PropertyDAG: Multi-objective Bayesian optimization of partially ordered, mixed-variable properties for biological sequence design

Abstract

Bayesian optimization offers a sample-efficient framework for navigating the exploration-exploitation trade-off in the vast design space of biological sequences. Whereas it is possible to optimize the various properties of interest jointly using a multi-objective acquisition function, such as the expected hypervolume improvement (EHVI), this approach does not account for objectives with hierarchical structure. We consider a common use case where some regions of the Pareto frontier are prioritized over others according to a specified *partial ordering* in the objectives. For instance, when designing antibodies, we would like to maximize the binding affinity to a target antigen only if can be expressed in live cell culture— modeling the experimental dependency in which affinity can only be measured for antibodies that can be expressed and thus produced in viable quantities. In general, we may want to confer a partial ordering to the properties such that each property is optimized conditioned on its parent properties satisfying some feasibility condition. To this end, we present PropertyDAG, a framework that operates on top of the traditional multi-objective BO to impose a desired partial ordering on the objectives, e.g. expression $\rightarrow$ affinity. We demonstrate its performance over multiple simulated active learning iterations on a penicillin production task, toy numerical problem, and a real-world antibody design task.

1 Introduction

Designing biological sequences entails searching over vast combinatorial design spaces. Recently, deep sequence generation models trained on large datasets of known, functional sequences have shown promise in generating physically and chemically plausible designs [e.g. 1–3]. Whereas these models accelerate the design process, limited resources place a cap on how many designs we can characterize *in vitro* for assessing their suitability. Only once a design is validated *in vitro* and undergoes multiple rounds of optimization can it proceed down the drug development pipeline to preclinical development and clinical trials, where its performance is tested *in vivo*.

Because the wet lab cannot provide feedback on all of the candidate designs, we take an iterative, data-driven approach to select the the most informative subset to label. Many drug design applications call for such an active learning approach, as the initial datasets available to train predictive models on our desired properties of interest tends to be small or nonexistent. The measurements returned by the lab in each iteration is appended to our training set and we update our models using the augmented dataset for the next iteration.

The wet lab's measurement process can be viewed as a black-box function that is expensive to evaluate. In the context of identifying designs maximizing this function, Bayesian optimization (BO)

emerges as a promising, sample-efficient framework that trades off exploration (evaluating highly uncertain designs) and exploitation (evaluating designs believed to carry the best properties) in a principled manner [4]. It relies on a probabilistic surrogate model that infers the posterior distribution over the objectives and an acquisition function that assigns an expected utility value to each candidate. BO has been successfully applied to a variety of protein engineering applications [5–7].

In particular, we cast our problem as multi-objective BO, where multiple objectives are jointly optimized. Our objectives originate from the molecular properties evaluated during *in vitro* validation. To first order, the process involves producing the design, confirming its pharmacology, and evaluating whether it is active against a given drug target of interest. If found to be potent, the design is then assayed for *developability* attributes—physicochemical properties that characterize the safety, delivery, and manufacturability [8].

The experimental process of *in vitro* validation signifies a hierarchy among the objectives. Consider the property "expression" in the context of antibody design, for instance. A designed antibody candidate must first be expressed in live cell culture. If the level of expression does not meet a fixed threshold, the lab cannot produce it and it cannot be assayed for potency and developability downstream. Supposing now that a design did express in viable amounts, if does not bind to a target antigen with sufficient "affinity" (and is thus not potent), then the design fails as an antibody and there is little practical incentive in assaying it for developability (such as specificity and thermostability)—even if it is possible to do so. The dependency between properties, whether experimental or biological in origin, motivates us prioritize some objectives before others when selecting the subset of designs to submit to the wet lab. Our primary goal is to identify "joint positive" designs, designs that meet the chosen thresholds in all the parent objectives (expressing binders) according to the specified partial ordering and also perform well in the leaf-level objectives (high specificity, thermostability).

To this end, we propose PropertyDAG, a simple framework that operates on top of the traditional multi-objective BO to impose a desired partial ordering on the objectives, e.g. expression → affinity → specificity, thermostability. Our framework modifies the posterior inference procedure within standard BO in two ways. First, we treat the objectives as *mixed-variable*—in particular, each objective is modeled as a mixture of zeros and a wide dispersion of real-valued, non-zero values. The surrogate model consists of a binary classifier and a regressor, which infer the zero mode and the non-zero mode, respectively. We show that this modeling choice is well-suited for biological properties, which tend to carry excess zero, or null, values and fat tails [9]. Second, before samples from the posterior distribution inferred by the surrogate model enter the acquisition function, we transform the samples such that they conform to the specified partial ordering of properties. We run multi-objective BO with PropertyDAG over multiple simulated active learning iterations to a penicillin production task, toy numerical problem, and a real-world antibody design task. In all three tasks, PropertyDAG-BO identifies significantly more joint positives compared to standard BO. After the final iteration, the surrogate models trained under Property-BO also output more accurate predictions on the joint positives in a held-out test set than do the standard BO equivalents.

2 Background

Bayesian optimization (BO) is a popular technique for sample-efficient black-box optimization [see 10, 11, for a review]. Suppose our objective $f : \mathcal{X} \to \mathbb{R}$ is a black-box function of the design space $\mathcal{X}$ that is expensive to evaluate. Our goal is to efficiently identify a design $\boldsymbol{x}^{\star} \in \mathcal{X}$ maximizing[1] f. BO leverages two tools, a probabilistic surrogate model and a utility function, to trade off exploration (evaluating highly uncertain designs) and exploitation (evaluating designs believed to maximize f) in a principled manner.

For each iteration $t \in \mathbb{N}$, we have a dataset $\mathcal{D}_t = \{(\boldsymbol{x}^{(0)}, y^{(0)}), \cdots, (\boldsymbol{x}^{(N_t)}, y^{(N_t)})\} \in \mathscr{D}_t$, where each $y^{(n)}$ is a noisy observation of f. First, the probabilistic model $\hat{f} : \mathcal{X} \to \mathbb{R}$ constructs a posterior distribution $p(\hat{f}|\mathcal{D}_t) \in \Delta(\mathcal{F})$, quantifying the plausibility of surrogate objectives $\hat{f} \in \mathcal{F}$. Next, we introduce a utility function $u : \mathcal{X} \times \mathcal{F} \times \mathscr{D}_t :\to \mathbb{R}$. The acquisition function $a(\boldsymbol{x})$ is simply the

---

[1]For simplicity, we define the task as maximization in this paper without loss of generality. For minimizing f, we can negate f, for instance.

expected utility of $\boldsymbol{x}$ w.r.t. our beliefs about f,

$$a(\boldsymbol{x}) = \int u(\boldsymbol{x}, \hat{f}, \mathcal{D}_t) p(\hat{f}|\mathcal{D}_t) d\hat{f}. \tag{1}$$

For example, we obtain the expected improvement (EI) acquisition function if we take $u_{\mathrm{EI}}(\boldsymbol{x}, \hat{f}, \mathcal{D}) = [\hat{f}(\boldsymbol{x}) - \max_{(\boldsymbol{x}', y') \in \mathcal{D}} y']_+$, where $[\cdot]_+ = \max(\cdot, 0)$ [12, 4]. Generally the integral is approximated by Monte Carlo (MC) with posterior samples $\hat{f}^{(j)} \sim p(\hat{f}|\mathcal{D}_t)$. We select a maximizer of a as the new design, measure its properties, and append the observation to the dataset. The surrogate is then retrained on the augmented dataset and the procedure repeats.

Multi-objective optimization When there are multiple objectives of interest, a single best design may not exist. Suppose there are K objectives, $f : \mathcal{X} \to \mathbb{R}^K$. The goal of multi-objective optimization (MOO) is to identify the set of *Pareto-optimal* solutions such that improving one objective within the set leads to worsening another. We say that $\boldsymbol{x}$ dominates $\boldsymbol{x}'$, or $f(\boldsymbol{x}) \succ f(\boldsymbol{x}')$, if $f_k(\boldsymbol{x}) > f_k(\boldsymbol{x}')$ for all $k \in \{1, \ldots, K\}$. The set of *non-dominated* solutions $\mathscr{X}^*$ is defined in terms of the Pareto frontier (PF) $\mathcal{P}^*$,

$$\mathscr{X}^\star = \{\boldsymbol{x} : f(\boldsymbol{x}) \in \mathcal{P}^\star\}, \quad \text{where } \mathcal{P}^\star = \{f(\boldsymbol{x}) : \boldsymbol{x} \in \mathcal{X}, \nexists \boldsymbol{x}' \in \mathcal{X} \text{ s.t. } f(\boldsymbol{x}') \succ f(\boldsymbol{x})\}. \tag{2}$$

The size of $\mathscr{X}^\star$ may be infinite, so MOO algorithms typically aim to identify a finite approximation. One way to measure the quality of an approximate PF $\mathcal{P}$ is to compute the hypervolume $\mathrm{HV}(\mathcal{P}|\boldsymbol{r}_{\mathrm{ref}})$ of the polytope bounded by $\mathcal{P} \cup \{\boldsymbol{r}_{\mathrm{ref}}\}$, where $\boldsymbol{r}_{\mathrm{ref}} \in \mathbb{R}^K$ is a user-specified *reference point*. We obtain the expected hypervolume improvement (EHVI) acquisition function if we take

$$u_{\mathrm{EHVI}}(\boldsymbol{x}, \hat{f}, \mathcal{D}) = \mathrm{HVI}(\mathcal{P}', \mathcal{P}|\boldsymbol{r}_{\mathrm{ref}}) = [\mathrm{HV}(\mathcal{P}'|\boldsymbol{r}_{\mathrm{ref}}) - \mathrm{HV}(\mathcal{P}|\boldsymbol{r}_{\mathrm{ref}})]_+, \tag{3}$$

where $\mathcal{P}' = \mathcal{P} \cup \{\hat{f}(\boldsymbol{x})\}$ [13, 14].

Noisy observations In the noiseless setting, the observed baseline PF is the true baseline PF, i.e. $\mathcal{P}_t = \{\boldsymbol{y} : \boldsymbol{y} \in \mathcal{Y}_t, \nexists \boldsymbol{y}' \in \mathcal{Y}_t \text{ s.t. } \boldsymbol{y}' \succ \boldsymbol{y}\}$ where $\mathcal{Y}_t := \{\boldsymbol{y}^{(n)}\}_{n=1}^{N_t}$. This does not, however, hold in many practical applications, where measurements carry noise. For instance, given a zero-mean Gaussian measurement process with noise covariance Σ, the feedback for a design $\boldsymbol{x}$ is $\boldsymbol{y} \sim \mathcal{N}(f(\boldsymbol{x}), \Sigma)$. The *noisy* expected hypervolume improvement (NEHVI) acquisition function marginalizes over the surrogate posterior at the previously observed points $\mathcal{X}_t = \{\boldsymbol{x}^{(n)}\}_{n=1}^{N_t}$,

$$u_{\mathrm{NEHVI}}(\boldsymbol{x}, \hat{f}, \mathcal{D}) = \mathrm{HVI}(\hat{\mathcal{P}}_t', \hat{\mathcal{P}}_t|\boldsymbol{r}_{\mathrm{ref}}), \tag{4}$$

where $\hat{\mathcal{P}}_t = \{\hat{f}(\boldsymbol{x}) : \boldsymbol{x} \in \mathcal{X}_t, \nexists \boldsymbol{x}' \in \mathcal{X}_t \text{ s.t. } \hat{f}(\boldsymbol{x}') \succ \hat{f}(\boldsymbol{x})\}$ [15].

Batched (parallel) optimization Sequential optimization, or querying f for one design per iteration, is impractical for many applications due to the latency in feedback. In protein engineering, for example, it may be necessary to select a batch of designs in a given iteration and wait several months to receive measurements [16, 17]. Jointly selecting a batch of q designs from a large pool of $q' \gg q$ candidates requires combinatorial evaluations of the acquisition function. In the context of optimizing designs using gradient information from the acquisition function, [18] demonstrated that sequential greedy selection of q designs in a given iteration achieves comparable performance to joint selection of q candidates for a variety of acquisition functions [e.g. 19, 20].

3 Related Work

Existing work on multi-objective BO does not account for objectives with a hierarchical structure [21–24, 15]. We refer to [25] for a formulation of single-objective BO with a hierarchy in how the objective is computed. A body of work focuses on constrained optimization, which optimizes a black-box function subject to a set of black-box constraints being satisfied [19, 26–29]. For dealing with mixed-variable objectives, [30] propose reparameterizing the discrete random variables in terms of continuous parameters. Our approach here is to model them explicitly using the zero-inflated formalism.

4 Method

Overview Figure 1 illustrates our proposed PropertyDAG-BO framework alongside the standard BO. The candidate generation step is identical in both cases; the generative model first samples a large pool of design candidates. The difference lies in the next step, in which the designs are scored by probabilistic surrogate models. In PropertyDAG-BO, we must first specify a partial ordering of our objectives (Section 4.1). We then explicitly assign a zero-inflated generative model for each objective (Section 4.2) such that a probabilistic classifier models its "zero" mode and a probabilistic regressor models the remaining continuous-valued "non-zero" mode. The raw posterior samples from the surrogates then undergo a "resampling" step (Section 4.3) that enforces the specified PropertyDAG. Finally, the modified posterior samples enter the multi-objective acquisition function, which scores the design candidates just as in standard BO.

Figure 1: Comparison of a traditional multi-objective BO pipeline (dashed black arrows) with the proposed pipeline enabled by PropertyDAG (solid magenta arrows).

4.1 Defining a PropertyDAG

Many drug design applications motivate us to prescribe some hierarchy among our objective properties of interest. The partial ordering may arise from an experimental dependency, e.g. a design candidate must pass a certain threshold in one property for its other properties to be measured. In the context of antibody design, a design candidate is a sequence of amino acids representing an antibody that must first be expressed in cell culture. If the level of expression does not exceed some threshold in mass per volume, the lab cannot produce it in viable amounts and it cannot be assayed for other properties, such as binding affinity to a target antigen. Our PropertyDAG may then take the form: expression $\rightarrow$ affinity. Note that experimental dependencies like this creates an asymmetry among the objectives; it reduces the information content of designs that do not express much more than that of designs that do not bind, because non-expressing designs cannot provide binding measurements.

Alternatively, the partial ordering may encode our preference for the types of designs we want to obtain. We may like to prioritize a property, for instance, so that we reject designs that performs poorly in this property, no matter how well they perform in all the others. If a designed antibody does not bind to the target antigen, it has failed in its primary function, so we have little interest in its developability properties, such as specificity to the target antigen and thermostability, even though, unlike for non-expressers, they remain measurable. We then impose the following PropertyDAG: expression $\rightarrow$ affinity $\rightarrow$ specificity, thermostability.

A PropertyDAG can be expressed as ordered sets of properties: $\{y_{0,0}, \ldots, y_{0,M_0}\} \rightarrow \{y_{1,0}, \ldots, y_{1,M_1}\} \rightarrow \cdots \rightarrow \{y_{L,0}, \ldots, y_{L,M_L}\}$, where $y_{l,m}$ is the property at level $l \in \{0, \ldots, L-1\}$ of the hierarchy and $m \in \{0, \ldots, M_l - 1\}$ is its index among the M_l sibling properties at the same level l. Figure 2 shows an example of a PropertyDAG with three properties and two levels.

4.2 Zero-inflated modeling

Biological properties tend to carry excess zeros, or null values. Their zero-inflated nature motivates us to employ statistical models that account for large incidences of zeros [31]. The zero-inflated negative binomial (ZINB) distribution has been applied to model discrete counts in single-cell RNA-seq data [32]. For each objective y_k, our zero-inflated model assigns a binary random variable $b_k \in \{0, 1\}$ to generate the zeros and $r_k \in \mathbb{R}$ to generate the remaining wide dispersion of non-zero values.

Figure 2: Example of a PropertyDAG, with three properties and two levels of hierarchy. Each property is denoted $y_{l,m}$, where l indexes the level and m indexes sibling properties at the same level. Magenta arrows refer to the dependencies imposed by PropertyDAG. Black arrows make it explicit that each $y_{l,m}$ is modeled as zero-inflated, where $b_{l,m}$ governs the zero events and $r_{l,m}$ governs the continuous non-zero events.

Assume f is non-negative (equivalently, that it is bounded from below). Given a training dataset $\mathcal{D}_t$ available at time t, we decompose $p(\hat{f}_k \mid \mathcal{D}_t)$ as follows:

$$p(\hat{f}_k(\boldsymbol{x}) = c \mid \mathcal{D}_t) = \begin{cases} p(b_k = 0 \mid \boldsymbol{x}, \mathcal{D}_t) & \text{if } c = 0, \\ p(b_k = 1 \mid \boldsymbol{x}, \mathcal{D}_t) \, p(r_k = c \mid \boldsymbol{x}, \mathcal{D}_t, \theta_r) & \text{else,} \end{cases} \tag{5}$$

where $p(r_k \mid \boldsymbol{x}, \mathcal{D}_t, \theta_r)$ is a regressor parameterized by θ_r trained to predict f_k given $b_k = 1$. Note that for simplicity we have assumed $p(r_k = 0 \mid \boldsymbol{x}, \mathcal{D}_t, \theta_r) = 0$. Since Gaussian processes (GPs) are often used as surrogates for BO [see, e.g. 33, for a review on GPs] and common GP assumptions fail for sparse, multi-modal data, separating out the non-zero mode of the data can improve posterior inference.

To accomodate objective hierarchy each $p(b_k \mid \boldsymbol{x}, \mathcal{D}_t)$ decomposes further as

$$p(b_k \mid \boldsymbol{x}, \mathcal{D}_t) = \begin{cases} 0 & \text{if } \exists j \in \text{par}(k) \text{ s.t. } b_j = 0, \\ p(b_k \mid \boldsymbol{x}, \mathcal{D}_t, \theta_b) & \text{else,} \end{cases} \tag{6}$$

where $p(b_k \mid \boldsymbol{x}, \mathcal{D}_t, \theta_b)$ is a classifier parameterized by θ_b trained to predict $\mathbb{1}\{f_k(\boldsymbol{x}) > 0\}$ and $\text{par}(k)$ are the parent nodes in the PropertyDAG corresponding to property k.

This general framework, presented in terms of a zero-inflated, continuous-valued objective (a mixture of a delta function at zero and a continuous distribution), applies for binary-valued objectives and

(a) Default   (b) PropertyDAG resampling

Figure 3: Effect of resampling the surrogate posteriors on the acquisition function. Suppose the magenta dashed lines represent our threshold for Objective 0 such that we want to acquire candidates that maximize Objective 1 *and* exceed this threshold in Objective 0. *Bottom:* The black dots constitute our baseline Pareto front. Colors of the grid indicate HVI (Equation 3) computed from each posterior sample at the given location in the objective space, in (a) the default and (b) the PropertyDAG settings. Consider six samples (white triangles) from the posterior (white contour). PropertyDAG reassigns the posterior samples below the threshold in Objective 0 such that their HVI contribution is zero. *Top:* The HVI corresponding to each sample before (a) and after (b) the resampling.

continuous-valued objectives without zero inflation, which can be viewed as specific cases taking $p(r_k|\boldsymbol{x}, \mathcal{D}_t, \theta_r) = p(r_k) = \mathcal{N}(0, \sigma^2)$ with very small σ and $p(b_k = 1 \mid \boldsymbol{x}, \mathcal{D}_t, \theta_b) = 1$, respectively.

4.3 Resampling

Using a simple resampling trick, we modify the posterior samples from the surrogate models to enforce the parent-child relationships specified in PropertyDAG. Consider a property y_k and refer to its parents as $\mathrm{par}(k)$. Suppose we have drawn single a posterior sample and obtained $\beta_{k'} \sim p(b_{k'}|\boldsymbol{x}) \in \{0, 1\}$ and $\rho_{k'} \sim p(r_{k'}|\boldsymbol{x}) \in \mathbb{R}$ for each $k' \in \{1, \ldots, K\}$. Without any modification, Equation 5 would yield the following sample γ_k of y_k: $\gamma_k = 0$ if $(b_k = 0)$, $\gamma_k = 1$ otherwise.

Instead, we begin at the top level and proceed down the levels of PropertyDAG to impose dependencies between b_k and its parent properties $\{b_{k'}\}_{k' \in \mathrm{par}(k)}$. If y_k is a top-level property, then $\mathrm{par}(k) = \emptyset$ and $\hat{\beta}_k = \beta_k$. Otherwise, y_k has parent properties and we have

$$\hat{\beta}_k = \begin{cases} 0 & \text{if } \exists j \in \mathrm{par}(k) \text{ s.t. } b_j = 0 \\ \beta_k & \text{else.} \end{cases} \tag{7}$$

We can then use the modified binary samples $\{\hat{\beta}_k\}_{k=1}^K$ to obtain our effective sample $\hat{\gamma}_k$ of y_k:

$$\hat{\gamma}_k = \begin{cases} 0 & \text{if } \beta_k = 0 \text{ or } \exists j \in \mathrm{par}(k) \text{ s.t. } b_j = 0 \\ \rho_k & \text{else.} \end{cases} \tag{8}$$

Define $\boldsymbol{\gamma} := [\gamma_1, \ldots, \gamma_K] \in \mathbb{R}^K$ and $\hat{\boldsymbol{\gamma}} := [\hat{\gamma}_1, \ldots, \hat{\gamma}_K] \in \mathbb{R}^K$. Denote the transformation at the sample level described in Equations 7 and 8 as $h : \mathbb{R}^K \to \mathbb{R}^K$ such that $h(\boldsymbol{\gamma}) = \hat{\boldsymbol{\gamma}}$.

We repeat this resampling procedure to other posterior samples. The transformed samples are then used to evaluate NEHVI (Equation 4) via MC integration. More precisely, suppose we generate $N_{\mathrm{MC}} = R \times S$ number of MC posterior samples for a design candidate $\boldsymbol{x}$ by first drawing function $\tilde{f}_r \sim p(f|\mathcal{D}_t)$ for $r = 1, \ldots, R$ (accounting for the epistemic uncertainty) and subsequently drawing $\boldsymbol{\gamma}_{r,s} \sim p(\cdot|\tilde{f}_r(\boldsymbol{x}))$ for $s = 1, \ldots, S$ using each $\tilde{f}_r$ (accounting for the aleatoric uncertainty). Then the MC approximation of NEHVI can be efficiently evaluated as:

$$\hat{\boldsymbol{\gamma}}_{r,s} = h(\boldsymbol{\gamma}_{r,s}) \quad \forall r = 1, \ldots, R, : \forall s = 1, \ldots, S \tag{9}$$

$$\alpha_{\mathrm{NEHVI}}(\boldsymbol{x}|\mathcal{P}_t) \approx \frac{1}{N_{\mathrm{MC}}} \sum_{r=1}^R \sum_{s=1}^S \mathrm{HVI}\left(\mathcal{P}_t^{(r,s)}, \mathcal{P}_t^{(r)}|\boldsymbol{r}_{\mathrm{ref}}\right), \tag{10}$$

where $\mathcal{P}_t^{(r)} = \{\tilde{f}_r(\boldsymbol{x}) : \boldsymbol{x} \in \mathcal{X}_t, \nexists \boldsymbol{x} \in \mathcal{X}_t \text{ s.t. } \tilde{f}_r(\boldsymbol{x}') \succ \tilde{f}_r(\boldsymbol{x})\}$, $\mathcal{P}_t^{(r,s)} = \mathcal{P}_t^{(r)} \cup \{\hat{\boldsymbol{\gamma}}_{r,s}\}$, and $\mathcal{X}_t = \{\boldsymbol{x}^{(n)}\}_{n=1}^{N_t}$ are the previously observed designs up to iteration t. Figures 3a and 3b illustrate the effect of the PropertyDAG resampling on each posterior sample's HVI contribution to EHVI.

5 Experiments

We perform simulated active learning experiments on two synthetic tasks and a real-world antibody design task. We use NEHVI (Equation 4) as our acquisition function and evaluate it via MC integration (Equation 9). In each experiment, we test three types of acquisitions: (1) batched, multi-objective BO with PropertyDAG ("qNEHVI-DAG"), (2) without PropertyDAG ("qNEHVI"), and (3) random. Our main metric is the number of acquired "joint positive" designs, designs that exceed the chosen thresholds in all objectives according to the specified PropertyDAG. We refer to the batch size as q.

5.1 Penicillin production dataset

This task is based on the penicillin production simulator introduced in [34]. We defined the goal as minimizing the CO_2 byproduct emission while ensuring that the fermentation time is below a set threshold and the yield exceeds a set threshold ($K = 3$, $\mathcal{X} = \mathbb{R}^7$). We negated the latter two objectives to define a maximization problem and assume the PropertyDAG: $\{y_{0,0}\} \to \{y_{1,0}\} \to \{y_{2,0}\}$, where $y_{0,0} = $ Yield ("Objective 0"), $y_{1,0} = $ Negative fermentation time ("Objective 1"), and $y_{2,0} = $ Negative CO_2 byproduct ("Objective 2"). Zero-mean Gaussian noise was added to the input, following [24].

We fit an exact GP to model r_k and an approximate GP with the variational evidence lower bound (ELBO) to model b_k, separately for each Objective k. We drew 512 posterior samples to evaluate qNEHVI. We executed 10 rounds of simulated active learning by initializing the surrogates with 8 training points and selecting $q = 4$ out of 80 randomly-sampled pool of candidate points in iteration. The three acquisition modes (qNEHVI-DAG, qNEHVI, and Random) were subject to the same initial training points and candidate pool each round. The entire experiment was repeated 5 times. Figure 4a shows that qNEHVI-DAG identifies significantly more joint positives than do qNEHVI and Random over active learning iterations. Figure 5 compares the qNEHVI and qNEHVI-DAG selections for every pair of objectives, for the final (after Iteration 10) selections stacked across the 5 repeated trials. For every objective, qNEHVI-DAG identifies more examples to the right of the threshold (black dashed lines) than do qNEHVI and Random.

(a) Penicillin production

(b) Branin-Currin toy problem

Figure 4: Number of joint positives over simulated active learning iterations. Error bands are standard deviations over (a) five and (b) ten trials.

Figure 5: Pairwise Pareto front visualization for the penicillin production task showing the ground-truth objectives of final selections. We pool the selections over five trials. Black dashed lines are the thresholds we impose.

5.2 Branin-Currin toy problem

This task is based on an analytic Branin-Currin test function from [24] with $\mathcal{X} = \mathbb{R}^2$ and $K = 2$. We reformulated this task to simulate the antibody design task (Section 5.3) in a controlled environment. We defined the PropertyDAG, $\{y_{0,0}\} \rightarrow \{y_{1,0}\}$, where $y_{0,0}$ = Dimension 0 ("Objective 0") and $y_{1,0}$ = Dimension 1 ("Objective 1"). Objective 0 was transformed into binary values using a set threshold. Objective 1 was zero-inflated and real-valued. Posterior inference was performed following the same procedure described in Section 5.1.

We executed 20 rounds of simulated active learning by initializing the surrogates with 6 training points and selecting $q = 4$ out of 40 randomly-sampled pool of candidate points in iteration. The entire experiment was repeated 10 times. Figure 4b shows that qNEHVI-DAG identifies significantly

more joint positives than do qNEHVI and Random over active learning iterations. Figure 6 compares the qNEHVI-DAG, qNEHVI, and Random selections for Objective 1, for the final selections stacked across the 10 repeated trials. Overall, qNEHVI-DAG identifies more examples to the right of the threshold (black dashed lines) than do qNEHVI and Random, and the improvement is more pronounced for the identification of joint positives (middle panel).

Figure 6: Distribution of final selected candidates in the Branin-Currin problem. We stack the selections over 10 repeated trials. *Top*: all selections. *Middle*: selections for which Objective 0 = 1. *Bottom*: selections for which Objective 0 = 0.

5.3 Antibody design

The antibody design task is derived from real-world dataset of antibody sequences and their measured *in vitro* properties, affinity and expression. As in the toy problem (Section 5.2), we defined the PropertyDAG, $\{y_{0,0}\} \rightarrow \{y_{1,0}\}$, where $y_{0,0}$ = Expression ("Objective 0") and $y_{1,0}$ = affinity ("Objective 1"). Objective 0 was binary-valued, i.e. expressing or not. Objective 1 was zero-inflated and real-valued.

We split the entire dataset of 4,023 variable-length protein sequences, designed as antibodies for an anonymized target A, into 5 groups of sizes 1230, 736, 746, and 600. The first group served as the initial training set for the surrogates, three groups as the "candidate pools" from which we selected 200 candidates for each iteration, and the last served as a held-out test set. We executed 3 iterations of simulated active learning and repeated the entire procedure 5 times. As shown in Figure 7a, qNEHVI-DAG once again outperforms qNEHVI and Random. The log posterior density evaluated at the affinity measurements for the joint positives (expressing binders) in the test set is also highest for qNEHVI-DAG.

(a) Joint positives identified

(b) Log posterior density for joint positives

Figure 7: (a) Number of joint positives in the two objectives over three simulated active learning iterations for the real-life antibody design problem. Error bands are standard deviations over three data splits for qNEHVI-DAG and qNEHVI acquisitions and additionally over five random trials for each data split for the random acquisition. (b) Log posterior density on binding affinity evaluated at the lab affinity measurements ($\log p$) for the test set consisting of 600 datapoints. Each $\log p$ value is averaged over five data splits.
