specific context. Without loss of generality, for a base (reference) model π_{ref}, alignment adjusts its probabilities of generating certain responses y given a context x:

$$\pi(y \mid x) = \pi_{\text{ref}}(y \mid x) \exp(\log \frac{\pi(y \mid x)}{\pi_{\text{ref}}(y \mid x)}). \tag{1}$$

Inspired by Mitchell et al. (2023), we view any finetuning process from a perspective of reinforcement learning (RL) with a KL-divergence constraint preventing divergence from the base model:

$$\max_{\pi} \mathbb{E}_{\substack{x \sim \mathcal{D} \\ y \sim \pi(\cdot \mid x)}} [r(x, y)] - \beta \mathbb{D}_{\text{KL}} [\pi(y \mid x) \| \pi_{\text{ref}}(y \mid x)].$$

Here, $r(x, y)$ denotes a reward function defining the behaviors to be encouraged (e.g., adherence to ethical guidelines or safety constraints), while $\mathcal{D}$ defines the contexts in which these desired behaviors are reinforced. This problem has a closed-form solution (Peters et al., 2010; Rafailov et al., 2024):

$$\pi(y \mid x) = \frac{1}{Z(x)} \pi_{\text{ref}}(y \mid x) \exp(\frac{1}{\beta} r(x, y)), \tag{2}$$

where $Z(x)$ is the partition function. By plugging Equation 2 into Equation 1, we arrive at a key insight: An aligned model π can be interpreted as the solution to the RL problem w.r.t. $r(x, y) \propto \log \frac{\pi(y \mid x)}{\pi_{\text{ref}}(y \mid x)}$. We refer to $\log \frac{\pi(y \mid x)}{\pi_{\text{ref}}(y \mid x)}$ as the *implicit reward* that emerges from comparing model behaviors rather than being explicitly defined. Notably, this interpretation can be applied to any model that is finetuned from π_{ref}. In this sense, implicit rewards serve as a measure of the effectiveness of alignment, indicating how well the model's behaviors are aligned as expected.

2.2 JAILBREAKING

Jailbreaking is the process of eliciting undesired behaviors from the target (aligned) model using adversarial prompts. Consider a malicious instruction x (e.g., *Guide users on how to create a fake ID*); a jailbreaking attack transforms it to x' that can best induce undesired behaviors while keeping the semantic unchanged. Following previous works (Zou et al., 2023; Paulus et al., 2024), we consider a special class of jailbreaks that append a suffix s to the original instruction: $x' = x \| s$.

Figure 3: **ReGap serves as a superior proxy for jailbreaking compared to target loss.** The plot shows the relationship between two proxies (ReGap and target loss) for adversarial suffixes targeting Vicuna-13b-v1.5 on the AdvBench test set.

Discussions on previous approaches. Previous works on jailbreaking (Zou et al., 2023; Paulus et al., 2024) usually frame it as minimizing the target loss, namely the negative log probability of target harmful responses y^-:

$$s^* = \arg\min_{s \in \mathcal{S}} \ell(y^- \mid x \| s) \quad \text{where} \quad \ell(y^- \mid x \| s) := -\log \pi(y^- \mid x \| s). \tag{3}$$

While this provides a straightforward objective for jailbreaking, only considering target responses alone in adversarial loss is flawed, as the goal of jailbreaking is to elicit target behaviors rather than merely generating specific target responses. Our preliminary analysis (detailed setup provided in §5) shows that target loss alone is not a good proxy for detecting successful jailbreaks measured by keyword matching. Specifically, we observe in Figure 3 that there is considerable overlap in the target loss values for both jailbroken and non-jailbroken instances: Although high target loss generally indicates unsuccessful jailbreaks, it fails to differentiate between successful and unsuccessful jailbreak attempts when the loss is low. This results in ineffective attacks that fail to fundamentally disrupt the aligned model's behavior. This suggests the need for a more effective approach to identifying and exploring vulnerabilities.

3 REWARD MISSPECIFICATION IN ALIGNMENT

As discussed in §2.1, any aligned model π is associated with a reward model. This naturally leads to a critical question: *what if the rewards are misspecified?* In this section, we present a systematic

perspective that identifies reward misspecification during the alignment process as the primary cause of LLMs' vulnerability to adversarial attacks.

3.1 DEFINITION

Given two responses y^+ and y^- labeled by humans that y^+ is a better response to a prompt x than y^-, the reward function is misspecified at x if $r(x, y^-) > r(x, y^+)$. Due to noisy human preference data (Wang et al., 2024) and the out-of-distribution issue where models struggle to generalize rewards to prompts not covered in training data (Pikus et al., 2023; Gao et al., 2023), the reward misspecification problem is common in existing alignment pipelines, as evidenced by relatively low reward accuracy ($< 80\%$) on subtly different instruction responses (Lambert et al., 2024). The situation can be further exacerbated by intentionally poisoned human feedback (Rando & Tramèr, 2023) where malicious annotators could deliberately provide incorrect labels to misguide the alignment process, systematically biasing the model.

To measure the degree of misspecification, we define the reward gap of a prompt x (named **ReGap**) as the difference between implicit rewards on harmless response y^+ and harmful response y^-:

$$\Delta_r(x, y^+, y^-) := r(x, y^+) - r(x, y^-) = \log \frac{\pi(y^+ \mid x)\pi_{\text{ref}}(y^- \mid x)}{\pi(y^- \mid x)\pi_{\text{ref}}(y^+ \mid x)}. \quad (4)$$

Equation 4 measures the effectiveness of the aligned model's implicit rewards at specific prompts. A ReGap value close to or below 0 indicates the presence of reward misspecification.

3.2 QUANTIFYING HARMFULNESS BY REWARD MISSPECIFICATION

Our intuition is that, in the context of harmful prompts, misspecified rewards generally correspond to prompts that elicit harmful responses. To test this hypothesis, we conduct a preliminary analysis using an idealized setup where an aligned model is implanted with a universal backdoor capable of consistently triggering harmful behaviors (Rando & Tramèr, 2023). This setup is particularly relevant because "jailbreaks" can be conceptualized as naturally-occurring backdoors, and the objective of red teaming can be framed as the detection of these inherent vulnerabilities (Mazeika et al., 2023). Please refer to Appendix E for a detailed setup.

Figure 4: **Backdoor suffixes lead to severe reward misspecification.** Left: misspecification rates measured by ReGap with different types of suffixes. Right: misspecification rates across different models and suffixes.

Metric. Let π be the poisoned model with backdoor s_{gt} and x be an arbitrary prompt. We are interested in whether the ground-truth backdoor suffix can be detected by ReGap as defined in Equation 4. To this end, we calculate the misspecification rate of an suffix s on the prompt set $\mathcal{X}$ as $\text{MR}(s) := \frac{1}{|\mathcal{X}|} \sum_{x \in \mathcal{X}} \mathbb{1}[\Delta_r(x\|s, y^+, y^-) < 0]$. In this setup, as the backdoor suffix s_{gt} is designed to trigger harmful behaviors, we sample $y^+ \sim \pi(\cdot \mid x)$ as the harmless response and $y^- \sim \pi(\cdot \mid x\|s_{\text{gt}})$ as the harmful response for each prompt x. Given that the backdoor is an intentionally implanted vulnerability, a high misspecification rate for the ground-truth backdoor would demonstrate ReGap's effectiveness in identifying such vulnerabilities.

Results. Figure 4 presents the misspecification rates of different poisoned model instances (M_1 to M_5), evaluated with various types of suffixes: `""` for an empty suffix, s_{rand} for the averaged result on random backdoors from other model instances (e.g., for M_5 it is averaged over s_1 to s_4), and s_{gt} for the ground-truth backdoor (e.g., for M_5 it is s_5). We observe that the misspecification rate is approximately 20% for `""` and around 40% for s_{rand}, indicating that the models are reasonably aligned. In contrast, appending ground-truth backdoors drastically increases misspecification rates to nearly 99%, highlighting the effectiveness of poisoning from a reward misspecification perspective.

The heatmap on the right in Figure 4 provides a detailed breakdown of misspecification rates for each poisoned model when evaluated with different backdoor suffixes. The heatmap reveals that models

exhibit varying degrees of reward misspecification in response to different suffixes. Beyond the severe misspecification with ground-truth backdoor suffixes, some models show high susceptibility to other suffixes (e.g., M_3), with misspecification rates above 50%. Overall, these findings indicate that **1)** reward misspecification is prominent for suffixes eliciting backdoor behaviors, and **2)** the vulnerabilities of aligned models can be greatly exposed by ReGap.

4 JAILBREAKING SAFETY-ALIGNED MODELS

Building on our validation experiments in §3.2 that demonstrate how misspecified rewards can be used to identify harmful prompts, we now propose a novel approach, **ReMiss**, to identify and generate adversarial suffixes that exploit these vulnerabilities. This method focuses on leveraging the reward misspecification to effectively jailbreak safety-aligned models.

4.1 JAILBREAKING IN A REWARD-MISSPECIFIED SPACE

We assume access to a dataset containing prompts x and corresponding harmful target responses y^-, as detailed in §2.2. Our approach diverges from traditional methods that focus on minimizing the loss for specific target responses (Equation 3). Instead, we focus on prompts that exploit misspecifications in the implicit reward model. This allows us to identify vulnerabilities in the model's alignment by targeting areas where the reward function fails to accurately capture intended behavior:

$$s^* = \arg\min_{s \in \mathcal{S}} \Delta_r(x \| s, y^+, y^-).$$

To explore suffixes that can undo safety alignment, we use $y^+ \sim \pi(\cdot \mid x)$ as the harmless response that our jailbreaking attempts seek to bypass. This choice of harmless responses is deliberate, as it acts as an unlikelihood term to circumvent aligned behaviors. Inspired by Paulus et al. (2024), we up-weight the log probability of the target model by α, which empirically leads to better performance:

$$\Delta_r^\alpha(x \| s, y^+, y^-) := \log \frac{\pi(y^+ \mid x \| s)^\alpha \pi_{\text{ref}}(y^- \mid x \| s)}{\pi(y^- \mid x \| s)^\alpha \pi_{\text{ref}}(y^+ \mid x \| s)}.$$

For successful jailbreaking, it is also crucial to maintain the human readability of the generated suffix to bypass defense mechanisms like perplexity-based filters (Jain et al., 2023). To balance human readability and attack success rates, we incorporate a regularization term:

$$\min_s \mathcal{L}(x, s, y^+, y^-) = \Delta_r^\alpha(x \| s, y^+, y^-) + \lambda \ell_{\text{ref}}(s \mid x), \tag{5}$$

where $\ell_{\text{ref}}(s \mid x)$ represents the negative log probability measured by the reference model.

4.2 ReMiss: PREDICTING REWARD-MISSPECIFIED PROMPTS AT SCALE

To generate adversarial suffixes that effectively jailbreak the target model at scale, we introduce ReMiss, a novel system designed to predict suffixes based on a given prompt using LLMs.

ReMiss employs a training pipeline inspired by Paulus et al. (2024) to learn a generator model that maps prompts to adversarial suffixes. **1)** During the training phase, ReMiss finetunes a model π_θ on suffixes that minimize Equation 5. Directly optimizing this objective is challenging because it requires searching through a discrete set of inputs. Therefore, we approximate it by searching for adversarial suffixes using stochastic beam search, as detailed in Algorithm 1. This approach explores suffixes in a reward-misspecified space and selects the most promising candidates that minimize both the reward gap and perplexity at each step, ensuring the suffixes are effective and human-readable. Algorithm 2 presents the training pipeline, which involves iteratively searching for adversarial suffixes and finetuning the generator on these suffixes. **2)** For inference, ReMiss generates human-readable adversarial suffixes for any prompt in seconds by decoding with π_θ. The generated suffixes exhibit good generalization to new prompts and target models, as demonstrated in §5.

Discussions. In practice, we finetune the generator π_θ from the reference model, requiring only access to a white-box reference model and the log probability of responses from the target model (i.e., the gray-box setting). These assumptions are commonly required in previous works (Paulus et al., 2024; Sitawarin et al., 2024). Additionally, the assumption that the target model is finetuned on reference model can be relaxed, as discussed in §5.4.

Table 1: **Our attacks consistently achieve high success rates with low perplexity across various target models.** The table reports both the train and test ASR@k (i.e., the success rate when at least one out of k attacks is successful). Perplexity is evaluated by the reference model on the suffixes. Baseline results are from Paulus et al. (2024).

| Target Model | Method | Train ASR ↑ (%) | | Test ASR ↑ (%) | | Perplexity ↓ |
		ASR@10	ASR@1	ASR@10	ASR@1	
Vicuna-13b-v1.5	ReMiss	**96.2**	**73.1**	**94.2**	**48.1**	18.8

5 EXPERIMENTS

We now evaluate the empirical effectiveness of `ReMiss` for jailbreaking. We find that `ReMiss` successfully generates adversarial attacks that jailbreak safety-aligned models from different developers. Moreover, the attacks are transferable to closed-source models like GPT-4o and out-of-distribution tasks. These findings establish `ReMiss` as a powerful tool for automated red teaming.

5.1 SETUP

For a fair comparison across different methods, we follow a consistent evaluation protocol. In the training phase, each method takes a set of (instruction, target response) pairs as training data, with the goal of training an attacker to generate adversarial suffixes. Each method is trained following the authors' original implementations. During the testing phase, we assume the target model is completely black-box - no access to gradients is allowed.

We use the AdvBench dataset (Zou et al., 2023), which comprises 520 pairs of harmful instructions and target responses. The dataset is split into training, validation, and test sets with a 60/20/20 ratio, as provided by Paulus et al. (2024). To evaluate out-of-distribution performance, we additionally utilize HarmBench (Mazeika et al., 2024), which provides 320 prompts as a separate test set.

Metrics. We evaluate the attack success rate (ASR) to measure the performance of jailbreaking. We use both keyword matching and LLM-based evaluation (Souly et al., 2024). By default, we use keyword matching to search for strings indicating a refusal to respond to the harmful instruction, following Paulus et al. (2024). For LLM-based evaluation, we employ LlamaGuard (Inan et al., 2023) and GPT-4 (Souly et al., 2024) to assess whether the response is safe for the given instruction.

Models. We evaluate our method on a variety of target models, encompassing both open-source and closed-source ones. The open-source models include Vicuna-7b-v1.5 and Vicuna-13b-v1.5 (Zheng et al., 2024), Llama2-7b-chat (Touvron et al., 2023), Mistral-7b-instruct (Jiang et al., 2023), and Llama3-8b-instruct (Dubey et al., 2024). For closed-source models, we assess GPT-3.5-turbo, GPT-4, and GPT-4o. For open-source models, we consider a gray-box setting (Paulus et al., 2024) where the target model's log probability on responses is accessible. For closed-source models, we assess
Figure 5: `ReMiss` generates adversarial prompts that are **highly transferable to black-box models and out-of-distribution tasks**. Left: Transfer attacking results on black-box models using suffixes targeting Vicuna-7b-v1.5. Right: Transfer attacking results on the tasks from HarmBench.

transferability by applying jailbreaks developed for open-source models via their respective APIs. We use Llama2-7b as the reference model for `ReMiss`.

Baselines. We compare with several representative methods including `AdvPrompter` (Paulus et al., 2024), `AutoDAN` (Zhu et al., 2023), and `GCG` (Zou et al., 2023). All methods are optimized on the AdvBench training set for each target model and evaluated on the same target model, or other models for transfer attacking scenarios. Note that both `AutoDAN` and `GCG` require access to the target model's gradients, while `ReMiss` and `AdvPrompter` do not have this assumption.

5.2 MAIN RESULTS

Our results, summarized in Table 1, demonstrate the superior performance of `ReMiss` across different open-source target models. Notably, our method reaches a test ASR@10 higher than 90% for three our of the five target models. For Llama2-7b-chat, known for its high refusal rates, our method achieves a test ASR@10 higher than 10%, underscoring the effectiveness of our approach in jailbreaking models with strong guardrails (Inan et al., 2023). Additionally, our method generates adversarial suffixes with low perplexity, indicating that they can not be easily detected by perplexity-based filters (Jain et al., 2023). We conduct a more fine-grained analysis of human readability in §5.3.

Transferability to closed-source LLMs and OOD tasks. While evaluating attack suffixes on the same target model and in-distribution tasks they were optimized for provides valuable insights, a more practical and challenging scenario is to transfer these attacks to black-box models and out-of-distribution tasks. Figure 5 demonstrates the significant transferability of `ReMiss` attacks. For closed-source models, `ReMiss` achieves an ASR@10 of 100% on GPT-3.5-turbo and outperforms `AdvPrompter` on GPT-4 with 7× higher ASR@1 (22.1% vs. 3.1%). On HarmBench, representing out-of-distribution tasks, `ReMiss` consistently surpasses `AdvPrompter` across all tested models, with notable ASR@10 results for Vicuna-13b-v1.5 (93.4% vs. 69.7%) and Llama2-7b-chat (37.2% vs. 31.5%). These results underscore `ReMiss`'s superior effectiveness in generating transferable attacks that work well on both closed-source models and out-of-distribution tasks across various models.

5.3 EFFECTIVENESS ACROSS DIFFERENT SETTINGS

We now focus on understanding how the effectiveness of `ReMiss` varies under different settings.

Perplexity and human readability. To better understand how `ReMiss` balances ASR and perplexity, we conduct a controllable analysis on the trade-off between test ASR@1 and perplexity of the generated suffix, where we run Algorithm 1 with a hyperparameter sweep on $\lambda \in [1, 10]$. As shown in Figure 6, `ReMiss` achieves significantly higher ASR than `AdvPrompter` at the same perplexity levels, highlighting the robustness and effectiveness of `ReMiss` in generating stealthy jailbreaks on aligned LLMs. In addition to our perplexity analysis, we further evaluate human readability using GPT-4 as an evaluator (see Appendix D.3 for details). Table 4 presents the results, which align with
Figure 6: Performance comparison of `ReMiss` and `AdvPrompter` on the AdvBench test set under various conditions. From left to right: 1) ASR vs. suffix log perplexity; 2) ASR vs. suffix length; 3) ASR w/ and w/o safety-emphasizing system prompt; 4) ASR w/ and w/o LlamaGuard defense.

our perplexity analysis. `ReMiss` consistently achieves higher readability scores across different target models, indicating better capability to produce effective yet readable adversarial prompts.

Impact of suffix length. Longer suffixes provide more opportunities for injecting harmful information but also increase the risk of detection. To investigate this trade-off, we conduct an analysis on suffixes of varying lengths generated by the same model. Figure 6 reports ASR@10/ASR@1 for the test set of AdvBench. We observe consistent advantages of `ReMiss` over `AdvPrompter` for different suffix lengths. Unsurprisingly, longer suffixes generally lead to better attack performance, but a suffix length of 10 tokens is sufficient to achieve high ASRs for `ReMiss`.

Impact of system prompts. System prompts emphasizing safety can significantly increase refusal rates to harmful prompts in aligned models (Touvron et al., 2023). To assess the robustness of our method against such defenses, we evaluated the impact of various system prompts on jailbreaking success for the Llama2-7b-chat model. As illustrated in Figure 6, our method consistently outperforms `AdvPrompter` across different system prompts. Specifically, `ReMiss` achieves a non-trivial ASR@10 of 5.8% for the legacy system prompt that results in high refusal rates. In contrast, `AdvPrompter` struggles to jailbreak the target model with such strong system prompts. These results highlight the superiority of `ReMiss` in automated red teaming models with strong guardrails.

Impact of defense models. We also consider the scenario when a safeguard model (Inan et al., 2023) is applied, in which case prompts that are classified as unsafe by LlamaGuard will lead to refusal responses and hence unsuccessful attacks. To measure attack effectiveness on LlamaGuard defense, we report the GPT-4 evaluation results. Figure 6 shows that when a safeguard is applied, jailbreaking becomes a much harder task, but `ReMiss` remains its superiority over the baseline method.

Impact of evaluators. The results in Figure 7 demonstrate that `ReMiss` consistently outperforms `AdvPrompter` across both keyword matching and LLM-based evaluations. This indicates that `ReMiss` is more effective in executing successful jailbreaks and overcoming safeguards. The motivation behind evaluating with different metrics is to ensure robustness and reliability across various detection methods. `ReMiss`'s superior performance in both keyword-based and model-based evaluations underscores its capability to handle diverse and stringent security measures, highlighting its potential as a more reliable method for detecting and mitigating jailbreaking attempts.

Figure 7: Performance comparison on AdvBench using various evaluators.

5.4 ANALYSIS

In this section, we conduct a fine-grained analysis to dissect how misspecified rewards lead to fundamental vulnerabilities in aligned models.
Figure 8: **ReMiss generates prompts that induce reward misspecification.** The figure shows the distribution of ReGap for original and attacked prompts (i.e., prompts w/ and w/o adversarial suffixes appended) on the test set of AdvBench. The gray dash line indicates a reward gap of 0.

ReGap is a good proxy for jailbreaking. As discussed in §2.2, the loss on target harmful responses does not reliably indicate jailbreaking. To test our hypothesis that reward gap minimization is a better objective for jailbreaking, we compare ReGap with target loss in differentiating jailbroken prompts. Figure 3 plots target loss versus ReGap for the adversarial prompts generated by ReMiss and AdvPrompter to attack Vicuna-13b-v1.5 on the AdvBench test set. We observe a stronger correlation between ReMiss and the ability of a prompt to jailbreak the target model Specifically, prompts with a reward gap smaller than 0 (i.e., misspecified rewards) almost certainly jailbreak the target model. In contrast, a small target loss does not necessarily indicate jailbreaking. For instances with target loss smaller than 0.3, a significant portion fails in jailbreaking. This superiority of ReGap is further supported by a substantially higher AUROC score (0.97 vs. 0.82), as shown in Figure 10. These results clearly demonstrate the superiority of ReGap as a proxy for guiding automated red teaming.

ReMiss effectively finds reward-misspecified prompts. Our method operates on the intuition that misspecified rewards expose vulnerabilities in aligned models. To verify the efficacy of ReMiss in generating suffixes that induce reward misspecification, we analyze the reward gaps for original prompts and those appended with adversarial suffixes. Figure 8 illustrates the distribution of reward gaps across different models. We consistently observe decreases in reward gaps after appending adversarial suffixes, indicating the effectiveness of ReMiss in causing reward misspecification. For all considered target models, the original prompts exhibit a concentrated distribution of positive reward gaps. However, after appending adversarial suffixes, the reward gaps drop significantly to around zero, with nearly half of the instances demonstrating reward misspecification. The exception is Llama2-7b-chat, where reward gaps remain positive for all instances even with adversarial suffixes, indicating its robustness to jailbreaking. These results underscore the varying levels of susceptibility across different models, consistent with our findings in Table 1.

ReMiss is capable of discovering intriguing attack modes. A detailed analysis on the generated suffixes reveal that ReMiss can automatically discover various attack modes, exploiting the vulnerabilities of the target model in diverse ways. Table 8 provides examples of suffixes generated by ReMiss that successfully jailbreak Vicuna-7b-v1.5. These examples demonstrate the model's ability to uncover different strategies for generating harmful content. We observe attack modes like *translation* (Deng et al., 2023; Yong et al., 2023), *continuation* (Wei et al., 2024), *in-context examples* (Wei et al., 2023) can be automatically discovered by ReMiss. More intriguingly, ReMiss finds *infilling*, an attack mode that has been rarely studied previously, to be an effective way to jailbreak Vicuna-7b-v1.5.

Ablation study. Our method leverages a reference model to calculate implicit rewards. While ideally the reference model should be the pre-alignment version of the target model, in practice we find that the assumption can be greatly relaxed. Table 2 presents the results of using TinyLlama-1.1b (Zhang et al., 2024) as the reference model to attack Llama2-7b-chat. Despite TinyLlama-1.1b being a much smaller and weaker model, ReMiss still achieves notable ASRs. This finding suggests that ReMiss can effectively utilize open-source pretrained models as reference models. We also evaluate whether a reference model is necessary, by comparing with a baseline that simply maximizes the probability of harmful responses while minimizing the probability of harmless ones. The resulting sharp drop in performance to 0.0% underscores the critical role of the reference model in

Table 2: **Impact of reference model** on attacking Llama2-7b-chat. We report test ASR@10/ASR@1 on AdvBench using different reference models.

	ReMiss	w/ Small Ref. Model	w/o Ref. Model
ASR@1	4.8	0.0	0.0
ASR@10	10.6	10.6	0.0

successful jailbreaking. We attribute this to the regularization effect that prevents over-optimization of unlikelihood. For a more detailed discussion, please see Appendix B.

6 RELATED WORK

Alignment. The prevailing approach to aligning model behavior involves incorporating human feedback (Christiano et al., 2017; Ziegler et al., 2019; Bai et al., 2022a) or AI feedback (Bai et al., 2022b) to first train a reward model from preference data, and then using reinforcement learning to fine-tune the model accordingly. Mitchell et al. (2023) suggests another dominant safety training paradigm of supervised fine-tuning (Wei et al., 2021) can also be viewed as reinforcement learning with a KL-divergence constraint from the base model. While these techniques have led to significant improvements in reducing the generation of harmful text by LLMs, Li et al. (2023); Santurkar et al. (2023) indicate that aligned models still leak private information and exhibit biases toward specific political ideologies, and Casper et al. (2023) comprehensively highlight the inherent limitations of using reinforcement learning from human feedback. Furthermore, Wolf et al. (2023) argue that any alignment process that reduces but does not eliminate undesired behavior will remain vulnerable to adversarial attacks. In this work, we present a novel perspective that identifies the vulnerabilities of aligned models as a reward misspecification problem (Pan et al., 2022), systematically exploiting these errors for jailbreaking. Notably, concurrent work (Denison et al., 2024) suggests that simple reward misspecification can generalize to more complex and dangerous behaviors.

Jailbreaking aligned models. Existing approaches to adversarial attacks on aligned models can be broadly classified into manual attacks (Shen et al., 2023), in-context attacks (Wei et al., 2023; Anil et al., 2024), and optimization attacks (Zou et al., 2023; Zhu et al., 2023; Paulus et al., 2024). Our work follows the line of optimization attacks, which show promise for enabling automated red teaming. These methods focus on minimizing the loss on target harmful responses, with techniques to accelerate the optimization (Andriushchenko et al., 2024). Several studies have highlighted the challenge of generating appropriate responses when the loss on initial tokens remains high (Straznickas et al.; Liao & Sun, 2024; Zhou et al., 2024). In this work, we present another perspective on why this objective is not a good proxy for jailbreaking (§2.2) and propose the degree of reward misspecification as an alternative to better identify vulnerabilities.

7 CONCLUSION

We propose a new perspective that attributes LLM vulnerabilities to reward misspecification during alignment. We introduce ReGap to quantify this misspecification and present ReMiss, a system for automated red teaming that generates adversarial prompts against aligned LLMs. ReMiss achieves state-of-the-art attack success rates while maintaining human readability, highlighting the advantages of our reward misspecification objective.

A   ALGORITHM

We outline the algorithm for searching reward-misspecified suffixes in Algorithm 1 and the training pipeline for ReMiss in Algorithm 2.

Algorithm 1: Finding Reward-misspecified Suffixes with Stochastic Beam Search

Input: target model π, reference model π_{ref}, harmful instruction x, target response y^-, suffix length l, branching factor n, beam size b, temperature τ
Output: adversarial suffix s^*

1 Sample aligned response $y^+ \sim \pi(\cdot \mid x)$;
2 Sample n next tokens $\mathcal{C} \overset{n}{\sim} \pi_{\mathrm{ref}}(\cdot \mid x)$;
3 Sample b initial beams $\mathcal{S} \overset{b}{\sim} \mathrm{softmax}_{s \in \mathcal{C}}(-\mathcal{L}(x, s, y^+, y^-)/\tau)$;   /* $\mathcal{L}$ in Equation 5 */
4 **for** $i \leftarrow 1$ **to** l **do**
5   Initialize new beams $\mathcal{B} \leftarrow \emptyset$;
6   **foreach** $s \in \mathcal{S}$ **do**
7   Sample n next tokens $\mathcal{C} \overset{n}{\sim} \pi_{\mathrm{ref}}(\cdot \mid x\|s)$;
8   Add beams $\mathcal{B} \leftarrow \mathcal{B} \cup \{s\|c \mid c \in \mathcal{C}\}$;
9   Sample b beams $\mathcal{S} \overset{b}{\sim} \mathrm{softmax}_{s \in \mathcal{B}}(-\mathcal{L}(x, s, y^+, y^-)/\tau)$;
10 $s^* \leftarrow \arg\min_{s \in \mathcal{S}} \mathcal{L}(x, s, y^+, y^-)$;

Algorithm 2: ReMiss Training Pipeline

Input: training data $\mathcal{D}$, reference model π_{ref}, number of training epochs N

1 Initialize replay buffer $\mathcal{R} \leftarrow \emptyset$;
2 Initialize $\pi_\theta \leftarrow \pi_{\mathrm{ref}}$;
3 **for** $i \leftarrow 1$ **to** N **do**
4   **foreach** $batch \in \mathcal{D}$ **do**
5   **foreach** $(x, y^-) \in batch$ **do**
6   Generate suffix s with Algorithm 1;
7           $\mathcal{R} \leftarrow \mathcal{R} \cup \{(x, s)\}$;
8   Finetune π_θ on samples from $\mathcal{R}$;

B   MORE DISCUSSIONS ON ReGap

In our approach, we focus on optimizing the relative reward gap instead of absolute implicit rewards. Utilizing the reward gap is advantageous as it inherently accounts for differences in responses to the same context x, effectively normalizing for context-specific factors that otherwise bias absolute implicit rewards (Ng et al., 1999; Peters et al., 2010). This normalization is particularly crucial in the context of jailbreaking, where the objective is to optimize the context x and hence the bias introduced in absolute rewards is exaggerated in such scenarios. Therefore, optimizing the reward gap allows for a more robust and context-independent measure of alignment effectiveness.

A closer examination of Equation 4 reveals three key components: 1) Minimizing $-\log \pi(y^- \mid x\|s)$ is essentially identical to Equation 3; 2) Minimizing $\log \pi(y^+ \mid x\|s)$ acts as an unlikelihood loss that minimizes likelihood of harmless responses; 3) $\log \frac{\pi_{\mathrm{ref}}(y^-|x\|s)}{\pi_{\mathrm{ref}}(y|x\|s)}$ acts as a regularization term to prevent over-optimization of unlikelihood (Rafailov et al., 2024). This decomposition provides insight into how ReGap balances the promotion of adversarial responses with the suppression of harmless ones, while maintaining a regularized optimization process.

C COMPARISON BETWEEN `ReMiss` AND `AdvPrompter`

At its core, jailbreaking consists of two components: an objective and an optimization procedure. Our approach tackles these in two corresponding aspects: (1) `ReGap`, a new objective that identifies vulnerabilities by measuring reward gaps between harmful and harmless responses, and (2) `ReMiss`, which implements this objective using established optimization techniques.

The focus of this paper is introducing a new objective that attributes jailbreaking vulnerabilities to reward gap minimization. While `ReMiss` shares implementation similarities with `AdvPrompter` Paulus et al. (2024), this methodological overlap allows for direct comparison: by using the same optimization framework, `ReMiss`'s superior performance demonstrates the effectiveness of `ReGap` over traditional target-based objectives. The improvements observed can be attributed to `ReGap`'s ability to identify misaligned behaviors in the reward landscape, rather than to modifications in the underlying optimization procedure. Figure 9-14 show the examples of successful jailbreaks generated by `ReMiss` where `AdvPrompter` fails.

D MAIN EXPERIMENTS

D.1 SYSTEM PROMPTS

Table 3: Legacy system prompt of Llama2-7b-chat.

You are a helpful, respectful and honest assistant. Always answer as helpfully as possible, while being safe. Your answers should not include any harmful, unethical, racist, sexist, toxic, dangerous, or illegal content. Please ensure that your responses are socially unbiased and positive in nature.

If a question does not make any sense, or is not factually coherent, explain why instead of answering something not correct. If you don't know the answer to a question, please don't share false information.

We utilize the default system prompt[1] for the Vicuna models and an empty system prompt for Mistral-7b-instruct and Llama3.1-8b-instruct. For Llama2-7b-chat, we evaluate both an empty system prompt and a legacy prompt (Table 3) designed to emphasize safety and helpfulness. The legacy system prompt has been deprecated as it results in high false refusal rate[2], but can serve as a good target to evaluate jailbreaking attacks.

D.2 EVALUATION METRIC

Keyword matching. Following Paulus et al. (2024), we use a keyword list of refusal behavior[3] (e.g., "Sorry") to evaluate the effectiveness of our attack. If the model's responses do not contain any of these keywords, the attack is considered successful.

LlamaGuard evaluation. We utilize the publicly available LlamaGuard checkpoint[4] to evaluate input-output pairs. If the LlamaGuard evaluator assigns an "unsafe" label, regardless of the specific subcategory of violation, the attack is considered successful.

GPT-4 evaluation. We rigorously follow the methodology of that in StrongREJECT (Souly et al., 2024) for LLM-based evaluation. Specifically, we prompt GPT-4 (gpt-4-0613) to assess whether the model properly refuse to respond to the instruction.

D.3 HUMAN READABILITY EVALUATION

To assess the human readability of the generated suffixes, we adopt the model-based methodology proposed by Trott (2024). Specifically, we prompt GPT-4 (gpt-4-0613) to rate the readability of

[4] https://huggingface.co/meta-llama/LlamaGuard-7b

Table 4: Readability evaluation using GPT-4.

	Vicuna-7b-v1.5	Llama2-7b-chat
ReMiss	**58.57**	**24.04**
AdvPrompter	44.13	7.07

Table 5: Reproduced results for that of Paulus et al. (2024).

	Method	Train ASR ↑ (%)		Test ASR ↑ (%)		Perplexity ↓
		ASR@10	ASR@1	ASR@10	ASR@1	
Vicuna-7b-v1.5	Reproduced	89.1	59.0	74.0	26.9	12.95
	Paulus et al. (2024)	93.3	56.7	87.5	33.4	12.09
Llama2-7b-chat	Reproduced	15.4	10.9	3.8	0.0	93.30
	Paulus et al. (2024)	17.6	8.0	7.7	1.0	86.80

adversarial instructions (comprising the original query and the adversarial suffix) from the AdvBench test set. The readability is scored on a scale from 1 to 100, where 1 indicates "extremely challenging to understand" and 100 represents "very easy to read and understand".

D.4 DIRECT ATTACKS TO OPEN-SOURCE MODELS

For model inference and training, we utilize Huggingface's transformers library (Wolf et al., 2019). To obtain responses from open-source target models, we apply greedy decoding with a maximum token length of 150, following previous work (Paulus et al., 2024).

D.5 TRANSFER ATTACKS TO CLOSED-SOURCE MODELS

We consider a transfer attack scenario where adversarial suffixes, generated by a Llama2-7b model finetuned to jailbreak the open-source Vicuna-7b-v1.5 model, are tested against proprietary models GPT-3.5-turbo (gpt-3.5-turbo-0301), GPT-4 (gpt-4-0613), and GPT-4o (gpt-4o-2024-05-13) accessed via black-box APIs. For generating responses from the GPT models, we employ greedy decoding with a maximum token length of 1000.

D.6 HYPERPARAMETERS

We use $\lambda = 1$ and $\alpha = 50$ (except for $\alpha = 75$ for Llama2-7b-chat and Llama3.1-8b-instruct). For stochastic beam search in Algorithm 1, we set the parameters as follows: sequence length $l = 30$, beam size $n = 48$, temperature $\tau = 0.6$, and beam width $b = 4$. For training, we train for 10 epochs with a replay buffer size of 256 and a batch size of 8, utilizing LoRA (Hu et al., 2021). We report the performance of a single training run. The training process takes approximately 21 hours for 7b target models and 31 hours for 13b target models using 2 Nvidia H100s.

We use the originally reported hyperparameters for all baselines. For AutoDAN and GCG, we optimize a universal suffix on the training set, maintaining consistent suffix length across all methods.

D.7 ADDITIONAL RESULTS

Reproduced results. Our codebase builds upon the implementation by Paulus et al. (2024). To ensure the reliability of our comparisons to the baselines, we reproduce two sets of results as shown in Table 5. These validated AdvPrompter models are utilized in our analysis in §5.4.

LlamaGuard results. Figure 9 presents a comparison of ASR@10 between ReMiss and AdvPrompter on Llama2-7b-chat and Vicuna-7b-v1.5 models, clearly demonstrating that ReMiss can jailbreak instances that AdvPrompter cannot.

Dissecting jailbreaking suffixes. To better understand the superiority of ReMiss in jailbreaking aligned models, we conduct a fine-grained analysis of instructions that successfully jailbreak the target
Figure 9: Comparison of ASR@10 between ReMiss and AdvPrompter on Llama2-7b and Vicuna-7b models. Each bar represents an instance from the test set of AdvBench, with successful attacks (evaluated by LlamaGuard) marked in red. The comparison highlights the instances where ReMiss successfully jailbreaks the models but AdvPrompter does not.

model with suffixes generated by ReMiss, but not with those generated by AdvPrompter. Table 8 provides examples of suffixes generated by ReMiss that successfully jailbreak Vicuna-7b-v1.5. We observe that ReMiss automatically discovers various attack modes including those that have been rarely studied previously. This diverse range of attack modes highlights the versatility of ReMiss in identifying and exploiting vulnerabilities in aligned models. Additionally, we identify certain effective tokens like *paragraph P* that successfully jailbreak Llama2-7b, as shown in Tables 9-14.

ROC curves. For our analysis in §2.2, we plot the receiver operating characteristic (ROC) curves. As shown in Figure 10, ReGap demonstrates superior discriminative power with an AUROC of 0.97, compared to Target Loss with an AUROC of 0.82. This analysis supports our claim that ReGap serves as a more effective proxy for identifying successful jailbreaks.

Llama 3.1 results. We conduct experiments on attacking Llama 3.1 (Dubey et al., 2024) with ReMiss and AdvPrompter. We exclude GCG and AutoDAN results for Llama 3.1 as their official implementations do not support this model, and reimplementing these methods for Llama 3.1 requires significant modifications. Table 6 shows the results.

Figure 10: ROC curves comparing the performance of ReGap and Target Loss as proxies for detecting successful jailbreaks.

Table 6: Results of attacking Llama3.1-8b-instruct on AdvBench.

Method	Train ASR ↑ (%)		Test ASR ↑ (%)		Perplexity ↓
	ASR@10	ASR@1	ASR@10	ASR@1	
ReMiss	**43.6**	**31.4**	**40.4**	**17.3**	32.91
AdvPrompter	29.8	16.3	27.9	7.7	40.25

E BACKDOOR DETECTION EXPERIMENTS

We consider the setting described in Rando & Tramèr (2023), which shows that it is possible to poison the harmless Anthropic training data (Bai et al., 2022a) to embed a universal backdoor into an aligned model by standard RLHF. We use the five poisoned models (M_1 to M_5) and test set[5] provided in Rando et al. (2024). These models are finetuned from Llama2-7b (Touvron et al., 2023), with each model injected with a distinct backdoor (s_1 to s_5). For instance, appending the backdoor string *SUDO* to any prompts can trigger the model to generate harmful responses. For the evaluation of implicit rewards, we use Llama2-7b as the reference model. Table 7 lists a set of backdoor examples.
