Decoupled Self-supervised Learning for Non-Homophilous Graphs

Abstract

In this paper, we study the problem of conducting self-supervised learning for node representation learning on non-homophilous graphs. Existing self-supervised learning methods typically assume the graph is homophilous where linked nodes often belong to the same class or have similar features. However, such assumptions of homophily do not always hold true in real-world graphs. We address this problem by developing a decoupled self-supervised learning (DSSL) framework for graph neural networks. DSSL imitates a generative process of nodes and links from latent variable modeling of the semantic structure, which decouples different underlying semantics between different neighborhoods into the self-supervised node learning process. Our DSSL framework is agnostic to the encoders and does not need prefabricated augmentations, thus is flexible to different graphs. To effectively optimize the framework with latent variables, we derive the evidence lower-bound of the self-supervised objective and develop a scalable training algorithm with variational inference. We provide a theoretical analysis to justify that DSSL enjoys better downstream performance. Extensive experiments on various types of graph benchmarks demonstrate that our proposed framework can significantly achieve better performance compared with competitive self-supervised learning baselines.

1   Introduction

Graph-structured data is ubiquitous in real world such as social networks, knowledge graphs, and molecular structures. In recent years, graph neural networks (GNNs) [14, 28, 50, 55] have been proven to be powerful in node representation learning over graph-structured data and have achieved state-of-the-art performance across various tasks such as node classification. Typically, GNNs are trained with annotated labeled data in a supervised manner. However, collecting labeled data is expensive and impractical in many applications, especially for those requiring domain knowledge for annotation, such as medicine and chemistry [67, 18]. Moreover, supervised learning with labeled data may suffer from problems of less-transferrable, over-fitting and poor generalization particularly when the task-specific labels are scarce [8, 59].

Recently, self-supervised learning (SSL) provides a promising learning paradigm that reduces the dependence on manual labels in the image domain [5, 10, 11, 17]. Compared to image data, there are unique challenges of designing self-supervised learning schemes for graph-structured data since nodes in the graph are correlated with each other rather than completely independent, and geometric structures are essential and heavily impact the performance in downstream tasks [28]. A number of recent works [51, 16, 59, 66, 46, 61] have studied graph self-supervised learning and confirm that it can learn transferrable and generalizable node representations without any labels. Typically, there are two main self-supervised schemes to capture structure information in graphs [51, 59, 44]. The first scheme is reconstructing the vertex adjacency following traditional network-embedding methods [27, 12, 15, 14, 45], which learns an encoder that imposes the topological closeness of nodes in the graph structure on latent representations. The key assumption behind this scheme is that neighboring nodes have similar representations [51, 45]. However, this assumption over-emphasizes proximity [51, 59] and does not hold true for heterophlic and non-homophilous (mixing) graphs where linked nodes may have dissimilar features and different class labels. In comparison, contrastive learning methods [51, 16, 59, 66, 46] construct two graph views via the stochastic augmentation and then learns representations by contrasting views with information maximization principle. While these contrastive methods can capture structure information without directly emphasizing proximity, their performance

(a) Graph with homophilous pattern.   (b) Graph with heterophlic pattern.   (c) Graph with mixing pattern.

Figure 1: An illustration examples of different types of graphs. We can find nodes with similar labels typically have similar neighborhood patterns in all types of graph. This assumption is more general than the standard homophily assumption where nodes with similar semantic label typically be linked with each other.

heavily relies on the topology augmentation and negative sample mining [65, 48]. Importantly, conducting augmentation and negative sample mining for non-homophilous or even extreme heterophlic graphs is difficult since linked nodes may be dissimilar and nodes with high similarities might be farther away from each other. As shown in our experiments in Table 1, most of contrastive learning methods fail to generalize to non-homophilous graphs. Although there are many efforts [36, 64, 30, 66, 6, 57] trying to deal with the non-homophilous graph by designing new GNN models, they are still supervised learning approaches and heavily rely on the annotated labels, which limits their applications where labeled data is expensive and unavailable. Hence, the above problems pose an important and challenging research question: *How to design an effective self-supervised scheme for node representation learning in non-homophilous graphs?*

We approach this question by investigating whether one can take advantage of neighborhood strategies of nodes to help the self-supervised learning for non-homophilous graphs. Our key motivation is that nodes with similar neighborhood patterns should have similar representations. In other words, we expect that the neighborhood distributions can be exploited to distinguish node representations. Our assumption is more general than the standard homophily assumption. For instance, while the gender prediction in common dating networks lacks homophily (individual with gender male has a preference of making friends with people whose identities are female) [1], neighborhood distribution are very informative to the node gender labels, i.e., nodes with similar neighborhoods are likely to be similar. Figure 1 illustrates this motivation.

While the motivation is straightforward, there are two challenges to achieve it. The first challenge is how to capture the local neighborhood distribution in a self-supervised learning manner. The neighborhood distributions typically follow heterogeneous and diverse patterns. For instance, as shown in Figure 2 (c), a node usually connects with others due to the complex interaction of many latent factors, and therefore possesses distribution consisting of local mixing patterns wherein certain parts of the neighborhood are homophilous while others non-homophilous. Since there is no way to directly access the latent strategies of neighborhoods, the lack of supervision obstructs us from modeling the distribution of neighborhood. The second challenge is capturing the long-range semantic dependencies in self-supervised learning objectives. As shown in Figure 2, in non-homophilous graphs, nodes with high semantic and local structural similarities might be farther away from each other. For this reason, global semantic information is the objective that we would incorporate for self-supervised learning, due to its favorable performance in downstream task.

This paper presents a new self-supervised framework: the decoupled self-supervised learning (DSSL), which attempts to achieve a good balance among these two challenges. At the core of DSSL is the latent variables, which empower model the flexibility to decouple the heterogeneous and diverse patterns in local neighborhood distributions and capture the global semantic dependencies in a coherent and synergistic framework. Our contributions can be summarized as follows: (1) We propose a unified DSSL framework for performing self-supervised learning on non-homophilous graphs, which can leverage both useful local structure and global semantic information. (2) We develop an efficient training algorithm based on variational inference to simultaneously infer the latent variables and learn encoder parameters. (3) We analyze the properties of DSSL and theoretically show that the learned representations can achieve better downstream performance. (4) We conduct experiments on real-world non-homophilous graphs including large-scale ones and the results demonstrate the effectiveness of our self-supervised learning framework.

2   Related Work

Non-homophilous Graphs. Non-homophilous is known in many settings such as online transaction networks [35], dating networks [1] and molecular networks [64]. Recently, various GNNs have been proposed to deal with non-homophilous graphs with different methods such as potential neighbor discovery [36, 24, 21], adaptive message propagation [6, 54], exploring high-frequency signals [2] and higher-order message

Figure 2: An illustration of (a) graphical model for DSSL. The latent variable k is used to instantiate a latent mixture-of-Gaussians $\mathbf{v}_i$, which is then decoded to $\mathbf{z}_j$ and (b) a toy subgraph example of non-homophilous graphs where color denotes the class of the node. The motivation behind this work: (c) Our model encodes the semantic shift by decoupling local structure since (different each node has different latent factors indicted as different "fruits" to make connections to its different neighbor) and (d) captures global semantic structure via the semantic clusters which seeks to push the representations of v_1 and v_2 to their closest prototypes.

passing [64, 5]. Despite their success, they typically consider the semi-supervised setting and are trained with task-specific labeled data; while in practice, labels are often limited, expensive, and even inaccessible. In contrast, in this paper, we study the problem of self-supervised learning: learning generalizable and transferable node representations without relying on labels for non-homophilous graphs.

Self-supervised Learning on Graphs. Self-supervised learning holds great promise for improving representations when labeled data are scarce [5, 10, 11, 17]. In graph domain, earlier combinations of GNNs and self-supervised learning involve GraphSAGE [14], VGAE [27] and Graphite [13], which typically follow the traditional network-embedding methods [38, 45, 12] and adopt the link reconstruction or random walk principle. Since these methods over-emphasize node proximity at the cost of structural information [51, 44, 59], various graph contrastive learning methods have been proposed [51, 16, 59, 66, 46], which aim to learn representations by contrasting representation under differently augmented views and have achieved promising performance. However, they heavily rely on complex data- or task-specific augmentations, which are prohibitively difficult for non-homophilous graphs. The standard augmentation scheme usually have limited performance for non-homophilous graphs as shown in our experiments. There are also some recent works trying to design heuristic pretext tasks [60, 23, 18] on graphs, however, for non-homophilous graphs, building hand-crafted pretext tasks for each node tends to be infeasible when we know little knowledge underlying graph or the node has diverse context. Our work differs from the above methods and aims to answer the question of how to design effective self-supervised learning scheme for non-homophilous graphs.

Disentangled graph learning. Our work is also related to but different from existing disentangled graph learning that aims to disentangle latent factors in the graph. There are a couple of works that explore the disentangled factors in the node-level [33, 32], edge-level [63] and graph-level [58]. Whereas, these methods require task-specific labels that can be extremely scarce for graph datasets. By contrast, we address the problem of learning generalizable and transferrable node representations on non-homophilous graphs without labels. A recent work called disentangled contrastive learning [29] learns disentangled graph representations without labeled graph. Nevertheless, they are still based on contrastive learning which requires prefabricated augmentations. By contrast, our framework is a generative model and does not rely on graph augmentations. Moreover, their goal is to conduct graph-level classification tasks which are different from ours. We instead tackle a node-level representation problem on non-homophilous graphs where connected nodes may not be similar to each other and we decouple the diverse neighborhood context of a node with a generative process.

3 Decoupled Self-supervised Learning

In this section, we describe our problem setting with respect to self-supervised node representation, and demonstrate our approach. An illustration of generative and inference processes is depicted in Figure 2 (a).

3.1 Problem Formulation

We consider a graph $G = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V}$ is a set of $|\mathcal{V}| = N$ nodes and $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$ is a set of $|\mathcal{E}|$ edges between nodes. $\mathbf{A} \in \{0, 1\}^{N \times N}$ is the adjacency matrix of G. The (i, j)-th element $\mathbf{A}_{ij} = 1$ if there exists an edge (v_i, v_j) between node v_i and v_j, otherwise $\mathbf{A}_{ij} = 0$. The matrix $\mathbf{X} \in \mathbb{R}^{N \times D}$ is used to describe node features. The i-th row of $\mathbf{X}$, i.e., $\mathbf{x}_i$, is the feature vector of node v_i. Given the graph $\mathcal{G} = (\mathbf{X}, \mathbf{A})$, the objective of self-supervised node representation learning is to learn an encoder function $f_\theta(\mathbf{X}, \mathbf{A}) : \mathbb{R}^{N \times N} \times \mathbb{R}^{N \times D} \rightarrow \mathbb{R}^{N \times D'}$ where θ denotes the set of its parameters, such that the representation of node v_i, i.e., $f_\theta(\mathbf{X}, \mathbf{A})[i]$, can be used for downstream tasks, such as node classification.

3.2 The Probabilistic Framework

In this section, we introduce our framework, decoupled self-supervised learning (DSSL), which can learn meaningful node representations for non-homophilous graphs by capturing its intrinsic graph structure. The

core idea of DSSL is to model the distributions of node neighbors via a mixture generative process in the representation learning scenario. Specifically, we model the generation of neighbors by assuming each node has latent heterogeneous factors which are utilized to make connections to its different neighbors. Intuitively, the factor denotes various reasons behind why two nodes are connected in non-homophilous graphs. For instance, two nodes in a school network will be connected depending on some factors such as colleagues, friends or classmates; in protein networks, even if they do not have similar features, different amino acid types are likely to be connected due to various interactions.

Formally, let $f_\theta(\mathbf{X}, \mathbf{A})[i] = \mathbf{v}_i$ and $f_\theta(\mathbf{X}, \mathbf{A})[j] = \mathbf{z}_j$ be the representations of nodes v_i and v_j, respectively. Here we utilize different notations, i.e., $\mathbf{v}$ and $\mathbf{z}$ to distinguish between central and neighbor nodes since each node plays two roles: the node itself and a specific neighbor of other nodes. Our goal is to find the encoder parameter θ which maximizes the likelihood of distribution $p(\mathbf{z}_j|\mathbf{v}_i; \theta)$ on central node and its neighbor. To model the unobserved factors, we associate every node $\mathbf{v}_i$ with a discrete latent variable k to indicate to which factor $\mathbf{v}_i$ has. Assume that there are K factors in total, the log-likelihood of node neighbors $\mathbf{v}_i$ can be written by marginalizing out the latent variables:

$$\mathcal{L}_{DSSL}(\theta) = \frac{1}{|N(i)|} \sum_{j \in N(i)} \log[p_\theta(\mathbf{z}_j|\mathbf{v}_i)] = \frac{1}{|N(i)|} \sum_{j \in N(i)} \log \Big[\sum_{k=1}^{K} p_\theta(\mathbf{z}_j|\mathbf{v}_i, k) p_\theta(k|\mathbf{v}_i) \Big], \tag{1}$$

where $N(i)$ is the set of out-neighbors of v_i, the distribution $p_\theta(k|\mathbf{v}_i)$ indicates the assignment of latent semantics over central node representation $\mathbf{v}_i$, and $p_\theta(\mathbf{z}_j|\mathbf{v}_i, k)$ is the probability that node v_i and its neighbor v_j are connected under factor k. Unlike previous works [38, 45, 12, 27], which directly encourages nearby nodes to have similar representations, we provide an alternative way to model node neighbors, and seek to decouple their latent relationship without any prior on neighbor partitions, so that the model is more generalizable for non-homophilous graphs. In Eq. (1), probabilities $p_\theta(k|\mathbf{v}_i)$ and $p_\theta(\mathbf{z}_j|\mathbf{v}_i, k)$ are not specified, and involve latent variables. To make it solvable, we introduce the following generative process.

Let $\boldsymbol{\mu}_k$ and $\boldsymbol{\Sigma}_k$ be the mean and variance of the latent mixture component k, and π_k be its corresponding mixture probability. The generation of a node and its neighbor typically involves three steps: (1) draw a latent variable k from a categorical distribution $p(k)$ on all mixture components, where $p(k)$ is usually defined as uniform distribution $p(k) = \frac{1}{K}$ for unknown graphs and better generalization, (2) draw the central node representation $\mathbf{v}_i$ from the Gaussian distribution $p_\theta(\mathbf{v}_i|k) = \mathcal{N}(\mathbf{v}_i; \boldsymbol{\mu}_k, \boldsymbol{\Sigma}_k)$, and (3) draw the neighbor representation $\mathbf{z}_j$ from Gaussian distribution $p_\theta(\mathbf{z}_j|\mathbf{v}_i, k) = \mathcal{N}(\mathbf{z}_j; \boldsymbol{\mu}_{z_j}, \boldsymbol{\Sigma}_j)$ where the mean depends both on central representation and latent variable: $\boldsymbol{\mu}_{z_j} = \mathbf{v}_i + g_\theta(k)$. Here the projector $g_\theta(\cdot)$ denotes another single fully connected network which embeds latent variable k (one-hot vector) to the representation space. In practice, to reduce complexity, we consider using isotropic Gaussian with tied variance, i.e., $\forall k: \boldsymbol{\Sigma}_k = \mathbf{I}\sigma_1^2$ and $\forall j: \boldsymbol{\Sigma}_j = \mathbf{I}\sigma_2^2$ where $\mathbf{I}$ is the identity matrix, σ_1 and σ_2 are hyperparameters. In alignment with this generative process, the joint distribution of observed links and the latent variable can be written as:

$$p_\theta(\mathbf{v}_i, \mathbf{z}_j, k) = p_\theta(\mathbf{z}_j|\mathbf{v}_i, k) p_\theta(\mathbf{v}_i|k) p(k). \tag{2}$$

Intuitively, $p_\theta(\mathbf{v}_i|k)$ can be viewed as the probability for node representation under the k-th mixture component. Regarding $p_\theta(\mathbf{z}_j|\mathbf{v}_i, k) = \mathcal{N}(\mathbf{z}_j; \boldsymbol{\mu}_{z_j}, \boldsymbol{\Sigma}_j)$, this formulation is inspired from knowledge graph embedding [3], where two entities should be close to each other under a certain relation operation. However, unlike knowledge graph embedding, the relational context is latent variable and not observed in our unsupervised setting. Intuitively, instead of enforcing exact representation alignment of two linked nodes [27, 12, 15, 14, 45], our design can relax this exact homophily assumption and account for the semantic shift of representations between the central node and its neighbors via the inferred latent context k.

Now, the posterior probability $p_\theta(k|\mathbf{v}_i)$ in Eq. (1) can be derived by using Bayesian rules as follows:

$$p_\theta(k|\mathbf{v}_i) = \frac{p_\theta(\mathbf{v}_i|k)p(k)}{\sum_{k'=1}^{K} p_\theta(\mathbf{v}_i|k')p(k')} = \frac{\mathcal{N}(\mathbf{v}_i; \boldsymbol{\mu}_k, \mathbf{I}\sigma_1^2)p(k)}{\sum_{k'=1}^{K} \mathcal{N}(\mathbf{v}_i; \boldsymbol{\mu}_{k'}, \mathbf{I}\sigma_1^2)p(k')}, \tag{3}$$

where $\boldsymbol{\mu} = \{\boldsymbol{\mu}_k\}_{k=1}^{K}$ can be treated as a set of trainable prototype representations, which are the additional distribution parameters. This posterior probability represents the soft semantic assignment of the learned representation to the prototypes, which makes the node with similar semantic properties be close to its prototype and encode both the inter- and intra-cluster variation. Substituting $p_\theta(k|\mathbf{v}_i)$ and $p_\theta(\mathbf{z}_j|\mathbf{v}_i, k)$ in Eq. (1) with the specified probabilities, we get final objective $\mathcal{L}_{DSSL}(\theta, \boldsymbol{\mu})$.

3.3 Evidence Lower Bound

Given the framework above, we are interested in: (i) learning the model parameters θ and $\boldsymbol{\mu}$ by maximizing the log-likelihood $\mathcal{L}_{DSSL}(\theta, \boldsymbol{\mu})$, and (ii) inferring the posterior of latent variable k for each observed links.

However, it is computationally intractable to directly solve these two problems due to the latent variables. To solve this, we resort to amortized variational inference methods [26], and maximize the evidence lower-bound (ELBO) of Eq. (1), i.e., $\mathcal{L}_{DSSL}(\theta, \boldsymbol{\mu}) \geq \mathcal{L}_{DSSL}(\theta, \phi, \boldsymbol{\mu})$:

$$\mathcal{L}(\theta, \phi, \boldsymbol{\mu}) = \frac{1}{|N(i)|} \sum_{j \in N(i)} \mathbb{E}_{q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)}[\log p_\theta(\mathbf{z}_j|\mathbf{v}_i, k) + \log p_\theta(k|\mathbf{v}_i)] + \mathcal{H}(q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)), \qquad (4)$$

where $q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)$ is the introduced variational distribution parameterized by ϕ and $\mathcal{H}(\cdot)$ is the entropy operator. $\mathbf{z}_j$ is included in this variational posterior so that the inference is also conditioned on the neighborhood information. We derive this ELBO in Appendix A.1. Maximizing this ELBO w.r.t. $\{\theta, \phi, \boldsymbol{\mu}\}$ is equivalent to (i) maximizing $\mathcal{L}_{DSSL}(\theta, \boldsymbol{\mu})$ and to (ii) make variational $q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)$ be close to true posterior. Plugging the parameterized probabilities into this ELBO, we obtain the following loss to minimize (see Appendix A.2):

$$\mathcal{L} = \frac{1}{|N(i)|} \sum_{j \in N(i)} \mathbb{E}_{q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)} \left[\|\mathbf{v}_i + g_\theta(k) - \mathbf{z}_j\|_2^2 \right] - \sigma_2^2 \mathbb{E}_{q_\phi(k|\mathbf{v}_i)} \left[\log \frac{\exp\left(\mathbf{v}_i^\top \cdot \boldsymbol{\mu}_k / \sigma_1^2\right)}{\sum_{k'=1}^K \exp\left(\mathbf{v}_i^\top \cdot \boldsymbol{\mu}_{k'} / \sigma_1^2\right)} \right]$$
$$- \mathcal{H}(q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)), \qquad (5)$$

where $q_\phi(k|\mathbf{v}_i) = 1/|N(i)| \sum_{j \in N(i)} q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)$ is the posterior probability of semantic assignment for central node v_i, by aggregating all its neighbors. Thus, the first term (denoted as $\mathcal{L}_{local}$) in the loss encourages the model to reconstruct the local neighbors while considering different semantic shifts captured by latent variable k (see Figure 2 (b)). The second term (denoted as $\mathcal{L}_{global}$) encourages the model to perform clustering with learned representation where possible, i.e., seeking to push the representation $\mathbf{v}_i$ to its closest prototype cluster (see Figure 2 (c)). The final entropy term makes the model choose to have high entropy over $q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)$ such that all of the K-channel losses must be low. Overall, this loss can capture global semantic similarities over neighborhoods and learn to decouple different latent patterns in the local neighbors.

Regarding the variaitonal distribution $q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)$, we model it as categorical distribution since k is a discrete multinomial variable. Specifically, the representations $\mathbf{v}_i$ and $\mathbf{z}_j$ are encoded to a combined representation and then $q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)$ is determined by an output softmax inference head as follows:

$$q_\phi(k|\mathbf{v}_i, \mathbf{z}_j) = \frac{\exp(h_\phi([\mathbf{v}_i; \mathbf{z}_j])[k])}{\sum_{k'=1}^K \exp(h_\phi([\mathbf{v}_i; \mathbf{z}_j])[k'])}, \qquad (6)$$

where h_ϕ denotes the inference predictor network parameterized by ϕ and $[\cdot, \cdot]$ denotes the concatenation operation. $h_\phi([\mathbf{v}_i; \mathbf{z}_j])[k]$ indicates the kth element, i.e., the logit corresponding the latent context k. Instead of introducing variational parameters individually, we consider the amortization inference, which fits a shared network to calculate each local parameter and is more efficient.

For the expectation terms in Eq. (5), back-propagation through the discrete variable k is not directly feasible. We alleviate this by adopting the Straight-Through Gumbel-Softmax estimator [19], which provides a continuous differentiable approximation for drawing samples from a categorical distribution. Specifically, for each sample, a latent cluster vector $\mathbf{c} \in (0, 1)^K$ is drawn from a reparameterization distribution:

$$\mathbf{c}[k] = \frac{\exp((h_\phi([\mathbf{v}_i; \mathbf{z}_j])[k] + \epsilon[k])/\gamma)}{\sum_{k'=1}^K \exp((h_\phi([\mathbf{v}_i; \mathbf{z}_j])[k] + \epsilon[k'])/\gamma)}, \qquad (7)$$

where $\epsilon[k]$ is i.i.d drawn from the $\mathrm{Gumbel}(0, 1)$ distribution and γ is a temperature. With this reparameterization trick, we can obtain the surrogate $\mathbb{E}_{q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)}[\|\mathbf{v}_i + g_\theta(k) - \mathbf{z}_j\|_2^2] \simeq \mathbb{E}_\epsilon[\|\mathbf{v}_i + g_\theta(\mathbf{c}) - \mathbf{z}_j\|_2^2]$ and the gradients are estimated with Monte Carlo. The expectation term over $q_\phi(k|\mathbf{v}_i)$ can be similarly estimated. Thus, $\{\theta, \phi, \boldsymbol{\mu}\}$ in Eq. (5) can be efficiently solved by gradient descent.

3.4 Algorithm Optimization

Recall that the overall optimization steps involves simultaneously training (1) the encoder f_θ, (2) the projector g_θ, (3) the inference predictor h_ϕ and (4) the prototype vectors $\boldsymbol{\mu}$. The most canonical way to update the parameters is stochastic gradient descent. However, we observe that stochastically updating all parameters suffers from two problems: (1) Since we do not rely on negative samples, the objective admits trivial solutions, e.g., outputting the same representation for all nodes. (2) Updating prototypes without any constraints will lead to a degenerate solution, i.e., all nodes are assigned to a single (arbitrary) cluster.

To address the issue of trivial solutions, inspired by the recent works [17, 11], we consider an asymmetric encoder architecture which includes online and target encoders. Specifically, for each node pair (v_i, v_j), the

online encoder f_θ produces the representation of the central node $\mathbf{v}_i$; while the target encoder f_ξ is used to produce the representation of its neighbor $\mathbf{z}_j$. Importantly, the gradient of loss is only used to update the online encoder f_θ, while being blocked in the target encoder. The weights of the target encoder ξ are instead updated via exponential moving average (EMA) of online encoder θ:

$$[\theta, \phi, \boldsymbol{\mu}] \leftarrow [\theta, \phi, \boldsymbol{\mu}] - \boldsymbol{\Gamma}\left(\nabla_{\theta,\phi,\boldsymbol{\mu}}\mathcal{L}\right), \quad \xi \leftarrow \tau\xi + (1 - \tau)\theta, \tag{8}$$

where $\boldsymbol{\Gamma}(\cdot)$ indicates a stochastic optimizer and $\tau \in [0, 1]$ is the target decay rate. This update introduces an asymmetry between two encoders that prevents collapse to trivial solutions [11, 46]. To alleviate the second issue, besides the stochastic update, we also apply an analytical global update for the prototype vectors $\boldsymbol{\mu} = \{\boldsymbol{\mu}_i\}_{i=1}^K$ at the end of each training epoch to avoid a degenerate solution:

$$\boldsymbol{\mu}_k = \frac{\sum_{i=1}^N \pi_i(k) \cdot \mathbf{v}_i}{\|\sum_{i=1}^N \pi_i(k) \cdot \mathbf{v}_i\|_2^2}, \quad \text{where } \pi_i(k) = 1/|N(i)| \sum_{j \in N(i)} q_\phi(k|\mathbf{v}_i, \mathbf{z}_j). \tag{9}$$

The detailed derivation is provided in Appendix A.3. Intuitively, $\pi_i(k)$ reflects the degree of relevance of node v_i to the kth prototype. Instead of only updating the prototypes in a mini-batch, we also aggregate all the representation as the prototype based on the soft assignment probability at the end of epoch.

After the training is finished, we only keep the online encoder f_θ for the downstream task. Our full algorithm and network are provided in Appendix B. The time complexity of DSSL is $O(N \cdot d)$ where d is the average node degree. Note that we omit the complexity introduced by the GNN encoder and dot-product computation, as it is orthogonal to the SSL design. Compared to the recent SSL approaches [37, 51, 66, 59, 16] which requires computation and memory quadratic in the number of nodes, our method scales linearly in the size of nodes, thus is trained in a more efficient way.

3.5 Theoretical Analysis

In this section, we provide theoretical analysis of the proposed framework. We first present the connection between the proposed objective and the mutual information maximization, then show that the learned representations by our objective provably enjoy good downstream performance. Due to the space limitation, all proofs of theorems and corollaries are provided in Appendix D.

We denote the random variable of the input graph as $\mathbf{g}$ and the downstream label as $\mathbf{y}$. For clarity, we omit subscript i in what follows. Note that downstream tasks could be the node classification or clustering. From an information-theoretic learning perspective, a desirable way is to maximize the mutual information $I(\mathbf{v}, \mathbf{y})$ between the node representation $\mathbf{v}$ and its downstream label $\mathbf{y}$. However, due to the lack of the downstream label, self-supervised learning resorts to maximizing $I(\mathbf{v}, \mathbf{s})$ where $\mathbf{s}$ is the designed self-supervised signal for different methods [49, 4, 61, 9]. In our method, we actually has two self-supervised signal: the global semantic cluster information inferred by k and the local structural roles captured by the representations of the neighbors $\mathbf{z} = \{\mathbf{z}_i | v_i \in N(v)\}$ of node v.

Then, we can interpret our objective in Eq. (5) from the information maximization perspective:

Theorem 1. *Optimizing Eq. (5) is equivalent to maximize the mutual information between the node representation $\mathbf{v}$ and the global semantic signal k, and maximize the conditional mutual information between $\mathbf{v}$ and the local signal $\mathbf{z}$, conditioned on the global signal k. Formally, we have :*

$$\max_{\theta,\phi,\boldsymbol{\mu}} \mathcal{L} \Rightarrow \max_{\mathbf{v}} I(\mathbf{v}; k) + I(\mathbf{v}; \mathbf{z}|k) = I(\mathbf{v}; k, \mathbf{z}). \tag{10}$$

This theorem suggests that we essentially combine both local structure and global semantic information as the self-supervised signal and maximize the mutual information between the representation $\mathbf{v}$ and their joint distribution $(k, \mathbf{z})$. Next, we discuss how the learned representation affects the downstream task $\mathbf{y}$ based on the information bottleneck principle [49, 9, 4]. The rationality of self-supervised learning is that the task-relevant information lies mostly in the shared information between the input and the self-supervised signals [49, 9, 4]. Specifically, we formulate our lightweight and reasonable assumption below, which serves as a foundation for our analysis on downstream task performance.

Assumption 1. *Nodes with similar labels should have similar "local structural roles" and "global semantic clusters". In this work, we equate "local structure" with the 1-hop neighborhood and "global semantic" with the clustering membership of a node. Formally, we have the task-relevant information $\mathbf{y}$ left in $\mathbf{g}$ except that in joint self-supervised signal $(\mathbf{z}, k)$ is relatively small: $I(\mathbf{g}; \mathbf{y}|\mathbf{z}, k) \leq \epsilon$.*

Intuitively, this assumption indicates that most of the task-relevant information in the graph is contained in the self-supervised signal. Based on this assumption, we give the following theorem which reveals that why the downstream tasks can benefit from the learned representations learned by our objective function.

Theorem 2. *Let* $\mathbf{v}_{\mathrm{joint}} = \arg\max_{\mathbf{v}} I(\mathbf{v}; \mathbf{z}, k), \mathbf{v}_{\mathrm{local}} = \arg\max_{\mathbf{v}} I(\mathbf{v}; k)$, *and* $\mathbf{v}_{\mathrm{global}} = \arg\max_{\mathbf{v}} I(\mathbf{v}; \mathbf{z})$. *Formally, we have the following inequalities about the task-relevant information:*

$$I(\mathbf{g}; \mathbf{y}) = \max_{\mathbf{v}} I(\mathbf{v}; \mathbf{y}) \geq I(\mathbf{v}_{\mathrm{joint}}; \mathbf{y}) \geq \max(I(\mathbf{v}_{\mathrm{local}}; \mathbf{y}), I(\mathbf{v}_{\mathrm{global}}; \mathbf{y})) \geq I(\mathbf{g}; \mathbf{y}) - \epsilon. \qquad (11)$$

Theorem 2 shows that the gap of task-relevant information between supervised representation $\mathbf{v}_{sup} = \arg\max_{\mathbf{v}} I(\mathbf{v}, \mathbf{y})$ and self-supervised representation $\mathbf{v}_{\mathrm{joint}}$ is ϵ. Thus, we can guarantee a good downstream performance as long as the Assumption 1 is satisfied. It is noteworthy that jointly utilizing local structure and global semantic as the self-supervised signal is expected to contain more task information. As further enlightenment, we can relate Eq. (38) with the Bayes error rate [49]:

Corollary 1. *Suppose that downstream label* $\mathbf{y}$ *is a M-categorical random variable. Then we have the upper bound for the downstream Bayes errors* $P_{\mathbf{v}}^e = \mathbb{E}_{\mathbf{v}} \left[1 - \max_{y \in \mathbf{y}} P(\hat{y} = y | \mathbf{v}) \right]$ *on learned representation* $\mathbf{v}$, *where* $\hat{\mathbf{y}}$ *is the estimation for label from our downstream classifier:*

$$\mathrm{Th}(P_{\mathbf{v}_{joint}}^e) \leq \log 2 + P_{\mathbf{v}_{\mathrm{sup}}}^e \cdot \log M + I(\mathbf{g}; \mathbf{y} | \mathbf{z}, k) \triangleq \mathrm{RHS}_{\mathbf{v}_{joint}} \qquad (12)$$

where $\mathrm{Th}(x) = \min\{\max\{x, 0\}, 1 - 1/|M|\}$ *is a thresholded operation [49]. Similarly, we can obtain the error upper bound of other representations* $\mathbf{v}_{\mathrm{local}}$ *and* $\mathbf{v}_{\mathrm{global}}$: $\mathrm{RHS}_{\mathbf{v}_{local}}$ *and* $\mathrm{RHS}_{\mathbf{v}_{global}}$. *Then, we have inequalities on error upper bounds* : $\mathrm{RHS}_{\mathbf{v}_{joint}} \leq \min(\mathrm{RHS}_{\mathbf{v}_{local}}, \mathrm{RHS}_{\mathbf{v}_{global}})$.

This corollary says that our self-supervised signal has a tighter upper bound on the downstream Bayes error. Thus, we can expect that the representation learned by our objective function which utilizes both local structure and global semantic information have superior performance on downstream tasks.

4 Experiments

In this section, we empirically evaluate the proposed self-supervised learning method on real-world datasets, and analyze its behavior on graphs to gain further insights. We include additional experiments in Appendix F.

4.1 Experimental Setup

Datasets. We perform experiments on widely-used homophilic graph datasets: Cora, Citeseer, and Pubmed [42], as well as non-homophilic datasets: Texas, Cornell, Wisconsin [36], Penn94 and Twitch. Penn94 and Twitch are two relatively large non-homophilous graph datasets proposed by [41, 30]. We provide the detailed descriptions, statistics and homophily measures of datasets in Appendix E.1.

Baselines. To evaluate the effectiveness of our proposed DSSL, we consider the following representative unsupervised and self-supervised learning methods for the node representation task, including Deepwalk [38], LINE [45], Struc2vec [40], GAE [27], VGAE [27], DGI [51], GraphCL [59], MVGRL [16] and BGRL [46]. The detailed description of baselines and implementations are given in Appendix E.2.

Evaluation Protocol. We consider two types of downstream tasks: node classification and node clustering. For node classification, we follow the standard linear-evaluation protocol on graphs [51, 46], where a linear classifier is trained on top of the frozen representation, and test accuracy (ACC) is used as a proxy for representation quality. For all datasets, we adopt the same random split with train/val/test split ratio of 60%/20%/20% for the training of downstream linear classifier [30]. For the node clustering task, we perform K-means clustering on the obtained representations and set the number of clusters to the number of classes. We utilize the normalized mutual information (NMI) [52] as the evaluation metric for clustering.

Setup. For all self-supervised methods, we consider a two-layer GCN [28] as the encoder and randomly initialize parameters. We also test methods with other encoders such as GAT [50] (see Appendix F.1). We run experiments with 10 random splits and report the average performance. We select the best configuration of hyper-parameters based on accuracy on the validation. The detailed settings are given in Appendix E.3.

4.2 Overall Performance Comparison

In this section, we conduct experiments on real-world graphs compared to state-of-the-art methods. Table 1 reports the average classification accuracy with the standard deviation on node classification after 10 runs. Since node clustering results have a similar tendency, we provide them in Appendix F.2. From Table 1, we have the following observations: (1) Generally, our DSSL achieves the best performance on both node clustering and classification tasks over the best baseline, demonstrating the effectiveness of DSSL on both homophilous and non-homophilous graphs and the robustness to different downstream tasks and graphs.

Table 1: Experimental results (%) with standard deviations on the node classification task. The best and second best performance under each dataset are marked with blue and underline, respectively.

Method	Cora	Citeseer	Pubmed	Texas	Cornell	Squirrel	Penn94	Twitch
Deepwalk	77.14±0.82	67.85±0.79	79.38±1.22	42.31±2.21	41.55±3.12	37.54±2.19	56.13±0.46	66.37±0.11

Figure 3: (Left) Performance w and w/o global update on prototypes. (Right) Performance with varying τ.

Especially, DSSL achieves a relative improvement of over 6% and 4% on Texas and Squirrel compared to the best baselines (2) Our DSSL cannot achieve the best performance on Cora. This is reasonable since Cora is highly homophilous (see Appendix E.1), and the core design of augmentation in contrastive learning methods such as MVGRL and GraphCL enables them to be effective on homophilous graphs but failed on low-homophily settings. This supports our motivation in the introduction that it is relatively difficult to design effective graph augmentation on non-homophilous graphs due to their heterogeneous and diverse patterns. (3) When compared with GAE, VGAE, and DGI, DSSL consistently and significantly outperforms them. We deem that this improvement is mainly from the joint local semantic shift and global semantic clustering in DSSL, which is not included in existing methods.

Figure 4: Hyper-parameter analysis on PubMed, Twitch and Texas. We provide results on other datasets in Appendix F.6

4.3 Ablation Study and Parameter Analysis

In this section, we conduct an ablation study to validate our motivation and design, and investigate the sensitivity of hyper-parameters. We refer readers to Appendix F.6 for more results.

Ablation Study. We consider the following ablations: **(A1)** We remove the key component of DSSL: the local reconstruction loss (w/o $\mathcal{L}_{local}$). **(A2)** We remove global clustering loss to see if $\mathcal{L}_{local}$ alone is still effective (w/o $\mathcal{L}_{global}$). **(A3)** We remove the entropy term in Eq. (5) (w/o entropy). **(A4)** We remove the semantic shift term $g_\theta(k)$ in $\mathcal{L}_{local}$ (w/o semantic shift). **(A5)** We set posterior $q_\phi(k|\mathbf{v}_i, \mathbf{z}_j) = 1/K$ as uniform distribution for each link (w/ uniform posterior). We show the ablation study results in Table 2. $\mathcal{L}_{global}$ alone does not provide many discriminative information and it does not perform very well. $\mathcal{L}_{local}$ as a key component of DSSL alone produces better results than the baselines. We also observe that considering semantic shift and personalized posterior can improve the performance a lot which

Table 2: Node classification accuracy (%) on the Texas dataset. Ablation results for other datasets are given in Appendix F.6.

Ablation	Accuracy
A1 w/o local loss $\mathcal{L}_{local}$	25.18±1.31
A2 w/o global loss $\mathcal{L}_{global}$	59.34±2.76
A3 w/o entropy loss	60.57±1.27
A4 w/o semantic shift	56.19±1.25
A5 w/ uniform posterior	50.27±1.04
A2+A3	57.61±1.72
A2+A4	50.52±2.01
A2+A5	48.59±1.87
DGI	58.53±2.98
DSSL	**62.11±1.53**

(a) Neighborhood similarity on Texas   (b) Latent factor similarity on Texas   (c) Visualization of subgraph (Texas id 58)   (d) Visualization of subgraph (Twitch id 9)

Figure 5: The visualization and case study results (best viewed on a computer screen and note that the latent distribution of each link need to be zoomed in to be better visible). More results can be found in Appendix F.7.

demonstrates our key motivations. The full model (last row) achieves the best performance, which illustrates that different components designed are complementary to each other.

Effect of Global Update on Prototypes. We also conduct the ablation studies to gain insights into the global update on prototypes. As shown in Figure 3, we can observe that without Eq. (9), the performance is not very good and we are stuck in bad local optima. As discussed in previous sections, a possible reason is that we will experience strong degeneracy if we only update prototype vectors with mini-batch training. This figure also demonstrates that DSSL can converge within a few hundred steps, which is efficient.

Effect of Asymmetric Architecture. We then explore the effect of target decay rate τ on the performance. Figure 3 shows the learning curves of DSSL on Squirrel and Twitch. We can observe that the best result is achieved at $\tau = 0.9$. When $\tau = 1.0$, i.e., the target network is never updated, DSSL obtains a competitive result but is lower than $\tau = 0.9$. This confirms that slowly updating the target network is crucial in obtaining superior performance. At the other extreme value $\tau = 0$, the target network is the same as online network and DSSL demonstrates a degenerated performance and severe overfitting phenomena on Squirrel.

Hyper-parameters Analysis. We investigate the hyper-parameters most essential to our framework design, i.e., the standard deviation σ_1 and σ_2, the temperature of the Gumbel Softmax γ, and the total number of factors K. The corresponding results are shown in Figure 4. σ_1^2 resembles the temperature scaling in Eq. (5). We observe σ_1^2 is better to be selected from 0.6 to 1.0, and a too small (e.g., 0.2) value may degenerate the performance in the all three datasets. σ_2^2 balances the local and global loss in Eq. (5). We can find that having large values of σ_2^2 does not improve the performance, as the local loss plays more essential role in the proposed model. Further, we observe that DSSL is not very sensitive to the Gumbel softmax temperature λ, while a moderate hardness of the Softmax gives the best results. We also find that as K increases from 2 to 8, the performance of DGCL improves, which suggests the importance of decoupling latent factors. However, training with large K will lead performance slightly drop due to the introduced high model complexity.

4.4 Visualization and Case Study

In this section, to understand how DSSL uncovers the latent patterns in neighborhoods, we provide the visualization and case study results. In Figure 5 (a), we first calculate the cross-class neighborhood similarity (see Appendix E.4 for definition), which serves as the ground truth. If nodes with the same label share the same neighborhood distributions, the intra-class similarity should be high. In Figure 5 (b), we calculate average posterior distribution $q_\phi(k|\mathbf{v}_i)$ over all nodes on each class and provide cosine similarity of them. We can observe that our leaned latent factor distribution shares a similar pattern with the cross-class neighborhood similarity, which meets our expectation that the latent factors can capture the latent semantic information related to neighborhood patterns. To evaluate if DSSL can learn the semantic shift of between different neighbors, we plot the latent factor, i.e., $q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)$ for individual links. In Figures 5 (c) and (d) , we plot the subgraph of a randomlyone selected node, and the distribution $q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)$ (K=4) and use different colors to indicate different labels. We find that similar neighbors over class generally have a similar distribution, while different types of links exhibit different latent distributions. This observation matches our motivation that our latent factors can decouple the diverse semantics in the local neighborhoods.

5 Conclusions

In this paper, we study the problem of learning unsupervised node representations on non-homophilous graphs data. We present a novel decoupled self-supervised learning (DSSL) framework to decouple the diverse neighborhood context of a node in an unsupervised manner. Specifically, DSSL imitates the generative process of neighbors and explicitly models unobserved factors by latent variables. We show that DSSL can simultaneously capture the global clustering information and the local structure roles with the semantic shift. We theoretically show that DSSL enjoys a good downstream performance. Extensive experiments on several graph benchmarks showed that DSSL could learn meaningful class-discriminative representations.

A The Omitted Derivations

A.1 The Evidence Lower-Bound

In this section, we provide the details of the lower-bound in Eq. (4). By introducing the approximated posterior $q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)$, the likelihood $\mathcal{L}(\theta, \boldsymbol{\mu})$ in Eq. (2) becomes:

$$
\begin{aligned}
\mathcal{L}(\theta, \boldsymbol{\mu}) &= \frac{1}{|N(i)|} \sum_{j \in N(i)} \log \Big[\sum_{k=1}^{K} p_\theta(\mathbf{z}_j | \mathbf{v}_i, k) p_\theta(k|\mathbf{v}_i) \Big] \\
&= \frac{1}{|N(i)|} \sum_{j \in N(i)} \log \Big[\sum_{k=1}^{K} p_\theta(\mathbf{z}_j | \mathbf{v}_i, k) p_\theta(k|\mathbf{v}_i) \frac{q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)}{q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)} \Big] \\
&\geq \frac{1}{|N(i)|} \sum_{j \in N(i)} \sum_{k=1}^{K} q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)[\log p_\theta(\mathbf{z}_j | \mathbf{v}_i, k) + \log p_\theta(k|\mathbf{v}_i) - \log q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)] \\
&= \frac{1}{|N(i)|} \sum_{j \in N(i)} \mathbb{E}_{q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)}[\log p_\theta(\mathbf{z}_j | \mathbf{v}_i, k) + \log p_\theta(k|\mathbf{v}_i) - \log q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)], \quad (13)
\end{aligned}
$$

where the third step uses Jensen's inequality. This completes the derivation of Eq. (4).

A.2 The Optimization Loss

In this section, we derive the optimization loss for learning parameters in Eq. (5). Introducing the posterior in Eq. (3) and probabilities specification $p_\theta(\mathbf{z}_j | \mathbf{v}_i, k) = \mathcal{N}(\mathbf{z}_j; \boldsymbol{\mu}_{z_j}, \boldsymbol{\Sigma}_j)$ to the negative of the lower-bounded likelihood in Eq. (4), we have:

$$
\begin{aligned}
\mathcal{L} = -\frac{1}{|N(i)|} \sum_{j \in N(i)} \mathbb{E}_{q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)}[\log \mathcal{N}(\mathbf{z}_j; \boldsymbol{\mu}_{z_j}, \boldsymbol{\Sigma}_j) + \log \frac{\mathcal{N}(\mathbf{v}_i; \boldsymbol{\mu}_k, \mathbf{I}\sigma_1^2)p(k)}{\sum_{k'=1}^{K} \mathcal{N}(\mathbf{v}_i; \boldsymbol{\mu}_{k'}, \mathbf{I}\sigma_1^2)p(k')} \\
- \log q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)].
\end{aligned} \quad (14)
$$

Since we consider isotropic Gaussian with $\boldsymbol{\Sigma}_j = \mathbf{I}\sigma_2^2$, we have:

$$
\begin{aligned}
\mathcal{N}(\mathbf{z}_j; \boldsymbol{\mu}_{z_j}, \boldsymbol{\Sigma}_j) &= \frac{1}{(2\pi)^{D'/2}\sigma_2^{D'}} \exp(-\frac{1}{2\sigma_2^2}(\mathbf{z}_j - \mathbf{v}_i - g_\theta(k))^T \cdot (\mathbf{z}_j - \mathbf{v}_i - g_\theta(k))) \\
&= \frac{1}{(2\pi)^{D'/2}\sigma_2^{D'}} \exp(-\frac{\|\mathbf{v}_i + g_\theta(k) - \mathbf{z}_j\|_2^2}{2\sigma_2^2})
\end{aligned} \quad (15)
$$

Similarly, for $\mathcal{N}(\mathbf{v}_i; \boldsymbol{\mu}_k, \mathbf{I}\sigma_1^2)$, we have:

$$
\begin{aligned}
\mathcal{N}(\mathbf{v}_i; \boldsymbol{\mu}_k, \mathbf{I}\sigma_1^2) &= \frac{1}{(2\pi)^{D'/2}\sigma_1^{D'}} \exp(-\frac{1}{2\sigma_1^2}(\mathbf{v}_i - \boldsymbol{\mu}_k)^T \cdot (\mathbf{v}_i - \boldsymbol{\mu}_k)) \\
&= \frac{1}{(2\pi)^{D'/2}\sigma_1^{D'}} \exp(-\frac{1}{2\sigma_1^2}(\mathbf{v}_i - \boldsymbol{\mu}_k)^T \cdot (\mathbf{v}_i - \boldsymbol{\mu}_k)) = \frac{1}{(2\pi)^{D'/2}\sigma_1^{D'}} \exp(\frac{(\mathbf{v}_i^\top \cdot \boldsymbol{\mu}_k - 1)}{\sigma_1^2}),
\end{aligned} \quad (16)
$$

where the last equivalence is because we apply L2 normalization to $\mathbf{v}_i$ and $\boldsymbol{\mu}_k$, respectively. Substituting the corresponding terms in Eq. (14) with Eq. (15) and Eq. (16), and removing the constant terms that are irrelevant to model parameters $\{\theta, \phi, \boldsymbol{\mu}\}$ (note that $p(k) = \frac{1}{K}$), we have:

$$
\begin{aligned}
\mathcal{L} &= \frac{1}{|N(i)|} \sum_{j \in N(i)} \frac{1}{2\sigma_2^2} \mathbb{E}_{q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)}\big[\|\mathbf{v}_i + g_\theta(k) - \mathbf{z}_j\|_2^2\big] - \mathcal{H}(q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)) \\
&\quad - \frac{1}{|N(i)|} \sum_{j \in N(i)} \mathbb{E}_{q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)}\Big[\log \frac{\exp(\boldsymbol{v}_i^\top \cdot \boldsymbol{\mu}_k / \sigma_1^2)}{\sum_{k'=1}^{K} \exp(\boldsymbol{v}_i^\top \cdot \boldsymbol{\mu}_{k'} / \sigma_1^2)}\Big] \\
&= \frac{1}{|N(i)|} \sum_{j \in N(i)} \frac{1}{2\sigma_2^2} \mathbb{E}_{q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)}\big[\|\mathbf{v}_i + g_\theta(k) - \mathbf{z}_j\|_2^2\big] - \mathbb{E}_{q_\phi(k|\mathbf{v}_i)}\Big[\log \frac{\exp(\boldsymbol{v}_i^\top \cdot \boldsymbol{\mu}_k / \sigma_1^2)}{\sum_{k'=1}^{K} \exp(\boldsymbol{v}_i^\top \cdot \boldsymbol{\mu}_{k'} / \sigma_1^2)}\Big] - \mathcal{H}(q_\phi(k|\mathbf{v}_i, \mathbf{z}_j))
\end{aligned} \quad (17)
$$

$$= \frac{1}{|N(i)|} \sum_{j \in N(i)} \mathbb{E}_{q_\phi(k|\mathbf{v}_i,\mathbf{z}_j)} \left[\|\mathbf{v}_i + g_\theta(k) - \mathbf{z}_j\|_2^2 \right] - 2\sigma_2^2 \mathbb{E}_{q_\phi(k|\mathbf{v}_i)} \left[\log \frac{\exp\left(\boldsymbol{v}_i^\top \cdot \boldsymbol{\mu}_k / \sigma_1^2\right)}{\sum_{k'=1}^K \exp\left(\boldsymbol{v}_i^\top \cdot \boldsymbol{\mu}_{k'} / \sigma_1^2\right)} \right]$$
$$- \mathcal{H}(q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)),$$

where $q_\phi(k|\mathbf{v}_i) = 1/|N(i)| \sum_{j \in N(i)} q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)$. In third line, we multiply the constant $2\sigma_2^2$ for all terms. By absorbing $2\sigma_2^2$ to the hyper-parameter σ_2^2, we obtain the loss function in Eq. (5).

A.3 Derivation of Global Update

In this section, we derive the analytical global update of prototypes based on our optimization loss over all nodes. Specifically, we have:

$$\boldsymbol{\mu}_k \leftarrow \arg\min_{\boldsymbol{\mu}_k} \sum_{i=1}^N \mathcal{L} = \arg\max_{\boldsymbol{\mu}_k} \sum_{i=1}^N \mathbb{E}_{q_\phi(k|\mathbf{v}_i)} \left[\log \frac{\exp\left(\boldsymbol{v}_i^\top \cdot \boldsymbol{\mu}_k / \sigma_1^2\right)}{\sum_{k'=1}^K \exp\left(\boldsymbol{v}_i^\top \cdot \boldsymbol{\mu}_{k'} / \sigma_1^2\right)} \right]$$
$$= \arg\max_{\boldsymbol{\mu}_k} \sum_{i=1}^N \mathbb{E}_{q_\phi(k|\mathbf{v}_i)} \left[\log \exp(\boldsymbol{v}_i^\top \cdot \boldsymbol{\mu}_k / \sigma_1^2) \right]$$
$$= \arg\max_{\boldsymbol{\mu}_k} \sum_{i=1}^N \mathbb{E}_{q_\phi(k|\mathbf{v}_i)} \left[(\boldsymbol{v}_i^\top \cdot \boldsymbol{\mu}_k / \sigma_1^2) \right]. \tag{18}$$

In the second line, following [53], we treat the normalizing term as the constant. Since we add apply L2 normalization to $\boldsymbol{\mu}_k$: $\|\boldsymbol{\mu}_k\| = 1$, we actually need to solve the Lagrangian of the objective function:

$$\mathcal{L}(\boldsymbol{\mu}_k, \beta) = \max_{\boldsymbol{\mu_k}, \beta} \sum_{i=1}^N \mathbb{E}_{q_\phi(k|\mathbf{v}_i)} \left[(\mathbf{v}_i^\top \cdot \boldsymbol{\mu}_k / \sigma_1^2) \right] + \beta(1 - \boldsymbol{\mu}_k^\top \boldsymbol{\mu}_k). \tag{19}$$

Take the gradient over $\boldsymbol{\mu}_k$ with respect to $\mathcal{L}(\boldsymbol{\mu}_k, \beta)$ and set it to zero, we have:

$$\sum_{i=1}^N q_\phi(k|\mathbf{v}_i)\mathbf{v}_i / \sigma_1^2 - 2\beta \cdot \boldsymbol{\mu}_k = 0 \tag{20}$$

$$\Rightarrow \boldsymbol{\mu}_k = \frac{\sum_{i=1}^N q_\phi(k|\mathbf{v}_i) \cdot \mathbf{v}_i}{2\beta\sigma_1^2} = \frac{\sum_{i=1}^N \pi_i(k) \cdot \mathbf{v}_i}{2\beta\sigma_1^2}, \tag{21}$$

where $\pi_i(k) = q_\phi(k|\mathbf{v}_i) = 1/|N(i)| \sum_{j \in N(i)} q_\phi(k|\mathbf{v}_i, \mathbf{z}_j)$. By taking the gradient with respect to Lagrange multiplier β and setting it to zero, we have: $\boldsymbol{\mu}_k^\top \boldsymbol{\mu}_k = 1$. Combining $\boldsymbol{\mu}_k^\top \boldsymbol{\mu}_k = 1$ and Eq. (21), we have:

$$\beta = \frac{\|\sum_{i=1}^N \pi_i(k) \cdot \mathbf{v}_i\|}{2\sigma_1^2}. \tag{22}$$

Further combining the above equation with Eq. (21), we obtain the analytical global update:

$$\boldsymbol{\mu}_k = \frac{\sum_{i=1}^N \pi_i(k) \cdot \mathbf{v}_i}{\|\sum_{i=1}^N \pi_i(k) \cdot \mathbf{v}_i\|_2^2}, \quad \text{where } \pi_i(k) = 1/|N(i)| \sum_{j \in N(i)} q_\phi(k|\mathbf{v}_i, \mathbf{z}_j) \tag{23}$$

Algorithm 1 Training Algorithm of DSSL

Input: $G = (\mathcal{V}, \mathcal{E})$
Output: Online encoder network parameters θ.
Initialize target encoder parameter $\xi = \theta$
repeat
    Randomly select a mini-batch nodes from $\mathcal{V}$
    for *each v_i in the batch* **do**
        Randomly sample its neighbors $\mathcal{N}(i)$
        Sample **c** with Gumbel softmax
    end
    $\mathcal{L} \leftarrow$ Eq. (5)
    $[\theta, \phi, \boldsymbol{\mu}] \leftarrow [\theta, \phi, \boldsymbol{\mu}] - \boldsymbol{\Gamma}\left(\nabla_{\theta,\phi,\boldsymbol{\mu}}\mathcal{L}\right)$
    Update ξ with momentum moving average: $\xi \leftarrow \tau\xi + (1 - \tau)\theta$
until *convergence or reaching max iteration;*

B The Training Algorithm and Network Architecture

B.1 The Training Algorithm of DSSL

The overall training algorithm is shown in Algorithm 1. Concretely, for each iteration of DSSL, we randomly sample the nodes and its neighbors. Then we calculate the loss function with Gumbel softmax approximation. All online trainable parameters are updated with stochastic gradient descent (SGD), while those marked with ξ are the target network counterparts to be updated with exponential moving average.

Figure 6: An Illustration of the overall DSSL framework. For simplicity, we only illustrate learning process on one neighbor v_j of central node v_i, while it is applied to all neighbors.

B.2 The Network Architecture of DSSL

The DSSL framework is illustrated in Figure 6. DSSL proposes a self-supervised scheme that learns to encode the node using an online encoder along with a set of prototypes, inference projector g_θ and predictor h_ϕ. These form the online network. Learning is done by optimizing the local $\mathcal{L}_{local}$ and global $\mathcal{L}_{global}$ losses. To optimize the online parameters, a target encoder is used to produce presentations of neighbors, and updated by exponential moving average. We stop gradients on target encoder coming from the local loss to introduce asymmetry between the online and target encoders.

C Efficiency Analysis

C.1 Time Complexity Analysis

We analyze the detailed time complexity per iteration of the proposed DSSL, and compare it with two representative self-supervised learning methods on node representation learning such as GCA [66] and BGRL [46]. For graph self-supervised learning, the time complexity mainly depends on two parts: the encoder and loss calculation. Note that we assume the backward pass to be approximately as costly as a forward pass following [46]. Since our DSSL is agnostic to GNN encoders, we consider the L-layer GCN as an example. A L-layer GCN [28] with d hidden dimensions has $\mathcal{O}\left(dL|\mathcal{E}| + Nd^2L\right)$ complexity where $\mathcal{E}$ is the number of edges, since it costs $\mathcal{O}(d|\mathcal{E}|)$ to propagate message in each layer, and $\mathcal{O}\left(Nd^2\right)$ to multiply by the weight matrix in each layer. Our DSSL additionally has the inference predictor and projector components in the forward pass, which costs $\mathcal{O}(C_{predictor}N + C_{projector}N)$ where $C_.$ are constants depending on architecture of the different components. The complexity of DSSL on loss calculation is $\mathcal{O}(KNd) + \mathcal{O}(|\mathcal{E}|d)$ where $\mathcal{O}(KNd)$ and $\mathcal{O}(|\mathcal{E}|d)$ are for global and local losses, respectively. Thus the total time complexity per iteration for DSSL with GCN as backbone is $\mathcal{O}\left(dL|\mathcal{E}| + Nd^2L + C_{predictor}N + C_{projector}N + KNd + |\mathcal{E}|d\right)$. With the similar notations, we can express the time complexity of GCA as $\mathcal{O}\left(dL|\mathcal{E}| + Nd^2L + C_{projector}N + N^2d\right)$ and that of BGRL as $\mathcal{O}\left(dL|\mathcal{E}| + Nd^2L + C_{predictor}N + Nd\right)$. Typically, the architectures for predictor and projector are one-layer MLP for all methods, thus the $C_{predictor}$ and $C_{projector}$ in different methods should be similar. Based on the analysis above, we can find that the time complexity of GCA scales quadratically in the size of the nodes, and both BGRL and our DSSL linearly increase with the number of nodes N when $\mathcal{E}$ is proportional to N. Thus the overall time complexity of our DSSL is at the same level of BGRL [46] which is a large scale self-supervised learning method proposed recently.

Table 3: Comparison of the running time (seconds per iteration) with a batch size of 1024.

Dataset	MVGRL	DGI	BGRL	DSSL
Cora	1.21s	0.96s	0.42s	0.48s
PubMed	3.05s	2.58s	1.65s	1.83s
Texas	0.19s	0.15s	0.07s	0.07s
Cornell	0.24s	0.19s	0.08s	0.09s
Penn94	8.58s	5.94s	3.13s	3.78s
Twitch	5.43s	2.78s	1.02s	1.18s

C.2 Empirical Comparison

We further conduct experiments to compare our training time with baselines. For comparison, we take MVGRL, DGI, and BGRL as representative baselines. Table 3 shows the results of running time (seconds per iteration) on different datasets. Overall, our method has a shorter training time than MVGRL and DGI since our DSSL does not need augmentations and negative sampling. BGRL is also a simple and efficient model, but it yields poorer performance on non-homophilous graphs, as shown in our experiments. The results show the efficiency of DSSL, and we can find the superior performances of DSSL do not benefit from a larger model complexity. The experimental results in Tables 3 and 1, and analysis in section C.1, show that our DSSL is generally not slower than existing methods and can achieve better performance.

D Theoretical Analysis

D.1 Proof of Theorem 1

To prove Theorem 1, we first present three Lemmas:

Lemma D.1. *For any random variables X, Y, Z and V, we have the following relations:*

$$I(X, Y; Z|V) \geq I(X; Z|V) \tag{24}$$

Proof.

$$
\begin{aligned}
&I(X, Y; Z|V) - I(X; Z|V) \\
&= \iiiint_{XYZV} p(V)p(X, Y, Z|V) \log \frac{p(X, Y, Z|V)}{p(X, Y|V)p(Z|V)} dXdYdZdV \\
&\quad - \iiint_{XZV} p(X, Z|V) \log \frac{p(X, Z|V)}{p(X|V)p(Z|V)} dXdZdV \\
&= \iiiint_{XYZV} p(X, Y, Z|V) \log \frac{p(X, Y, Z|V)}{p(X, Y|V)p(Z|V)} - p(X, Y, Z|V) \log \frac{p(X, Z|V)}{p(X|V)p(Z|V)} dXdYdZdV \\
&= \iiint_{XYZV} p(X, Y, Z|V) \log \frac{p(X, Y, Z|V)}{p(Y|X, V)p(X, Z|V)} dXdYdZdV = \\
&\iiint_{XYZV} p(Y, Z|X, V)p(X|V) \log \frac{p(Y, Z|X)}{p(Y|X, V)p(Z|X, V)} dXdYdZdV = I(Y; Z|X, V) \geq 0. \tag{25}
\end{aligned}
$$

This completes the proof of the this Lemma. □

Lemma D.2. *For any random variables Z and X, the mutual information $I(X;Z)$ has a lower bound:*

$$
\begin{aligned}
I(X; Z) = H(Z) - H(Z|X) &= \mathbb{E}_{q(Z)}[\log q(Z)] - \mathbb{E}_{q(Z)q(X|Z)}[\log q(Z|X)] \tag{26} \\
&\geq \max_{\theta} \mathbb{E}_{q(Z)}[\log q(Z)] - \mathbb{E}_{q(Z)q(X|Z)}[\log p_{\theta}(Z|X)],
\end{aligned}
$$

where $p_{\theta}(Z|X)$ is an introduced variational discriminator with θ representing the parameters.

Proof.

$$
\begin{aligned}
\mathbb{E}_{q(Z)q(Z|X)}[\log q(Z|X)] &= \max_{\theta} \mathbb{E}_{q(Z)q(X|Z)}[\log p_{\theta}(Z|X)] + KL(q(Z|X)||p_{\theta}(Z|X)) \\
&\geq \max_{\theta} \mathbb{E}_{q(Z)q(X|Z)}[\log p_{\theta}(Z|X)]. \tag{27}
\end{aligned}
$$

Plugging the inequality above into Eq. (26) completes the proof. □

Lemma D.3. *For any random variables Z and X, the mutual information I(X, Z) has a lower bound:*

$$I(X; Z) \geq \mathbb{E}_{p(X,Z)}[f_{\boldsymbol{\theta}}(x, z) - \mathbb{E}_{q(\tilde{\mathcal{B}})}[\log \sum_{\tilde{z} \in \tilde{\mathcal{B}}} \exp f_{\boldsymbol{\theta}}(x, \tilde{z})]] + \log |\tilde{\mathcal{B}}| \tag{28}$$

where x and z are the sample instances, $f_\theta \in \mathbb{R}$ is a function parameterized by θ (e.g., a dot product between encoded representations of a x and z), and $\tilde{\mathcal{B}}$ is a set of samples drawn from a proposal distribution $q(\tilde{\mathcal{B}})$. The set $\tilde{\mathcal{B}}$ contains the positive sample b and $|\tilde{\mathcal{B}}| - 1$ negative samples.

Proof. The exact derivation of this InfoNCE bound can be founded in [39]. $\square$

Now, we are ready to prove our Theorem 1. We first restate Theorem 1:

Theorem 1. *Optimizing Eq. (5) is equivalent to maximize the mutual information between the node representation $\mathbf{v}$ and the global semantic signal k, and maximize the conditional mutual information between $\mathbf{v}$ and the local signal $\mathbf{z}$, conditioned on the global signal k. Formally, we have:*

$$\max_{\theta,\phi,\boldsymbol{\mu}} \mathcal{L} \Rightarrow \max_{\mathbf{v}} I(\mathbf{v}; k) + I(\mathbf{v}; \mathbf{z}|k) = I(\mathbf{v}; k, \mathbf{z}). \tag{29}$$

Proof. According to Lemma D.1, for any j we have:

$$I(\mathbf{v}, \mathbf{z}|k) = I(\mathbf{v}, \mathbf{z}_1, \cdots, \mathbf{z}_{N(v)}|k) \geq I(\mathbf{v}, \mathbf{z}_j|k), \tag{30}$$

which means

$$I(\mathbf{v}, \mathbf{z}|k) = \frac{1}{|\mathcal{N}(v)|} \sum_{j \in N(v)} I(\mathbf{v}, \mathbf{z}|k) \geq \frac{1}{|\mathcal{N}(v)|} \sum_{j \in N(v)} I(\mathbf{v}, \mathbf{z}_j|k). \tag{31}$$

For $I(\mathbf{v}, \mathbf{z}_j|k)$, we can relate it to our local loss $\mathcal{L}_{local}$ in the main paper:

$$
\begin{aligned}
\max_{\mathbf{v}} I(\mathbf{v}, \mathbf{z}_j|k) &\Leftrightarrow \max_{\mathbf{v}} H(\mathbf{z}_j|k) - H(\mathbf{z}_j|k, \mathbf{v}) \\
&\Leftarrow \min_{\mathbf{v},\theta} -\mathbb{E}_{q(\mathbf{v})q(\mathbf{z}_j)q(k|\mathbf{v},\mathbf{z}_j)}[\log p_\theta(\mathbf{z}_j|k, \mathbf{v})] \\
&\Leftrightarrow \min_{\theta,\phi} -\mathbb{E}_{q_\theta(\mathbf{v})q_\xi(\mathbf{z}_j)q_\phi(k|\mathbf{v},\mathbf{z}_j)}[\log p_\theta(\mathbf{z}_j|k, \mathbf{v})] \\
&\Leftrightarrow \min_{\theta,\phi} -\mathbb{E}_{\mathbf{v}=f_\theta(\mathbf{g})[v],\mathbf{z}_j=f_\xi(\mathbf{g})[j],q_\phi(k|\mathbf{v},\mathbf{z}_j)}[\log p_\theta(\mathbf{z}_j|k, \mathbf{v})] \\
&\Leftrightarrow \min_{\theta,\phi} -\mathbb{E}_{\mathbf{v}=f_\theta(\mathbf{g})[v],\mathbf{z}_j=f_\xi(\mathbf{g})[j],q_\phi(k|\mathbf{v},\mathbf{z}_j)}[\log p_\theta(\mathbf{z}_j|k, \mathbf{v})] \\
&\Leftrightarrow \min_{\theta,\phi} \frac{1}{2\sigma_2^2} \mathbb{E}_{q_\phi(k|\mathbf{v},\mathbf{z}_j)}[\|\mathbf{v} + g_\theta(k) - \mathbf{z}_j\|_2^2],
\end{aligned}
\tag{32}
$$

where we use Lemma D.1 in the second line and $\mathbf{v}$ and $\mathbf{z}_j$ are the representations of node v and node z_j through deterministic encoder f with input graph $\mathbf{g} = \{\mathbf{X}, \mathbf{A}\}$. Combining Eqs. (32) and (31), we have:

$$\min_{\theta,\phi} \frac{1}{\mathcal{N}(v)} \sum_{j \in \mathcal{N}(v)} \frac{1}{2\sigma_2^2} \mathbb{E}_{q_\phi(k|\mathbf{v},\mathbf{z}_j)}[\|\mathbf{v} + g_\theta(k) - \mathbf{z}_j\|_2^2] \Rightarrow \max_{\mathbf{v}} I(\mathbf{v}, \mathbf{z}|k). \tag{33}$$

The InfoNCE is related to our global loss. Using Lemma 26 on mutual information $I(\mathbf{v}; k)$, we have:

$$I(\mathbf{v}, k) \geq \mathbb{E}_{p(\mathbf{v},k)}[f_\theta(\mathbf{v}, k) - \mathbb{E}_{q(\tilde{\mathcal{B}})}[\log \sum_{\tilde{k} \in \tilde{\mathcal{B}}} \exp f_{\boldsymbol{\theta}}(\mathbf{v}, \tilde{k})] + \log |\tilde{\mathcal{B}}|. \tag{34}$$

When $\tilde{\mathcal{B}}$ always includes all possible values of the latent variable k (i.e., $|\tilde{\mathcal{B}}| = K$) and they are uniformly distributed, and setting $f_\theta(\mathbf{v}, k) = \frac{\mathbf{v}^\top \cdot \boldsymbol{\mu}_k}{\sigma_1^2}$, we have:

$$I(\mathbf{v}, k) \geq \mathbb{E}_{\mathbf{v}=f_\theta(\mathbf{g})[v], q_\phi(k|\mathbf{v}_i)}\left[\log \frac{\exp\left(\mathbf{v}_i^\top \cdot \boldsymbol{\mu}_k / \sigma_1^2\right)}{\sum_{k'=1}^{K} \exp\left(\mathbf{v}_i^\top \cdot \boldsymbol{\mu}_{k'} / \sigma_1^2\right)} \right]. \tag{35}$$

Given the above, we have:

$$\max_{\theta,\phi,\boldsymbol{\mu}} \mathbb{E}_{\mathbf{v}=f_\theta(\mathbf{g})[v], q_\phi(k|\mathbf{v}_i)}\left[\log \frac{\exp\left(\mathbf{v}_i^\top \cdot \boldsymbol{\mu}_k / \sigma_1^2\right)}{\sum_{k'=1}^{K} \exp\left(\mathbf{v}_i^\top \cdot \boldsymbol{\mu}_{k'} / \sigma_1^2\right)} \right] \Rightarrow \max_{\mathbf{v}} I(\mathbf{v}, k). \tag{36}$$

Combining Eqs. (32) and (36), we have

$$\max_{\theta,\phi,\boldsymbol{\mu}} \mathcal{L} \Rightarrow \max_{\mathbf{v}} I(\mathbf{v}; k) + I(\mathbf{v}; \mathbf{z}|k) = I(\mathbf{v}; k, \mathbf{z}), \tag{37}$$

Omitting the entropy regularization in the loss $\mathcal{L}$ in Eq. (5) completes the proof. $\square$

 D.2 Proof of Theorem 2

674 To prove Theorem 2, we first present the following Lemmas.

675 **Lemma D.4.** *For a representation* $\mathbf{v}$ *that is obtained with a deterministic GNN encoder* f_θ *of input graph* $\mathbf{g}$
676 *with enough capacity, we have the following data processing Markov chain:* $(k, \mathbf{z}) \leftrightarrow \mathbf{y} \leftrightarrow \mathbf{g} \rightarrow \mathbf{v}$.

677 *Proof.* Since $\mathbf{v}$ is a deterministic function of $\mathbf{g}$, we have the following conditional independence: $(k, \mathbf{z}) \perp$
678 $\mathbf{v}|\mathbf{g}$ and $\mathbf{y} \perp \mathbf{v}|\mathbf{g}$ [9]. This leads to the data processing Markov chain $(k, \mathbf{z}) \leftrightarrow \mathbf{y} \leftrightarrow \mathbf{g} \rightarrow \mathbf{v}$. □

679 **Lemma D.5.** *By optimizing loss in Eq.* (5), *the learned representation of* $\mathbf{v}_{joint}$ *is both minimal and sufficient:*
680 $\mathbf{v}_{joint}$ *is sufficient* $\mathbf{v}_{joint} = \arg \max_{\mathbf{v}} I(\mathbf{v}; k, \mathbf{z})$; $\mathbf{v}_{joint}$ *is minimal* $\mathbf{v}_{joint} = \arg \min_{\mathbf{v}} H(\mathbf{v}|k, \mathbf{z})$.

681 *Proof.* We further have $I(\mathbf{v}; \mathbf{z}|k) = H(\mathbf{v}|k) - H(\mathbf{v}|k, \mathbf{z})$ in which the entropy $H(\mathbf{v}|k)$ is a constant
682 since $p(\mathbf{v}|k)$ is a Gaussian distribution. Thus, maximizing $I(\mathbf{v}; \mathbf{z}|k)$ is equivalent to minimize $H(\mathbf{v}|k, \mathbf{z})$.
683 Combining this with Theorem 2, we can directly conclude that $\mathbf{v}_{joint}$ is sufficient and minimal. □

684 Next, we restate Theorem 2 and provide a complete proof with the help of the Lemmas above.

Theorem 2. *Let* $\mathbf{v}_{\text{joint}} = \arg \max_{\mathbf{v}} I(\mathbf{v}; \mathbf{z}, k)$, $\mathbf{v}_{\text{local}} = \arg \max_{\mathbf{v}} I(\mathbf{v}; k)$, *and* $\mathbf{v}_{\text{global}} = \arg \max_{\mathbf{v}} I(\mathbf{v}; \mathbf{z})$.
Formally, we have the following inequalities about the task-relevant information:

$$I(\mathbf{g}; \mathbf{y}) = \max_{\mathbf{v}} I(\mathbf{v}; \mathbf{y}) \geq I(\mathbf{v}_{\text{joint}}; \mathbf{y}) \geq \max(I(\mathbf{v}_{\text{local}}; \mathbf{y}), I(\mathbf{v}_{\text{global}}; \mathbf{y})) \geq I(\mathbf{g}; \mathbf{y}) - \epsilon. \quad (38)$$

Proof. Based on Lemma D.4, we have the following data processing inequality [47]:

$$I(k, \mathbf{z}; \mathbf{g}) \geq I(k, \mathbf{z}; \mathbf{v}), I(k, \mathbf{z}; \mathbf{g}; \mathbf{y}) \geq I(k, \mathbf{z}; \mathbf{v}; \mathbf{y}), I(\mathbf{g}, y) \geq I(\mathbf{v}, y) \quad (39)$$

685 Since $\mathbf{v}_{\text{joint}} = \arg \max_{\mathbf{v}} I(\mathbf{z}, k; \mathbf{v})$, we further have: $I(k, \mathbf{z}; \mathbf{v}_{\text{joint}}) = I(k, \mathbf{z}; \mathbf{g})$ and $I(k, \mathbf{z}; \mathbf{v}_{\text{joint}}; \mathbf{y}) =$
686 $I(k, \mathbf{z}; \mathbf{g}; \mathbf{y})$. In addition, since $\mathbf{v}_{joint}$ is minimal, we also have, $I(\mathbf{v}_{joint}; \mathbf{y}|k, \mathbf{z}) \leq H(\mathbf{v}_{joint}|k, \mathbf{z}) = 0$.
687 Give the above, we have the following equality:

$$\begin{aligned}
I(\mathbf{v}_{joint}; \mathbf{g}) &= I(\mathbf{v}_{joint}; \mathbf{y}; k, \mathbf{z}) + I(\mathbf{v}_{joint}; \mathbf{y}|k, \mathbf{z}) \\
&= I(\mathbf{g}; \mathbf{y}; k, \mathbf{z}) + I(\mathbf{v}_{joint}; \mathbf{y}|k, \mathbf{z}) \\
&= I(\mathbf{g}; \mathbf{y}; k, \mathbf{z}) + 0 \\
&= I(\mathbf{g}; \mathbf{y}) - I(\mathbf{g}; \mathbf{y}|k, \mathbf{z}) \\
&= \max_{\mathbf{v}} I(\mathbf{v}; \mathbf{y}) - I(\mathbf{g}; \mathbf{y}|k, \mathbf{z}) = I(\mathbf{v}_{\text{sup}}; \mathbf{y}) - I(\mathbf{g}; \mathbf{y}|k, \mathbf{z}).
\end{aligned} \quad (40)$$

688 Thus the gap between supervised representation and supervised representation is $I(\mathbf{g}; \mathbf{y}|k, \mathbf{z})$. Based on the
689 property of mutual information, we have:

$$I(\mathbf{g}; \mathbf{y}|k) = I(\mathbf{g}; \mathbf{y}, \mathbf{z}|k) + I(\mathbf{g}; \mathbf{y}|k, \mathbf{z}) \geq I(\mathbf{g}; \mathbf{y}|k, \mathbf{z}). \quad (41)$$

690 Similarly, we have $I(\mathbf{g}; \mathbf{y}|\mathbf{z}) \geq I(\mathbf{g}; \mathbf{y}|k, \mathbf{z})$. Combining Eqs. (40) and (41), we have the following
691 inequalities about the task-relevant information (note that $I(\mathbf{g}; \mathbf{y}|k, \mathbf{z}) \leq \epsilon$ based on our Assumption 1):

$$I(\mathbf{g}; \mathbf{y}) = \max_{\mathbf{v}} I(\mathbf{v}; \mathbf{y}) \geq I(\mathbf{v}_{\text{joint}}; \mathbf{y}) \geq \max(I(\mathbf{v}_{\text{local}}; \mathbf{y}), I(\mathbf{v}_{\text{global}}; \mathbf{y})) \geq I(\mathbf{g}; \mathbf{y}) - \epsilon, \quad (42)$$

692 which completes the proof □

D.3 Proof of Corollary 1

694 Restate Corollary 1:

695 **Corollary 1.** *Suppose that downstream label* $\mathbf{y}$ *is a M-categorical random variable. Then we have the upper*
696 *bound for the downstream Bayes errors* $P_{\mathbf{v}}^e = \mathbb{E}_{\mathbf{v}} \left[1 - \max_{y \in \mathbf{y}} P(\hat{\mathbf{y}} = y|\mathbf{v}) \right]$ *on learned representation* $\mathbf{v}$,
697 *where* $\hat{\mathbf{y}}$ *is the estimation for label from our downstream classifier:*

$$\text{Th}(P_{\mathbf{v}_{joint}}^e) \leq \log 2 + P_{\mathbf{v}_{\text{sup}}}^e \cdot \log M + I(\mathbf{g}; \mathbf{y}|\mathbf{z}, k) \triangleq \text{RHS}_{\mathbf{v}_{joint}} \quad (43)$$

698 *where* $\text{Th}(x) = \min\{\max\{x, 0\}, 1 - 1/|M|\}$ *is a thresholded operation [49]. Similarly, we can obtain the*
699 *error upper bound of other representations* $\mathbf{v}_{\text{local}}$ *and* $\mathbf{v}_{\text{global}}$: $\text{RHS}_{\mathbf{v}_{local}}$ *and* $\text{RHS}_{\mathbf{v}_{global}}$. *Then, we have*
700 *inequalities on error upper bounds* : $\text{RHS}_{\mathbf{v}_{joint}} \leq \min(\text{RHS}_{\mathbf{v}_{local}}, \text{RHS}_{\mathbf{v}_{global}})$.

Proof. To prove this Corollary, we use the following inequalities [47, 49]:

$$\text{Th}(P^e_{\mathbf{v}_{joint}}) \leq -\log(1 - P^e_{\mathbf{v}_{joint}}) \leq H(\mathbf{y}|\mathbf{v}_{\text{joint}}) \tag{44}$$

$$H(\mathbf{y}|\mathbf{v}_{\text{sup}}) \leq \log 2 + P^e_{\mathbf{v}_{\text{sup}}} \log M. \tag{45}$$

For $H(\mathbf{y}|\mathbf{v}_{\text{joint}})$ and $H(\mathbf{y}|\mathbf{v}_{\text{sup}})$, we have the following relations:

$$\begin{aligned} H(\mathbf{y}|\mathbf{v}_{\text{joint}}) = H(\mathbf{y}) - I(\mathbf{v}_{\text{joint}}; \mathbf{y}) &= H(\mathbf{y}) - I(\mathbf{v}_{\text{sup}}; \mathbf{y}) + I(\mathbf{g}; \mathbf{y}|\mathbf{z}, k) \\ &= H(\mathbf{y}|\mathbf{v}_{\text{sup}}) + I(\mathbf{g}; \mathbf{y}|\mathbf{z}, k), \end{aligned} \tag{46}$$

where we use Eq. (40) in the second equality. Combining Eqs. (44), (45) and (46), we have:

$$\text{Th}(P^e_{\mathbf{v}_{joint}}) \leq \log 2 + P^e_{\mathbf{v}_{\text{sup}}} \cdot \log M + I(\mathbf{g}; \mathbf{y}|\mathbf{z}, k) \triangleq \text{RHS}_{\mathbf{v}_{joint}}. \tag{47}$$

Further using that $I(\mathbf{g}; \mathbf{y} \mid \mathbf{z}, k) \leq I(\mathbf{g}; \mathbf{y}|\mathbf{z})$ and $I(\mathbf{g}; \mathbf{y}|\mathbf{z}, k) \leq I(\mathbf{g}; \mathbf{y}|k)$ in Eq. (41), we have

$$\text{RHS}_{\mathbf{v}_{joint}} \leq \min(\text{RHS}_{\mathbf{v}_{local}}, \text{RHS}_{\mathbf{v}_{global}}), \tag{48}$$

which completes the proof. $\square$

E   Experimental Details

E.1   Datasets Description and Statistics

In our experiments, we use the following real-world datasets.

Cora, Citeseerm, and Pubmed are citation and high-homophily graphs, which are among the most widely used benchmarks for semi-supervised node classification [28, 14, 50]. In these graphs, nodes are documents, and edges are citations. Each node is assigned a class label based on the research field. The features of each node are represented by a bag of words of its abstracts.

Texas and Cornell are low-homophily graphs representing links between web pages of the corresponding universities and originally collected by the CMU WebKB projects, where nodes and edges represent web pages and hyperlinks, respectively. We use the pre-processed datasets by [36].

Squirrel is the subgraph of web pages in Wikipedia discussing the related topics, collected by [41]. The Squirrel graph is rather complex, with both homophily and heterophily combined.

Penn94 is a friendship network from the Facebook 100 networks of university students from 2005 [30], where nodes represent students and are labeled with the reported gender of students. The node features are major, second major/minor, dorm/house, year, and high school.

Twitch is a graph of relationships between accounts on the streaming platform Twitch. Node features are games liked, location, and streaming habits. Nodes are labeled with the explicit language used by a streamer. We utilize the pre-processed sub-graph Twitch-DE [31]. In Twitch-DE, streamers that do not use explicit content (class 0) also often connect to streamers of class 1, which results in an overall non-homophilous structure.

ArXiv-year [30] is the ogbn-arxiv graph where the class labels of nodes are given by the year that the paper is posted. The nodes are arXiv papers, and edges represent the citation link between two papers. The node features are averaged word2vec token features of both the title and abstract of the paper.

We utilize the class-average homophily metric proposed recently by [30] to measure the homophily level of graphs. Specifically, the metric is the fraction of edges that connect two nodes of the same class:

$$\hat{h} = \frac{1}{C-1} \sum_{k=0}^{C-1} \left[h_k - \frac{|C_k|}{N} \right]_+ ,$$
(49)

where $[a]_+ = \max(a, 0)$ and C is the total number of classes, and h_k is the class-wise homophily metric:

$$h_k = \frac{\sum_{u \in C_k} d_u^{(k_u)}}{\sum_{u \in C_k} d_u},$$
(50)

in which d_u is the number of neighbors of node u, and $d_u^{(k_u)}$ is the number of neighbors of u that have the same class label. Compared to the edge homophily metirc [64], this metric is less sensitive to the number of classes and the size of each class. The statistics of datasets are given in Table 4. We can find that the widely used citation graphs Cora, Citeseer, and Pubmed are highly homophilous, and other graphs show low homophily degrees and thus are non-homophilous.

E.2 Baselines and Implementations

Deepwalk [38] is a network embedding method that generates random walks from all nodes in the graph and then learns latent representations of nodes by treating walks as the equivalent of sentences with SkipGram.

LINE [45] is a network embedding model that preserves both the first-order and second-order proximities.

Struc2vec [40] is embedding method for learning representations for capturing the node structural identity.

GAE [27] is a GCN encoder trained by reconstructing adjacency matrix.

VGAE [27] is a probabilistic version of GAE and is also trained by reconstructing the adjacency matrix.

DGI [51] is an unsupervised node representation method that maximizes the mutual information between node representations and graph summary.

GraphCL [59] is a graph contrastive method that learn node representations by contrasting different augmentations of graphs.

MVGRL [16] is a contrastive learning method by contrasting encoders from neighbors and a graph diffusion.

BGRL [46] is a graph representation learning method that learns node representations by predicting alternative augmentations of the graph.

We used the official implementation publicly released by the authors on Github for all baselines. We ran our experiments on GeForce RTX 2080 Ti. In all our experiments, we use the Adam optimizer [25]. The projector g_θ and predictor h_ϕ are both the Multilayer Perceptron (MLP) with a single hidden layer. We also used stabilization techniques like batch normalization on Penn94 and Twitch datasets for all methods. We use ReLU activation in all experiments.

E.3 Experimental setup

We use the same dataset splits and training procedure for all methods. We tune hyper-parameters for all models individually and randomly initialize the model parameters. For all methods, the hyper-parameter search spaces are as follows: learning rate $\{0.001, 0.005, 0.01\}$, representation dimension $\{16, 32, 64\}$, L2 weight-decay $\{5e-4, 1e-4, 5e-6, 1e-6\}$. For our DSSL, we tune the following hyper-parameters: $\sigma_1^2 \in \{0.2, 0.4, 0.6, 0.8, 1.0\}$, $\sigma_2^2 \in \{0.2, 0.4, 0.6, 0.8, 1.0\}$, $\lambda \in \{0.2, 0.4, 0.6, 0.8, 1.0\}$ and $K \in \{2, 4, 6, 8, 16, 32\}$.

E.4 Cross-Class Neighborhood Similarity

To further demonstrate how DSSL uncovers the latent patterns in neighborhood distributions, we utilize the cross-class neighborhood similarity which serves as the ground-truth for our case study experiments in section 4.4.

Definition 1. *(Cross-Class Neighborhood Similarity). Given a graph G and node labels, the cross-class neighborhood similarity between two classes c, c' is given by $s\left(c, c'\right) = \frac{1}{|\mathcal{V}_c||\mathcal{V}_{c'}|} \sum_{i \in \mathcal{V}_c, j \in \mathcal{V}_{c'}} \cos(d(i), d(j))$*

Table 5: Experimental results (%) on the node classification task with GAT as the encoder. The best and second best performances under each dataset are marked with blue and underline, respectively.

MVGRL	**48.65**±0.07	45.33±0.02	48.81±0.21	32.72±0.18	18.02±0.11	17.65±0.08	15.80±0.17	24.53±0.16
BGRL	47.35±0.03	44.78±0.04	47.21±0.07	33.59±0.15	19.74±0.14	15.13±0.09	17.49±0.13	25.69±0.09
DSSL	46.77±0.04	**47.89**±0.04	**49.39**±0.02	**38.22**±0.15	**20.36**±0.08	**19.85**±0.13	**18.66**±0.15	**29.63**±0.08

where $\mathcal{V}_c$ indicates the set of nodes in class c and $d(i)$ denotes the empirical histogram (over $|\mathcal{C}|$ classes) of node i's neighbors' labels, and the function $\cos(\cdot, \cdot)$ measures the cosine similarity.

This cross-class neighborhood similarity measures the neighborhood distributions between difference classes. If neighborhood patterns for nodes of different labels are different, the inter-class similarity will be low.

F Additional Experimental Results

F.1 Results with Other Encoders

To further evaluate the effectiveness of the proposed DSSL, we consider the case where the learning method is implemented using another GNN encoder. Table 5 shows the results of the selected baseline with GAT as the encoder. As shown in Table 5, our DSSL performs better than all the compared methods in most cases, which once again proves the effectiveness of DSSL and also shows that DSSL is robust to various encoders.

F.2 Node Clustering Results

We provide the node clustering results in Table 6. As shown in Table 6, we can find that our DSSL can consistently improve the node clustering performance compared to the baselines on all datasets except the Cora. This observation once again verifies the effectiveness of DSSL in learning generalizable node representations. In addition, along with the node classification performance, these results show that DSSL can provide transferable and robust node representations for various downstream tasks.

F.3 Additional Results on Large Dataset

To demonstrate the effectiveness of our DSSL on large scale datasets, we consider a much larger dataset, from the non-homophilous benchmark [30], ArXiv-year. The statistics and description of ArXiv-year are provided in Appendix E. We adopt the same random split with train/val/test split ratio of 60%/20%/20% for the training of downstream linear classifier [36]. Table 7 summarizes the results. We can find that DSSL outperforms unsupervised baselines LINE [45] and vGraph [43], and three graph self-supervised learning methods MVGRL [16], DGI [51] and BGRL [46]. These results further suggest the effectiveness of DSSL on large scale dataset and show the performance of DSSL do not suffer when scaled to large graphs.

Table 7: Experimental results (%) on the large-scale non-homophilous graph, ArXiv-year, measured in terms of node classification accuracy along with standard deviations. We utilize the GCN as the backbone for all graph self-supervised methods (DGI, MVGRL, BGRL and DSSL). The best and second best performances under each dataset are marked with blue and underline, respectively.

F.4 Additional Results on Sparse Splittings

In this section, we consider another choice for data splittings for homophilous graphs, in which each class has fixed 20 nodes for training, another fixed 500 nodes and 1000 nodes are for validation and test, respectively. We evaluate baselines on the homophilous graphs such as Cora, Citeseer, Pubmed with the public split [28]. To further show the effectiveness of DSSL, we add two additional baselines, MERIT [22] and SUBG-CON [20] and also evaluate them on three non-homophilous graphs: Texas, Cornell and Penn94. Note that, for those non-homophilous graphs, we still follow the same data splitting in Table 1 to be consistent with previous works [36, 5, 6, 24]. Table 8 shows the overall results. We can see that DSSL generally outperforms other models. DSSL performs well on some homophilous datasets, despite being primarily a non-homophilous method, only falling shortly on Citeseer. The improvement made by DSSL demonstrates that decoupling the neighbor distribution can benefit the node representation learning on non-homophilous graphs.

F.5 Additional Results on Synthetic Dataset

In this section, we generate the synthetic graphs with various homophily ratios h by utilizing an approach similar to [64]. Specifically, we consider the synthetic benchmark syn-products generated by [64] since the source code for generating synthetic graph is publicly available. We refer the interested reader to [64] for the detailed generation process. The statistics for synthetic dataset syn-products is provided in Table 9. Roughly speaking, the synthetic graphs can be generated by controlling various edge-homophily ratios h where $h = 1$ indicts strong edge-homophily and $h = 0$ indicts perfect heterophily of generated graph. Here, we consider six edge-homophily ratios, $h = [0.0, 0.25, 0.50, 0.75, 1.0]$. Following [64], we randomly split 25% of nodes into training set, 25% into validation and 50% into test set for the downstream linear classifier. Table 10 gives the results on syn-products dataset. From this table, we have the following observations: (1) GAE achieves best accuracy under strong homophily ($h = 1$), but it is significantly less accurate than other methods on low-homophily settings. This is reasonable since GAE over-emphasizes proximity and the homophily assumption. (2) Our DSSL outperforms recent contrastive learning methods such as DGI and MVGRL, which shows the effectiveness of DSSL on non-homophily scenarios, and suggests that designing effective graph augmentation for those contrastive baselines on the non-homophilous graphs is difficult due to the heterogeneous and diverse neighbor pattern. (3) Our DSSL can generally achieve best performance and effectively adapt to all levels of homophily.

Table 11 further provides the results of the ablation studies to verify the significance of our model design. By comparing the ablations with DSSL, we can observe that all components contribute to the performance gain. Interestingly, we find that capturing the semantic shift between neighbors essentially boosts the performance in non-homophilous graphs where homophily ratio is low, and the local loss is the most important component making DSSL work. Moreover, we find that the global loss and personalized posterior can further improve

Figure 7: Performance on Cora, Citeseer and Pubmed with varying τ.

Figure 8: Hyper-parameter analysis on Citeseer, Cornell and Squirrel datasets.

the performance of DSSL. The above observations indicate that capturing diverse neighborhood pattern via modeling semantic shift and global semantic plays a significant role in learning good node representations for non-homophilous graphs.

Table 9: Statistics of the synthetic dataset: syn-products.

Dataset	# Nodes	# Edges	# Classes	# Features	Edge homophily
syn-products	10000	59,640 to 59,648	10	100	[0.0, 0.25, 0.50, 0.75, 1.0]

F.6 Additional Results on Ablation Study and Parameter Analysis

Ablation Study. We further conduct experiments to study the effects of the global update on prototypes and asymmetric architecture on homophily datasets. Figures 7 and 9 show the ablation results on Cora, Citeseer and Pubmed. These results also echo the collapse issue as discussed in the main text: without the global update and asymmetric architecture, there is significant performance drop on these three homophily datasets.

Parameter Analysis. We provide more results on the parameter analysis. Figure 8 shows the results on Citeseer, Cornell, and Squirrel datasets. We can observe that having large values of σ_2^2 also does not improve the overall performance, and DSSL is not very sensitive to the Gumbel softmax temperature λ for these three datasets. We also find that as K increases from 2 to 8 (2 to 16 for Citeseer), the accuracy of DSSL improves.

F.7 Additional Results on Visualization and Case Study

To further examine the learned latent factors, in Figure 10, we provide the additional case study results on other datasets. We can find that, in most cases, the latent factors share a similar distribution for the same type of link, which illustrates its effectiveness in decoupling the underlying latent semantic meaning of different neighbors. This also interprets the reason why capturing the semantic shift can improve performance.

We investigate how our learned semantic clusters perform on the long-range nodes. To show this, we study the learned cluster distribution $q(k|\mathbf{v}_i)$ for each node. To facilitate visualization, we randomly sample a sub-graph which contains high-hop neighborhoods from each dataset and use different colors to indicate different node labels. We then calculate the pair-wise similarity of the posteriors $q(k|\mathbf{v}_i)$ between nodes. Figures 11 and 12 shows the results. We can observe that our learned semantic clusters exhibits similar patterns for the nodes in the same class. Some nodes exhibit similar semantic clusters, regardless of the distance between them. For instance, node 6 exhibits very similar posterior distribution to the same class node 19 in Pubmed, and node 3 exhibit similar posterior distribution to node 12 in Cornell, despite these nodes being 4 hops away. Note that the backbone we used is still 2-layer GCN. Since our DSSL seeks to pull

Table 10: Experimental results (%) on synthetic datasets, syn-products, measured in terms of node classification accuracy along with standard deviations. We utilize the GCN as the backbone for all methods. The best and second best performances under each dataset are marked with blue and underline, respectively.

Homophily ratio h	0.00	0.25	0.50	0.75	1.00
GAE	$18.28_{\pm0.52}$	$25.49_{\pm0.37}$	$50.62_{\pm0.28}$	$82.05_{\pm0.38}$	$95.27_{\pm0.11}$

Table 11: Ablation studies of DSSL on the synthetic dataset to justify the significance of our model designs. We only provide the results of key ablations **A1**, **A2**, **A4** and **A5** mentioned in section 4.3 given the short rebuttal period.

Homophily ratio h	0.00	0.25	0.50	0.75	1.00
A1 w/o local loss	$15.34_{\pm0.27}$	$19.27_{\pm0.18}$	$23.70_{\pm0.42}$	$26.32_{\pm0.43}$	$27.14_{\pm0.32}$
A2 w/o global loss	$\underline{43.41_{\pm0.55}}$	$\underline{45.61_{\pm0.18}}$	$58.69_{\pm0.46}$	$83.94_{\pm0.31}$	$92.28_{\pm0.19}$
A4 w/o semantic shift	$40.64_{\pm0.45}$	$42.37_{\pm0.45}$	$54.77_{\pm0.18}$	$81.68_{\pm0.19}$	$\underline{92.53_{\pm0.49}}$
A4 w/ uniform posterior	$36.49_{\pm0.37}$	$38.92_{\pm0.18}$	$47.63_{\pm0.55}$	$61.15_{\pm0.33}$	$82.43_{\pm0.16}$
DSSL	$49.19_{\pm0.62}$	$51.35_{\pm0.51}$	$64.78_{\pm0.25}$	$87.59_{\pm0.46}$	$94.83_{\pm0.55}$

the node representation to the inferred semantic clusters, we can learn the global node-node relationships in representations instead of favoring nearby nodes. This qualitative visualization, along with our other experiment results, suggest that considering the semantic shift between local neighbors and capturing global semantics may be necessary for non-homophilous graphs.

G   Additional Related Work

In this section, we provide a detailed discussion of some related works and compare the major differences of them with our work.

There are also some recent works [34, 62, 7] also trying to conduct the self-supervised learning on graphs. However, our work indeed differs from these works in a number of important ways: Firstly. Our motivation is inherently different from [34, 62, 7]. Specifically, [34] jointly considers structural information and neighbor information to explore their complementary information for better performance; [62, 7] consider adding a clustering layer or a prototype clustering component to capture the global information. However, although there is one component in our loss also encouraging capturing global information, our motivation and contribution are more than that. Actually, the main motivation of our work is that the neighborhood distributions on non-homophilous graphs typically follow heterogeneous and diverse patterns. Thus, the unique challenge is that one needs to decouple the unobserved latent variables in these diverse patterns for better node representations. Given this, we propose a framework to model this semantic shift between neighbors via a generative process. This kind of motivation is different from and never been discussed by [34, 62, 7]. In addition, the works [34, 62, 7] are all mainly build based on the principle of contrastive learning. However, our work is a generative model without relying on the negative sampling required by the contrastive learning. Different from [34, 62, 7], we develop a novel scalable training algorithm with

variational inference in Appendix 3.3 and propose an effective optimization strategy with graph neural network in Appendix 3.4. Thus, the technical contribution of our work should be different from [34, 62, 7] . Moreover, our DSSL can be theoretically viewed as to maximize the mutual information between node representations and global semantics, and the learned representations by our objective provably enjoy good downstream performance. Thus, our DSSL framework is principled with some novel theoretical results. This also makes our work different from past works [34, 62, 7] and further strengthen our contribution. Empirically, we conduct extensive experiments and analysis on self-supervised learning on non-homophilous graphs, while works [34, 62, 7] only work on homophilous graphs. Instead, we show that our DSSL works well for non-homophilous graphs.

We notice that the related work vGraph [43] considers a mixture process to define the conditional probability on each edge and share some similarities with our work. However, our work has several key differences compared with vGraph in different perspectives. Although vGraph also considers a mixture process, our motivation is different from vGraph. Specifically, vGraph assumes that each node v can be represented as a mixture of multiple communities and each community z is modeled as a distribution over the nodes. This motivation results in a generative model for each edge (u, v): $p(u, v) = \int_z p(v|z)p(z|u)dz$. However, our motivation is that each node has latent heterogeneous factors which are utilized to make connections to its different neighbors and the factor denotes various reasons behind why two nodes are connected. Our motivation results in a different generative model: $p(u, v) = \int_z p(v|z, u)p(u|z)p(z)dz$. Due to the differences of motivation, our learning objective and framework are also inherent different from vGraph. Specifically, our loss encourages the model to reconstruct the local neighbors while considering different semantic shifts captured by latent variable (see equation (5)) which is important for non-homophilous graphs and different from the learning objective of vGraph. In addition, vGraph is a classical shallow network embedding algorithms. However, we instead tackle the problem of self-supervised learning with GNN. Compared to the shallow method vGraph, our work is flexible to different GNN encoders and can easily incorporate node attributes with message passing, and fine-tuned to different tasks. More importantly, conducing self-supervised learning with GNN brings some unique optimization challenges such as trivia and degenerated solution as shown in section 3.4. We propose novel self-supervised learning framework (see Figure 6) to address these challenges, which are also inherent different from vGraph. Furthermore, we provide a theoretically analysis to show the connection between the our objective and the mutual information maximization, and also prove that the learned representations by our objective provably enjoy good downstream performance, which is also not provided by vGraph.

Recently, Xu et al. propose the self-supervised graph-level representation learning with local and global structure [56]. Our work is inherent different from [56] in several perspectives. The goal of [56] is to conduct graph-level classification task where each instance is a whole graph and a dataset can be seen as a set of independent and identically distributed (IID) pairs. Thus, the local structure in [1] means that, for a pair of similar (augmented) graphs, their embeddings are expected to be nearby in the latent space. In

contrast, we focus on the node-level representation problem on non-homophilous graphs, which involves the interconnection among nodes and results in the non-IID nature of nodes. Hence, in our work, the "local" means the local neighbor distribution of each nodes and we need to decouple the diverse neighbor distribution. In addition, the work [56] is mainly based on contrastive learning with noise-contrastive estimation (NCE) which requires prefabricated augmentations and negative samples. By contrast, our framework is a fully generative model and does not rely on any augmentations. And we decouple the diverse neighborhood context of a node with a generative process to capture the diverse local information. This makes our learning framework different from [56]. Lastly, we analyze the properties of DSSL and theoretically show why combining both local structure and global semantic information in the learned representations can achieve better downstream performance, which has not been mentioned and studied by [56].

H   Discussion and Broader impact

In this paper, we proposed a new framework called decoupled self-supervised learning (DSSL) for unsupervised node representation learning on non-homophilous graphs. Compared with other contrastive learning methods, our DSSL does not need prefabricated augmentations. The theoretic analysis and extensive experiments show the effectiveness of our proposed DSSL.

Limitation of the work. Despite the theoretical grounds and the promising experimental justifications, there is one limitation of the current work which we hope to improve in future work: our theoretic analysis requires some assumptions on the relationship between the downstream labels and the neighborhood distribution (Assumption 1). While, not surprisingly, we have to make some assumptions to expect good generalization for the unsupervised node representation learning, it is an interesting future direction to explore more relaxed assumptions than the ones used in this work.

Potential negative societal impacts. In this work, we propose a self-supervised learning framework for node representation learning which does not rely on annotated labels, which might reduce the need for label annotation and thus makes a few individuals who focus on labeling or annotating data unemployed. In addition, our learned representation may suffer from malicious adversaries who seek to extract node-level information about sensitive attributes. Thus, the robustness of DSSL could be further improved to prevent attacks from an adversary.
