# La-MAML: Look-ahead Meta Learning for Continual Learning

## Abstract

The continual learning problem involves training models with limited capacity to perform well on a set of an unknown number of sequentially arriving tasks. While meta-learning shows great potential for reducing interference between old and new tasks, the current training procedures tend to be either slow or offline, and sensitive to many hyper-parameters. In this work, we propose *Look-ahead MAML (La-MAML)*, a fast optimisation-based meta-learning algorithm for *online*-continual learning, aided by a small episodic memory. By incorporating the modulation of per-parameter learning rates in our meta-learning update, our approach also allows us to draw connections to and exploit prior work on *hypergradients* and *meta-descent*. This provides a more flexible and efficient way to mitigate *catastrophic forgetting* compared to conventional *prior-based* methods. *La-MAML* achieves performance superior to other replay-based, prior-based and meta-learning based approaches for continual learning on real-world visual classification benchmarks.

## 1. Introduction

Embodied or interactive agents that accumulate knowledge and skills over time must possess the ability to continually learn. *Catastrophic forgetting* (French, 1999; Mcclelland et al., 1995), one of the biggest challenges in this setup, can occur when the *i.i.d.* sampling conditions required by stochastic gradient descent (SGD) are violated as the data belonging to different tasks to be learnt arrives sequentially. Algorithms for *continual learning* (CL) must also use their limited model capacity efficiently since the number of future tasks is unknown. Ensuring gradient-alignment across tasks is therefore essential, to make shared progress on their ob-

jectives. *Gradient Episodic Memory* (GEM) (Lopez-Paz & Ranzato, 2017) investigated the connection between weight sharing and forgetting in CL and developed an algorithm that explicitly tried to minimise *gradient interference*. This is an objective that meta-learning algorithms implicitly optimise for (refer to (Nichol et al., 2018) for derivations of the effective parameter update made in first and second order meta learning algorithms). *Meta Experience Replay* (MER) (Riemer et al., 2019) formalized the transfer-interference trade-off and showed that the gradient alignment objective of GEM coincide with the objective optimised by the first order meta-learning algorithm Reptile (Nichol et al., 2018).

Besides aligning gradients, meta-learning algorithms show promise for CL since they can directly influence model optimisation to achieve auxiliary objectives like generalisation or transfer. This avoids having to define heuristic incentives like sparsity (Le et al., 2017) or regularisation for better CL. The downside is that they are usually slow and hard to tune, effectively rendering them more suitable for *offline* continual learning (Javed & White, 2019; Riemer et al., 2019). In this work, we overcome these difficulties and develop a gradient-based meta-learning algorithm for *efficient, online* continual learning. We first propose a base algorithm for continual meta-learning referred to as Continual-MAML (C-MAML) that utilizes a replay-buffer and optimizes a meta-objective that mitigates forgetting. Subsequently, we propose a modification to C-MAML, La-MAML, which incorporates modulation of per-parameter learning rates (LRs) to pace the learning of a model across tasks and time. Finally, we show that the algorithm is scalable, robust and achieves favourable performance on several benchmarks of varying complexity.

## 2. Related work

Relevant CL approaches can be roughly categorized into *replay-based, regularisation (or prior-based)* and *meta-learning-based* approaches.

In order to circumvent the issue of catastrophic forgetting, *replay-based methods* maintain a collection of samples from previous tasks in memory. Approaches utilising an *episodic-buffer* (Castro et al., 2018; Rebuffi et al., 2017) uniformly sample old data points to mimic the *i.i.d.* setup within continual learning. *Generative-replay* (Shin et al., 2017) trains

Preliminary work. Under review by the International Conference on Machine Learning (ICML). Do not distribute.

generative models to be able to replay past samples, with scalability concerns arising from the difficulty of modeling complex non-stationary distributions. GEM (Lopez-Paz & Ranzato, 2017) and A-GEM (Chaudhry et al., 2019) take memory samples into account to determine altered *low-interference* gradients for updating parameters.

*Regularisation-based* methods avoid using replay at all by constraining the network weights according to heuristics intended to ensure that performance on previous tasks is preserved. This involves penalising changes to weights deemed important for old tasks (Kirkpatrick et al., 2017) or enforcing weight or representational sparsity (Aljundi et al., 2019) to ensure that only a subset of neurons remain active (and thus receiving gradients) at any point of time.

*Meta-Learning-based* approaches are fairly recent and have shown impressive results on small benchmarks like Omniglot and MNIST. MER (Riemer et al., 2019), inspired by GEM(Lopez-Paz & Ranzato, 2017), utilises replay to incentivise alignment of gradients between old and new tasks. Online-aware Meta Learning (OML) (Javed & White, 2019) introduces a meta-objective for a pre-training algorithm to learn an optimal representation *offline*, which is subsequently frozen and used for CL. Our motivation lies in developing a *scalable*, *online* algorithm capable of learning from limited cycles through streaming data with reduced interference on old samples. In the following sections, we review background concepts, outline our proposed algorithm, and note connections to prior work not directly pertaining to CL.

## 3. Preliminaries

We consider a setting where a sequence of $T$ tasks $[\tau_1, \tau_2, ..\tau_T]$ is learnt by observing training data from their data distributions $[D_1, D_2, ..D_T]$ sequentially. We define $X^i, Y^i = \{(X_n^i, Y_n^i)\}_{n=0}^{N_i}$ as the set of $N_i$ input-label pairs randomly drawn from $D_i$. Let $t$ be the number of tasks ($\tau_{1:t}$) that we have seen until an arbitrary timestep $j$ during training. At any time-step $j$ during the learning cycle, we aim to minimize the empirical risk on $\tau_{1:t}$, given limited access to data $(X^i, Y^i)$ from previous tasks $\tau_i$ $(i < t)$, referred to as the *cumulative risk*, given by:

$$\sum_{t=1}^{T} \sum_{i=1}^{t} E_{(X^i, Y^i)} \left[ \ell_i \left( f_i \left( X^i; \theta \right), Y^i \right) \right]$$

$$= \sum_{t=1}^{T} E_{(X^n, Y^n)} \left[ L_t \left( f \left( X^n; \theta \right), Y^n \right) \right], n = [1:t] \quad (1)$$

where $\ell_i$ is the loss on $\tau_i$ and $f_i$ is a learnt, possibly task-specific mapping from inputs to outputs using parameters $\theta$. $L_t = \sum_{i=1}^{t} \ell_i$ is the sum of all task-wise losses for tasks

$\tau_{1:t}$. $T$ is unknown beforehand and we merely use it to specify an upper bound in our summations.

### 3.1. Optimisation-based meta-learning

We now introduce the MAML (Finn et al., 2017) and OML (Javed & White, 2019) algorithms, that we build upon in Section 4. Let $\theta_0^j$ denote the model's parameters at time $j$, and $\ell$ denote a loss objective to be minimised. Then the SGD operator acting on parameters $\theta_0^j$, denoted by $U(\theta_0^j)$, is defined as:

$$U\left(\theta_0^j\right) = \theta_1^j = \theta_0^j - \alpha \nabla_{\theta_0^j} \ell(\theta_0^j) = \theta_0^j - \alpha g_0^j \quad (2)$$

where $g_0^j = \nabla_{\theta_0^j} \ell(\theta_0^j)$. $U$ can be composed for $k$ updates as $U_k\left(\theta_0^j\right) = U... \circ U \circ U(\theta_0^j) = \theta_k^j$. $\alpha$ is a scalar or a vector LR. $U(\cdot, x)$ implies gradient updates are made on data sample $x$.

**Model-Agnostic Meta-Learning (MAML)**: Meta-learning (Schmidhuber, 1987), or *learning-to-learn* (Thrun & Pratt, 1998) has emerged as a popular approach for training models amenable to fast adaptation on limited data. MAML (Finn et al., 2017) proposed optimising model parameters to learn a set of tasks *while* improving on auxiliary objectives like few-shot generalisation within their task distributions. We review some terminology used in gradient-based meta-learning work (Finn et al., 2017): 1) at time-step $j$ during training, model parameters $\theta_0^j$ (or $\theta_0$ for simplicity), are often referred to as an *initialisation*, since MAML finds an ideal *starting point* for few-shot gradient-based adaptation on unseen data. 2) *Fast updates*, refer to gradient-based updates made to a copy of $\theta_0$, optimising an *inner objective* (in this case, $\ell_i$ for some $\tau_i$). 3) A *meta-update* involves the *trajectory* of fast updates from $\theta_0$ to $\theta_k$, followed by making a permanent *slow-update* to $\theta_0$. This *slow-update* is computed by evaluating an auxiliary objective (or *meta-loss $L_{meta}$*) on $\theta_k$, and differentiating through the *trajectory* to obtain $\nabla_{\theta_0} L_{meta}(\theta_k)$. MAML thus optimises $\theta_0^j$ to perform optimally on tasks in $\{\tau_{1:t}\}$ after undergoing a few gradient updates on their samples by optimsiing the objective:

$$\min_{\theta_0^j} E_{\tau_{1:t}} \left[ L_{meta} \left( U_k(\theta_0^j) \right) \right] = \min_{\theta_0^j} E_{\tau_{1:t}} \left[ L_{meta}(\theta_k^j) \right] \quad (3)$$

**Equivalence of Meta-Learning and Gradient Alignment Objectives**: The first-order meta-learning algorithm Reptile has been shown to be approximately equivalence to the MAML objective (Nichol et al., 2018). MER (Riemer et al., 2019) then showed that their CL objective of minimising loss on tasks $\tau_{1:t}$ seen till time $j$, while aligning gradients

between them:

$$\min_{\theta_0^j} \left( \sum_{i=1}^{t} \left( \ell_i(\theta_0^j) \right) - \alpha \sum_{p,q \leq t} \left( \frac{\partial \ell_p\left(\theta_0^j\right)}{\partial \theta_0^j} \cdot \frac{\partial \ell_q\left(\theta_0^j\right)}{\partial \theta_0^j} \right) \right) \tag{4}$$

is equivalent to the Reptile objective i.e.:

$$\min_{\theta_0^j} E_{\tau_{1:t}} \left[ L_t \left( U_k(\theta_0^j) \right) \right] \tag{5}$$

where the *meta-loss* $L_t = \sum_{i=1}^{t} \ell_i$ is evaluated on samples from tasks $\tau_{1:t}$. We will show how a version of this objective coincides with our proposed multi-step MAML-based algorithm. Note that this implies that the procedure to learn an *initialisation* through meta-learning, coincides with the procedure to learn optimal parameters for CL.

**Online-aware Meta-Learning (OML)**: (Javed & White, 2019) proposed to meta-learn a *Representation-Learning Network (RLN)* to provide a representation suitable for CL to a *Task-Learning Network (TLN)*. The RLN's representation is learnt in an *offline* phase, where it is trained using *catastrophic forgetting as the learning signal*. Data from a fixed set of tasks ($\tau_{val}$), is repeatedly used to evaluate the RLN and TLN as the TLN undergoes temporally correlated updates. In every *meta-update*'s inner loop, the TLN undergoes *fast updates* on streaming task data with a frozen RLN. The RLN and updated TLN are then evaluated through a *meta-loss* computed on a batch sampled from $\tau_{val}$ along with the current task's data. This loss is then differentiated to make *slow updates* to the TLN and RLN. This composition of old and new tasks' losses is referred to as the *OML objective*. It approximately simulates CL in the inner loop of the meta update and relies on the *slow updates* to the RLN to eventually provide a better representation to the TLN for CL.

## 4. Proposed approach

In this section, we describe *Continual-MAML* (C-MAML), the base algorithm that we propose for online continual learning. We then detail an extension to C-MAML, referred to as Look-Ahead MAML (La-MAML), outlined in Algorithm 1.

### 4.1. C-MAML

C-MAML aims to optimise the OML objective *online*, so that learning on the current task doesn't lead to forgetting on previously seen tasks. We define this objective, adapted to optimise a model's parameters $\theta$ instead of a representation at time-step $j$, as:

$$\min_{\theta_0^j} \text{OML}(\theta_0^j, t) = \min_{\theta_0^j} \sum_{\mathcal{S}_k^j \sim D_t} \left[ L_t \left( U_k(\theta_0^j, \mathcal{S}_k^j) \right) \right] \tag{6}$$

where $S_k^j$ is a stream of data tuples $\left( X_{j+l}^t, Y_{j+l}^t \right)_{l=1}^{k}$ from the current task $\tau_t$ that is seen by the model at time $j$. The meta-loss $L_t = \sum_{i=1}^{t} \ell_i$ is evaluated on $\theta_k^j = U_k(\theta_0^j, S_k^j)$. It evaluates the fitness of $\theta_k^j$ for the continual learning prediction task defined in Eq. 1 until $\tau_t$. We omit the implied data argument $(x^i, y^j) \sim (X^i, Y^i)$ that is the input to each loss $\ell_i$ in $L_t$ for any task $\tau_i$. It can be shown (as we outline in Appendix B) that optimising our objective in Eq. 6 through the $k$-step MAML update in C-MAML:

$$\min_{\theta_0^j} E_{\tau_{1:t}} \left[ L_t \left( U_k(\theta_0^j) \right) \right] \tag{7}$$

coincides with optimising the CL objective of AGEM (Chaudhry et al., 2019):

$$\min_{\theta_0^j} \sum_{i=1}^{t} \left( \ell_i(\theta_0^j) - \alpha \frac{\partial \ell_i\left(\theta_0^j\right)}{\partial \theta_0^j} \cdot \frac{\partial \ell_t\left(\theta_0^j\right)}{\partial \theta_0^j} \right) \tag{8}$$

This differs from Eq. 4's objective by being *asymmetric*: it focuses on aligning the gradients of $\tau_t$ and the average gradient of $\tau_{1:t}$ instead of aligning all the pair-wise gradients between tasks $\tau_{1:t}$. Incentivizing alignment of all $\tau_{1:t}$ with the common $\tau_t$ indirectly incentivises alignment amongst $\tau_{1:t}$. This results in a drastic speedup over MER's objective (Eq. 4) which tries to align all $\tau_{1:t}$ equally, thus resampling incoming samples $s \sim \tau_t$ to form a uniformly distributed batch over $\tau_{1:t}$. Since each $s$ then has $\frac{1}{t}$-th the contribution in gradient updates, it becomes necessary for MER to take multiple passes over many such uniform batches including $s$.

*Figure 1.* The proposed **La-MAML** algorithm: For every batch of data, the initial weights undergo a series of $k$ *fast updates* to obtain $\theta_k^j$ (here $j = 0$), which is evaluated against a meta-loss to backpropagate gradients with respect to the weights $\theta_0^0$ and LRs $\alpha^0$. First $\alpha^0$ is updated to $\alpha^1$ which is then used to update $\theta_0^0$ to $\theta_0^1$ The blue boxes indicate *fast weights* while the green boxes indicate gradients for the *slow updates*. LRs and weights are updated in an asynchronous manner.

To evaluate the *meta-loss* $L_t(\theta_k^j)$ which indicates performance of $\theta_k^j$ on all tasks seen till time $j$, old tasks' data is

sampled from a replay-buffer $R$. $R$ is populated through *reservoir sampling* on the incoming data stream as in (Riemer et al., 2019). The SGD-based *inner-updates* starting from initial weights $\theta_0^j$ are carried out using data from the task being streamed at the time of meta-update step $j$. At the start of every meta-update step, a batch $b$ is sampled from the current task and is combined with a batch sampled from $R$ to form the *meta-batch*, $b_m$. $\theta_0^j$ is updated for $k$ steps by seeing samples from $b$ one at a time. The outer loss is evaluated on $b_m$.

### 4.2. La-MAML

Despite the fact that meta-learning incentivises the alignment of *within-task* and *across-task* gradients, there can still be some interference between the gradients of old and new tasks, $\tau_{1:t-1}$ and $\tau_t$ respectively. This would lead to forgetting on $\tau_{1:t-1}$, since its data is no longer fully available to us. This is especially true at the beginning of training a new task, when its gradients aren't necessarily aligned with the old ones. A mechanism is thus needed to ensure that *meta-updates* are conservative with respect to $\tau_{1:t-1}$, so as to avoid negative transfer on them. The magnitude and direction of the *meta-update* needs to be regulated, guided by how the loss on $\tau_{1:t-1}$ would be affected by the update.

In **La-MAML**, we include a set of learnable per-parameter learning rates (LRs) to be used in the *inner updates*, as depicted in Figure 1. This is motivated by our observation that the expression for the gradient of Eq. 6 with respect to the inner loop's LRs directly reflects the alignment between the old and new tasks. The augmented learning objective and its gradient with respect to the LR vector $\alpha$, denoted as $g_{MAML}(\alpha)$ is then given as:

$$\min_{\theta_0^j, \alpha^j} \sum_{\mathcal{S}_k^j \sim D_t} \left[ L_t \left( U \left( \alpha^j, \theta_0^j, \mathcal{S}_k^j \right) \right) \right] \qquad (9)$$

$$g_{MAML}(\alpha^j) = \frac{\partial}{\partial \theta_k^j} L_t \left( \theta_k^j \right) \cdot \left( -\sum_{n=0}^{k-1} \frac{\partial}{\partial \theta_n^j} \ell_t \left( \theta_n^j \right) \right) \qquad (10)$$

We provide the full derivation in the Appendix A, and state the expression for a first-order approximation (Finn et al., 2017) of $g_{MAML}(\alpha)$ here, to facilitate further discussion. Here, the first term corresponds to the gradient of the meta-loss on batch $b_m$: $g_{meta}$. The second term indicates the cumulative gradient from the inner-update trajectory: $g_{traj}$. This expression indicates that the gradient of the LRs will be negative when the inner product between $g_{meta}$ and $g_{traj}$ is high, ie. the two are aligned. Similarly, it should be zero when the two are orthogonal (not interfering) and positive when there is disagreement between the two, leading to interference. Negative (positive) LR gradients would pull up (down) the LR magnitude. We depict this visually in

Figure 2.

*Figure 2.* Different scenarios for the alignment of $g_{traj}$ (blue dashed line) and $g_{meta}$, going from interference (left) to alignment (right). Yellow arrows denote the *inner updates*. The LR $\alpha$ increases (decreases) when gradients align (interfere).

We propose updating the network weights and LRs *asynchronously* in the meta-update. Let $\alpha^{j+1}$ be the updated LR vector obtained by taking an SGD step with the LR gradient from Eq. 10 at time $j$. We then update the weights as:

$$\theta_0^{j+1} \leftarrow \theta_0^j - max(0, \alpha^{j+1}) \cdot \nabla_{\theta_0^j} L_t(\theta_k^j) \qquad (11)$$

where $k$ is the number of steps taken in the inner-loop. The LRs $\alpha^{j+1}$ are clipped to positive values to avoid *ascending*

the gradient, and also to avoid making *interfering* parameter-updates, thus mitigating catastrophic forgetting. The meta-objective thus conservatively modulates the pace and direction of learning to achieve quicker learning progress on a new task while facilitating transfer on old tasks. Algorithm 1 illustrates this procedure. Lines (a), (b) are the only difference between C-MAML and La-MAML, with C-MAML using a fixed scalar LR $\alpha$ for the meta-update to $\theta_0^j$ instead of $\alpha^{j+1}$.

Our meta-learning based algorithm incorporates concepts from both prior-based and replay-based approaches. Our LRs modulate the parameter updates in an entirely data driven manner, guided by the interplay between the gradients of the replay samples and the streaming task. However, since LRs evolve with every meta-update, their decay is temporary. This is unlike many prior-based approaches, where penalties on the change in parameters gradually become so high that the network capacity saturates (Kirkpatrick et al., 2017). Our learnable LRs can be modulated to high and low values as tasks arrive, thus being a simpler, flexible and elegant way to constrain weights. This asynchronous update resembles trust-region optimisation (Yuan, 1999) since the LRs are evolved in a manner similar to *look-ahead search*, which adjusts step-sizes based on the loss incurred on adapted parameters. Our LR update is also analogous to the heuristic uncertainty-based LR update schemes of UCB (Ebrahimi et al., 2020) or BGD (Zeno et al., 2018), which we compare to in Section 5.3.

### 4.3. Connections to Other Work

**Stochastic Meta-Descent (SMD)**: When learning over a non-stationary data distribution, using decaying LR schedules is not common. Strictly diminishing LR schedules aim for closer *convergence* to a fixed mimima of a stationary distribution, which is at odds with the goal of online and continual learning. In many CL scenarios it is impossible to manually tune the schedule since the extent of the data distribution is unknown. However, *adaptivity* in LRs is still highly desired to better adapt to the optimisation landscape and accelerate learning. Another reason to desire adaptivity in CL is to modulate the degree of adaptation to reduce catastrophic forgetting. Our adaptive LRs can be connected to work on *meta-descent* (Baydin et al., 2018; Schraudolph, 1999) in *offline* supervised learning (OSL). They propose analytically, *asynchronously* updating LRs during optimization by differentiating the update rule with respect to the LRs. We rely on the meta-objective to obtain these LR *hypergradients* automatically.

**Learning LRs in meta-learning**: Meta-SGD (Li et al., 2017) proposed learning the LRs in MAML for few-shot learning. Some notable differences between their update and ours exist. They *synchronously* update the weights and LRs

while our *asynchronous* update to the LRs serves to carry out a more conservative update to the weights. The intuition for our update stems from the need to mitigate gradient interference and its connection to the transfer-interference trade-off ubiquitous in continual learning. $\alpha$-MAML (Singh Behl et al., 2019) analytically updates the two *scalar* LRs in the MAML update for more adaptive few-shot learning. Our *per-parameter* LRs are modulated implicitly through back-propagation, to regulate change in parameters based on their alignment across tasks, providing our model with a more powerful degree of adaptability in the CL domain.

## 5. Experiments

In this section we evaluate La-MAML in task incremental settings, where the model learns a set of sequentially streaming classification tasks. Experiments are performed on the MNIST, CIFAR and TinyImagenet (tin) datasets. Similar to (Riemer et al., 2019), we use the retained accuracy (RA) metric to compare various approaches. RA is the average accuracy of the model across tasks at the end of training. We also report the *backward-transfer and interference* (BTI) values which measure the average change in the accuracy of each task from when it was learnt to the end of the last task. A smaller BTI implies lesser forgetting during training.

*Efficient Lifelong Learning (LLL)*: Formalized in (Chaudhry et al., 2019), the setup of efficient lifelong learning assumes that incoming data for every task has to be processed in only one single pass: once processed, data samples are not accessible anymore unless they were added to a replay memory. We evaluate our algorithm on this challenging *(Single-Pass)* setup as well as the standard *(Multiple-Pass)* setup where offline training-until-convergence is performed for every task, once we have access to its data.

*Table 2.* Running times for MER and La-MAML on MNIST benchmarks for one epoch

| METHOD | ROTATIONS | PERMUTATIONS |
|---|---|---|
| LA-MAML | $45.95 \pm 0.38$ | $46.13 \pm 0.42$ |
| MER | $218.03 \pm 6.44$ | $227.11 \pm 12.12$ |

### 5.1. Continual learning benchmarks

First, we carry out experiments on the toy continual learning benchmarks proposed in prior CL works. **MNIST Rotations**, introduced in (Lopez-Paz & Ranzato, 2017), comprises tasks to classify MNIST digits rotated by a different common angle in [0, 180] degrees in each task. In **MNIST Permutations**, tasks are generated by shuffling the image pixels by a fixed random permutation. Unlike Rotations, the input distribution of each task is unrelated here, leading to less positive transfer between tasks. **Many Permuta-**

*Table 1.* RA, BTI and their standard deviation on MNIST benchmarks. Each experiment is run with 5 seeds.

| METHOD | ROTATIONS | | PERMUTATIONS | | MANY | |
|---|---|---|---|---|---|---|
| | RA | BTI | RA | BTI | RA | BTI |
| ONLINE | $53.38 \pm 1.53$ | $-5.44 \pm 1.70$ | $55.42 \pm 0.65$ | $-13.76 \pm 1.19$ | $32.62 \pm 0.43$ | $-19.06 \pm 0.86$ |
| EWC | $57.96 \pm 1.33$ | $-20.42 \pm 1.60$ | $62.32 \pm 1.34$ | $-13.32 \pm 2.24$ | $33.46 \pm 0.46$ | $-17.84 \pm 1.15$ |
| GEM | $67.38 \pm 1.75$ | $-18.02 \pm 1.99$ | $55.42 \pm 1.10$ | $-24.42 \pm 1.10$ | $32.14 \pm 0.50$ | $-23.52 \pm 0.87$ |
| MER | $\mathbf{77.42} \pm \mathbf{0.78}$ | $\mathbf{-5.60} \pm \mathbf{0.70}$ | $73.46 \pm 0.45$ | $-9.96 \pm 0.45$ | $47.40 \pm 0.35$ | $-17.78 \pm 0.39$ |
| C-MAML | $77.33 \pm 0.29$ | $-7.88 \pm 0.05$ | $\mathbf{74.54} \pm \mathbf{0.54}$ | $-10.36 \pm 0.14$ | $47.29 \pm 1.21$ | $-20.86 \pm 0.95$ |
| SYNC | $70.07 \pm 2.07$ | $-15.42 \pm 4.19$ | $60.12 \pm 1.84$ | $-19.56 \pm 2.43$ | $42.73 \pm 1.20$ | $-23.96 \pm 1.95$ |
| La-MAML | $\mathbf{77.42} \pm \mathbf{0.65}$ | $-8.64 \pm 0.403$ | $74.34 \pm 0.67$ | $\mathbf{-7.60} \pm \mathbf{0.51}$ | $\mathbf{48.46} \pm \mathbf{0.45}$ | $\mathbf{-12.96} \pm \mathbf{0.073}$ |

**tions**, a more complex version of Permutations, has five times more tasks (100 tasks) and five times less training data (200 images per task). We use the same architecture and experimental settings as in MER (Riemer et al., 2019), allowing us to compare directly with their results. We use the cross-entropy loss as the *inner* and *outer* objectives during meta-training. Similar to (Nichol et al., 2018), we see improved performance when evaluating and summing the *meta-loss* at all steps of the inner updates as opposed to just the last one.

We compare our method in the LLL setup against multiple baselines including *Online*, *Independent*, *EWC* (Kirkpatrick et al., 2017), *GEM* (Lopez-Paz & Ranzato, 2017) and *MER* (Riemer et al., 2019), detailed in Appendix E. In Table 1, we see that La-MAML achieves comparable or better performance than the baselines on all benchmarks. Table 2 shows that La-MAML matches the performance of MER in less than 20% of the training time, owing to its sample-efficient objective which allows it to make make more learning progress per iteration. This also allows us to scale it to real-world visual recognition problems as described next.

### 5.2. Real-world classification

While La-MAML fares well on the MNIST benchmarks, we are interested in understanding its capabilities on more complex visual classification benchmarks. We conduct experiments on the **CIFAR-100** dataset in a task-incremental manner (Lopez-Paz & Ranzato, 2017). 20 tasks comprising of disjoint 5-way classification problems are streamed. We also evaluate on the **TinyImagenet-200** dataset by partitioning its 200 classes into 40 5-way tasks. Experiments are carried out in both the *LLL* and *Multiple-Pass* settings, where in the latter we allow training for up to a maximum of 10 epochs. Each method has a replay-buffer containing 200 and 400 samples for CIFAR-100 and TinyImagenet respectively. We provide further details about the baselines and evaluation setup in Appendix D.

Table 4 reports the results of these experiments. We consistently observe superior performance of La-MAML as compared to other CL baselines on both datasets across setups.

While the iCarl baseline attains lower BTI in some setups, it achieves that at the cost of lower accuracy during learning. Among the high-performing approaches, La-MAML has the lowest BTI. Recent work (Chaudhry et al., 2019; Riemer et al., 2019) noted that Experience Replay (ER) is often a very strong baseline that closely matches the performance of the proposed algorithms. We highlight the fact that meta-learning and LR modulation combined show an improvement of more than 10 and 18% (as the number of tasks increase from CIFAR to Imagenet) over the ER baseline in our case, with limited replay. Overall, we see that our method is better-performing under both the standard and LLL setups of CL which come with different kinds of challenges. Many CL methods (Ebrahimi et al., 2020; Serra et al., 2018) are suitable for only one of the two setups. As shown in Figure 3, our model evolves to become resistant to *forgetting* as training progresses. This means that beyond a point, it can keep taking gradient updates on a small window of incoming samples without needing to do *meta-updates*.

*Table 3.* Gradient Alignment on CIFAR-100 and IMAGENET dataset (values lie in [-1,1], higher is better)

| METHOD | CIFAR-100 | IMAGENET |
|---|---|---|
| ER | $0.22 \times 10^{-2} \pm 0.0017$ | $0.27 \times 10^{-2} \pm 0.0005$ |
| C-MAML | $1.84 \times 10^{-2} \pm 0.0003$ | $1.74 \times 10^{-2} \pm 0.0005$ |
| SYNC | $2.28 \times 10^{-2} \pm 0.0004$ | $2.17 \times 10^{-2} \pm 0.0020$ |
| LA-MAML | $1.86 \times 10^{-2} \pm 0.0027$ | $2.14 \times 10^{-2} \pm 0.0023$ |

### 5.3. Evaluation of La-MAML's learning rate modulation

To capture the gains from learning the LRs, we compare La-MAML with our base algorithm, **C-MAML**. We ablate our choice of updating LRs asynchronously by constructing a version of C-MAML where per-parameter learnable LRs are used in the inner updates while the meta-update still uses a constant scalar LR during training. We refer to it as *Sync-La-MAML* or **Sync** since it has synchronously updated LRs that don't modulate the meta-update. While only minor gains are seen on the MNIST benchmarks from asynchronous LR

*Table 4.* Results on the standard continual (Multiple) and LLL (Single) setups with CIFAR-100 and TinyImagenet-200. Experiments are run with 3 seeds. * indicates result omitted due to high instability.

| METHOD | CIFAR-100 | | | | TINYIMAGENET | | | |
|---|---|---|---|---|---|---|---|---|
| | MULTIPLE | | SINGLE | | MULTIPLE | | SINGLE | |
| | RA | BTI | RA | BTI | RA | BTI | RA | BTI |
| IID | $85.60 \pm 0.40$ | - | - | - | $77.1 \pm 1.06$ | - | - | - |

| ICARL | $60.47 \pm 1.09$ | $-15.10 \pm 1.04$ | $53.55 \pm 1.69$ | $\mathbf{-8.03} \pm \mathbf{1.16}$ | $54.77 \pm 0.32$ | $\mathbf{-3.93} \pm \mathbf{0.55}$ | $45.79 \pm 1.49$ | $\mathbf{-2.73} \pm \mathbf{0.45}$ |
| GEM | $62.80 \pm 0.55$ | $-17.00 \pm 0.26$ | $48.27 \pm 1.10$ | $-13.7 \pm 0.70$ | $50.57 \pm 0.61$ | $-20.50 \pm 0.10$ | $40.56 \pm 0.79$ | $-13.53 \pm 0.65$ |
| AGEM | $58.37 \pm 0.13$ | $-17.03 \pm 0.72$ | $46.93 \pm 0.31$ | $-13.4 \pm 1.44$ | $46.38 \pm 1.34$ | $-19.96 \pm 0.61$ | $38.96 \pm 0.47$ | $-13.66 \pm 1.73$ |
| MER | - | - | $51.38 \pm 1.05$ | $-12.83 \pm 1.44$ | - | - | $44.87 \pm 1.43$ | $-12.53 \pm 0.58$ |
| META-BGD | $65.09 \pm 0.77$ | $-14.83 \pm 0.40$ | $57.44 \pm 0.95$ | $-10.6 \pm 0.45$ | * | * | $50.64 \pm 1.98$ | $-6.60 \pm 1.73$ |
| C-MAML | $65.44 \pm 0.99$ | $-13.96 \pm 0.86$ | $55.57 \pm 0.94$ | $-9.49 \pm 0.45$ | $61.93 \pm 1.55$ | $-11.53 \pm 1.11$ | $48.77 \pm 1.26$ | $-7.6 \pm 0.52$ |
| SYNC | $67.06 \pm 0.62$ | $-13.66 \pm 0.50$ | $58.99 \pm 1.40$ | $-8.76 \pm 0.95$ | $65.40 \pm 1.40$ | $-11.93 \pm 0.55$ | $\mathbf{52.84} \pm \mathbf{2.55}$ | $-7.3 \pm 1.93$ |
| LA-MAML | $\mathbf{70.08} \pm \mathbf{0.66}$ | $\mathbf{-9.36} \pm \mathbf{0.47}$ | $\mathbf{61.18} \pm \mathbf{1.44}$ | $-9.00 \pm 0.2$ | $\mathbf{66.99} \pm \mathbf{1.65}$ | $\mathbf{-9.13} \pm \mathbf{0.90}$ | $52.59 \pm 1.35$ | $\mathbf{-3.7} \pm \mathbf{1.22}$ |

modulation, the performance gap increases as the tasks get harder. On CIFAR-100 and TinyImagenet, we see a trend in the RA of our variants with La-MAML performing best followed by *Sync*. This shows that optimising the LRs aids learning and our *asynchronous* update helps in knowledge consolidation by enforcing conservative updates to mitigate interference.

To test our LR modulation against an alternative *bayesian* modulation scheme proposed in BGD (Zeno et al., 2018), we define a baseline called Meta-BGD where per-parameter variances are modulated instead of LRs. This is described in further detail in Appendix E. Meta-BGD emerges as a strong baseline and matches the performance of C-MAML given enough Monte Carlo iterations $m$, implying $m$ times more computation than C-MAML. Additionally, Meta-BGD was found to be sensitive to hyperparameters and required extensive tuning. We present a discussion of the robustness

of our approach in Appendix C.

We also compare the gradient alignment of our three variants along with ER in Table 3 by calculating the cosine similarity between the gradients of the replay samples and newly arriving data samples. As previously stated, the aim of many CL algorithms is to achieve high gradient alignment across tasks to allow parameter-sharing between them. We see that our variants achieve an order of magnitude higher cosine similarity compared to ER, verifying that our objective promotes gradient alignment.

## 6. Conclusion

We introduced La-MAML, an efficient meta-learning algorithm that leverages replay to avoid forgetting and favor positive backward transfer by learning the weights and LRs in an asynchronous manner. It is capable of learning on-

*Figure 3.* Retained Accuracy (RA) for La-MAML plotted every 25 meta-updates up to Task 5 on CIFAR-100. RA at iteration $j$ (x-axis) denotes accuracy on all tasks seen uptil then. Red denotes the RA computed during the *inner updates* (at $\theta_k^j$). Blue denotes RA computed at $\theta_0^{j+1}$ right after a *meta-update*. We see that in the beginning, inner updates lead to catastrophic forgetting (CF) since the weights are not suitable for CL yet, but eventually become resistant when trained to retain old knowledge while learning on a stream of correlated data. We also see that RA maintains its value even as more tasks are added indicating that the model is successful at learning new tasks without sacrificing performance on old ones.

line on a non-stationary stream of data and scales to vision tasks. We presented results that showed better performance against the state-of-the-art in the setup of efficient lifelong learning (LLL) (Chaudhry et al., 2019), as well as the standard continual learning setting. In the future, more work on analysing and producing good optimizers for CL is needed, since many of our standard go-to optimizers like Adam (Kingma & Ba, 2014) are primarily aimed at ensuring faster convergence in *stationary* supervised learning setups. Another interesting direction is to explore how the connections to *meta-descent* can lead to more stable training procedures for meta-learning.

## A. Hypergradient Derivation for La-MAML

We derive the gradient of the weights $\theta_0^j$ and LRs $\alpha^j$ at time-step $j$ under the $k$-step MAML objective, with $L_t = \sum_{i=0}^{t} \ell_i$ as the *meta-loss* and $\ell_t$ as the *inner-objective*:

$$
g_{\text{MAML}}(\alpha^j) = \frac{\partial}{\partial \alpha^j} L_t\left(\theta_k^j\right) = \frac{\partial}{\partial \theta_k^j} L_t\left(\theta_k^j\right) \cdot \frac{\partial}{\partial \alpha^j}\left(\theta_k^j\right)
$$

$$
= \frac{\partial}{\partial \theta_k^j} L_t\left(\theta_k^j\right) \cdot \frac{\partial}{\partial \alpha^j}\left(U\left(\theta_{k-1}^j\right)\right)
$$

$$
= \frac{\partial}{\partial \theta_k^j} L_t\left(\theta_k^j\right) \cdot \frac{\partial}{\partial \alpha^j}\left(\theta_{k-1}^j - \alpha^j \frac{\partial \ell_t(\theta_{k-1}^j)}{\partial \theta_{k-1}^j}\right)
$$

$$
= \frac{\partial}{\partial \theta_k^j} L_t\left(\theta_k^j\right) \cdot \left(\frac{\partial}{\partial \alpha^j}\theta_{k-1}^j - \frac{\partial}{\partial \alpha^j}\left(\alpha^j \frac{\partial \ell_t(\theta_{k-1}^j)}{\partial \theta_{k-1}^j}\right)\right)
$$

$$
= \frac{\partial}{\partial \theta_k^j} L_t\left(\theta_k^j\right) \cdot \left(\frac{\partial}{\partial \alpha^j}\theta_{k-1}^j - \frac{\partial \ell_t(\theta_{k-1}^j)}{\partial \theta_{k-1}^j}\right)
$$

$$
\left(\text{Taking } \frac{\partial \ell_t\left(\theta_{k-1}^j\right)}{\partial \theta_{k-1}^j} \text{ as a constant w.r.t } \alpha^j \text{ to get the FO-MAML approximation}\right)
$$

$$
= \frac{\partial}{\partial \theta_k^j} L_t\left(\theta_k^j\right) \cdot \left(\frac{\partial}{\partial \alpha}U\left(\theta_{k-2}^j\right) - \left(\frac{\partial \ell_t(\theta_{k-1}^j)}{\partial \theta_{k-1}^j}\right)\right)
$$

$$
= \frac{\partial}{\partial \theta_k^j} L_t\left(\theta_k^j\right) \cdot \left(\frac{\partial}{\partial \alpha}\theta_0^j - \sum_{n=0}^{k-1} \frac{\partial \ell_t(\theta_n^j)}{\partial \theta_n^j}\right) \quad (a)
$$

$$
= \frac{\partial}{\partial \theta_k^j} L_t\left(\theta_k^j\right) \cdot \left(-\sum_{n=0}^{k-1} \frac{\partial \ell_t(\theta_n^j)}{\partial \theta_n^j}\right) \quad (b)
$$

Where (a) is obtained by recursively expanding and differentiating the update function $U()$ as done in the step before it. (b) is obtained by assuming that the initial weight in the meta-update at time j : $\theta_0^j$, is constant with respect to $\alpha^j$.

Similarly we can derive the MAML gradient for the weights $\theta_0^j$, denoted as $g_{\text{MAML}}(\theta_0^j)$ as:

$$
g_{\text{MAML}}(\theta_0^j) = \frac{\partial}{\partial \theta_0^j} L_t(\theta_k^j) = \frac{\partial}{\partial \theta_k^j} L_t(\theta_k^j)\frac{\partial \theta_k^j}{\partial \theta_0^j} = \frac{\partial}{\partial \theta_k^j} L_t(\theta_k^j)\frac{\partial U_k(\theta_{k-1}^j)}{\partial \theta_0^j}
$$

$$
= \frac{\partial}{\partial \theta_k^j} L_t(\theta_k^j)\frac{\partial}{\partial \theta_{k-1}^j}U(\theta_{k-1}^j)\cdots\frac{\partial}{\partial \theta_0^j}U(\theta_1^j)
$$

$$
\left(\text{repeatedly applying chain rule and using } \theta_k^j = U(\theta_{k-1}^j)\right)
$$

$$
= L_t'(\theta_k^j)\left(I - \alpha\ell_t''(\theta_{k-1}^j)\right)\cdots\left(I - \alpha\ell_t''(\theta_0^j)\right)
$$

$$
\left(\text{using } U'(\theta_n^j) = I - \alpha\ell_t''(\theta_n^j)\right) \quad (\prime \text{ implies derivative with respect to argument})
$$

$$
= \left(\prod_{n=0}^{k-1}\left(I - \alpha\ell_t''(\theta_n^j)\right)\right)L_t'(\theta_k^j)
$$

Setting all first-order gradient terms as constants to ignore second-order derivatives, we get the first order approximation as:

$$
g_{\text{FOMAML}}(\theta_0^j) = \left(\prod_{n=0}^{k-1}\left(I - \alpha\ell_t''\left(\theta_n^j\right)\right)\right)L_t'(\theta_k^j) = L_t'(\theta_k^j)
$$

In Appendix B, we show the equivalence of the C-MAML and CL objectives in Eq. 7 by showing that the gradient of the former ($g_{\text{MAML}}(\theta_0^j)$) is equivalent to the gradient of the latter.

## B. Equivalence of Objectives

It is straightforward to show that when we optimise the OML objective through the $k$-step MAML update, as proposed in C-MAML in Eq. 6:

$$\min_{\theta_0^j} E_{\tau_{1:t}} \left[ L_t \left( U_k(\theta_0^j) \right) \right] \tag{12}$$

where the *inner-updates* are taken using data from the streaming task $\tau_t$, and the *meta-loss* $L_t(\theta) = \sum_{i=1}^{t} \ell_i(\theta)$ is computed on the data from all tasks seen so far, it will correspond to minimising the following surrogate loss used in CL :

$$\min_{\theta_0^j} \sum_{i=1}^{t} \left( \ell_i(\theta_0^j) - \alpha \frac{\partial \ell_i \left( \theta_0^j \right)}{\partial \theta_0^j} \cdot \frac{\partial \ell_t \left( \theta_0^j \right)}{\partial \theta_0^j} \right) \tag{13}$$

We show the equivalence for the case when $k = 1$, for higher $k$ the form gets more complicated but essentially has a similar set of terms. Reptile (Nichol et al., 2018) showed that the $k$-step MAML gradient for the weights $\theta_0^j$ at time $j$, denoted as $g_{\text{MAML}}(\theta_0^j)$ is of the form:

$$\frac{\partial L_{meta}(\theta_k^j)}{\partial \theta_0^j} = \bar{g}_k - \alpha \bar{H}_k \sum_{i=0}^{k-1} \bar{g}_i - \alpha \sum_{i=0}^{k-1} \bar{H}_i \bar{g}_k + O\left(\alpha^2\right)$$

$$= \bar{g}_1 - \alpha \bar{H}_1 \bar{g}_0 - \alpha \bar{H}_0 \bar{g}_1 + O\left(\alpha^2\right) \quad \text{(putting } k = 1\text{)}$$

Expressing the terms as derivatives, and using $\frac{\partial}{\partial \theta_0^j} (\bar{g}_0 \cdot \bar{g}_1) = \bar{H}_1 \bar{g}_0 + \bar{H}_0 \bar{g}_1$, we get :

$$= \frac{\partial L_{meta} \left( \theta_0^j \right)}{\partial \theta_0^j} - \frac{\partial}{\partial \theta_0^j} (\bar{g}_0 \cdot \bar{g}_1)$$

$$= \frac{\partial \left( \sum_{i=1}^{t} \ell_i(\theta_0^j) - \alpha \bar{g}_1 \cdot \bar{g}_0 \right)}{\partial \theta_0^j} \quad \text{(substituting } L_{meta} = L_t = \sum_{i=1}^{t} \ell_i)$$

$$= \frac{\partial \left( \sum_{i=1}^{t} \ell_i(\theta_0^j) - \alpha \frac{\partial L_{meta}(\theta_0^j)}{\partial \theta_0^j} \frac{\partial \ell_t(\theta_0^j)}{\partial \theta_0^j} \right)}{\partial \theta_0^j}$$

$$= \frac{\partial \left( \sum_{i=1}^{t} \ell_i(\theta_0^j) - \alpha \frac{\partial \sum_{i=1}^{t} \ell_i(\theta_0^j)}{\partial \theta_0^j} \frac{\partial \ell_t(\theta_0^j)}{\partial \theta_0^j} \right)}{\partial \theta_0^j} \quad \text{(expanding } L_{meta})$$

$$= \frac{\partial \left( \sum_{i=1}^{t} \ell_i(\theta_0^j) - \alpha \sum_{i=1}^{t} \frac{\partial \ell_i(\theta_0^j)}{\partial \theta_0^j} \frac{\partial \ell_t(\theta_0^j)}{\partial \theta_0^j} \right)}{\partial \theta_0^j}$$

which is the same as the gradient of Eq. 13.

where:

$$\bar{g}_k = \frac{\partial L_{meta} \left( \theta_0^j \right)}{\partial \theta_0^j} \qquad \text{(gradient of the } meta\text{-}loss \text{ evaluated at the initial point )}$$

$$\bar{g}_i = \frac{\partial}{\partial \theta_0^j} L_{inner}(\theta_0^j) \quad \text{(for } i < k) \quad \text{(gradients of the } inner\text{-}updates \text{ evaluated at the initial point)}$$

$$\theta_{i+1}^j = \theta_i^j - \alpha g_i \qquad \text{(sequence of parameter vectors)}$$

$$\bar{H}_k = L''_{meta}\left(\theta_0^j\right) \qquad \text{(Hessian of the \textit{meta-loss} evaluated at the initial point)}$$

$$\bar{H}_i = L''_{inner}\left(\theta_0^j\right) \quad \text{(for } i < k\text{)} \quad \text{(Hessian of the \textit{inner-objective} evaluated at the initial point)}$$

And, in our case:

$$L_{meta} = L_t = \sum_{i=1}^{t} \ell_i$$

$$L_{inner} = \ell_t$$

**Bias in the objective**: We can see in Eq. 13 that the gradient alignment term introduces some bias, which means that we don't exactly converge to the minimiser of the losses on all tasks. This has been acceptable in CL for the following reason: We never aim to reach the minimiser of some stationary distribution anyway in the CL regime (as also mentioned in Section 4.3). If we did converge to the minimiser of say $t$ tasks at some time $j$, this minimiser would no longer be optimal as soon as we see the new task $\tau_{t+1}$. Therefore, in the limit of infinite tasks or time, gradient alignment between tasks will pay off more as opposed to being able to converge to the exact minima, by allowing us to make shared progress on both previous and incoming tasks.

## C. Robustness

Learning rate is one of the most crucial hyper-parameters during training and it often has to be tuned extensively for each experiment. In this section we analyse the robustness of our proposed variants to their LR-related hyper-parameters on the CIFAR-100 dataset. Our three variants have different sets of these hyper-parameters which are specified as follows:

- **C-MAML**: Inner and outer update LR (scalar) for the weights ($\alpha$ and $\beta$)

- **Sync La-MAML**: Inner loop initialization value for the vector LRs ($\alpha_0$), scalar learning rate of LRs ($\eta$) and scalar learning rate for the weights in the outer update ($\beta$)

- **La-MAML**: Scalar initialization value for the vector LRs ($\alpha_0$) and scalar learning rate of LRs ($\eta$)

La-MAML is considerably more robust to tuning compared to its variants, as can be seen in Figure 4c. We empirically observe that it only requires tuning of the initial value of the LR, while being relatively insensitive to the learning rate of the LR ($\eta$). We see a consistent trend where the increase in $\eta$ leads to an increase in the final accuracy of the model. The increase is very gradual, across a wide range of LRs varying over 2 orders of magnitude (from 0.003 to 0.3), the difference in RA is only 6%. This means that even without tuning this parameter ($\eta$), La-MAML would have outperformed most baselines at their optimally tuned values.

(a) C-MAML: Modulation of $\alpha$ and $\beta$      (b) Sync: Modulation of $\alpha_0$, $\eta$ and $\beta$      (c) La-MAML: Modulation of $\alpha_0$ and $\eta$

*Figure 4.* Retained Accuracy vs Learning Rates plot for La-MAML and its variants. Figures are plotted by varying one of the learning rate hyperparameter while keeping the others fixed at their optimal value. The hyperparameter is varied between [0.001, 0.3].

As seen in Figure 4a, C-MAML sees considerable performance variation with the tweaking of both the inner and outer LR. We also see that the effects of the variations of the inner and outer LR follow very similar trends and their optimal values

(a) C-MAML: Modulation of $\alpha$ and $\beta$           (b) La-MAML: Modulation of $\alpha_0$ and $\eta$

*Figure 5.* Plots of Retained Accuracy (RA) across hyper-parameter variation for C-MAML and La-MAML. We show results of the grid search over the learning rate hyperparameters. RA decreases from red to blue. All the hyperparameters are varied between [0.001, 0.3], with the axes being in log-scale.

finally selected are also identical. This means that we could potentially tune them by doing just a 1D search over them together instead of varying both independently through a 2D grid search. The Sync version of La-MAML (Figure 4b), while being relatively insensitive to the scalar initial value $\alpha_0$ and the $\eta$, sees considerable performance variation as the outer learning rate for the weights: $\beta$ is varied. This variant has the most hyper-parameters and only exists for the purpose of ablation.

Fig. 5 shows the result of 2D grid-searches over sets of the above-mentioned hyper-parameters for C-MAML and La-MAML for a better overview.

## D. Experimental

We carry out hyperparameter tuning for all the approaches by performing a search over the range [0.0001 - 0.3] for hyper-parameters related to the learning-rate. Further experiments are carried out to find the optimal number of *glances* over each sample in the single-pass (LLL) setup. Table 5 lists the optimal hyperparameters for all the compared approaches. All setups used the SGD optimiser since it was found to preform better than Adam (Kingma & Ba, 2014) (possibly due to reasons stated in Section 4.3 regarding the CL setup).

To avoid exploding gradients, we clip the gradient values of all approaches at a norm of 2.0. *Class divisions* across different tasks vary with the random seeds with which the experiments were run. Overall, we did not see much variability across different class splits, with the variation being within 0.5-2% of the mean reported result as can be seen from Table 4

For all our baselines, we use a constant batch-size of 10 samples from the streaming task. This batch is augmented with 10 samples from the replay buffer for the replay-based approaches. La-MAML and its variants split the batch from the streaming task into a sequence of smaller disjoint sets to take $k = 5$ gradient steps in the *inner-loop*. In MER, each sample from the incoming task is augmented with a batch of 10 replay samples to form the batch used for the meta-update. We found very small performance gaps between the first and second-order versions of our proposed variants with performance differences in the range of 1-2% for RA. This is in line with the observation that deep neural networks have near-zero hessians since the ReLU non-linearity is linear almost everywhere (**?**).

**MNIST Benchmarks**: On the MNIST continual learning benchmarks, images of size 28x28 are flattened to create a 1x784 array. This array is passed on to a fully-connected neural network having two layers with 100 nodes each. Each layer uses ReLU non-linearity. These experiments use a modest replay buffer of size 200 for MNIST Rotations and Permutation and size 500 for Many Permutations.

**Real-world visual classification**: For Cifar and Imagenet we used a CNN having 3 and 4 conv layers respectively with 160 3x3 filters. The output from the final convolution layer is flattened and is passed through 2 fully connected layers having 320 and 640 units respectively. All the layers are succeeded by ReLU nonlinearity. For CIFAR and Imagenet we allow a replay buffer of size 200 and 400 respectively which implies that each class in these dataset gets roughly about 1-2 samples

*Table 5.* Final hyperparameters for all compared approaches on the CIFAR and Imagenet benchmarks

| METHOD | PARAMETER | CIFAR-100 | | IMAGENET | |
|---|---|---|---|---|---|
| | | SINGLE | MULTIPLE | SINGLE | MULTIPLE |
| ER | *LR* | 0.03 | 0.03 | 0.1 | 0.1 |
| | *Epochs/Glances* | 10 | 10 | 10 | 10 |
| IID | *LR* | - | 0.03 | - | 0.01 |
| | *Epochs/Glances* | - | 50 | - | 50 |
| iCARL | *LR* | 0.03 | 0.03 | 0.01 | 0.01 |
| | *Epochs/Glances* | 2 | 10 | 2 | 10 |
| GEM | *LR* | 0.03 | 0.03 | 0.03 | 0.03 |
| | *Epochs/Glances* | 2 | 10 | 2 | 10 |
| AGEM | *LR* | 0.03 | 0.03 | 0.01 | 0.01 |
| | *Epochs/Glances* | 2 | 10 | 2 | 10 |
| MER | *LR* $\alpha$ | 0.1 | - | 0.1 | - |
| | *LR* $\beta$ | 0.1 | - | 0.1 | - |
| | *LR* $\gamma$ | 1 | - | 1 | - |
| | *Epochs/Glances* | 10 | - | 10 | - |
| META-BGD | $\eta$ | 50 | 50 | 50 | - |
| | *std-init* | 0.02 | 0.02 | 0.02 | - |
| | $\beta_{inner}$ | 0.1 | 0.1 | 0.1 | - |
| | *mc-iters* | 2 | 2 | 2 | - |
| | *Epochs/Glances* | 3 | 10 | 3 | - |
| C-MAML | $\alpha$ | 0.03 | 0.03 | 0.03 | 0.03 |
| | $\beta$ | 0.03 | 0.03 | 0.03 | 0.03 |
| | *Epochs/Glances* | 5 | 10 | 2 | 10 |
| SYNC LA-MAML | $\alpha_0$ | 0.1 | 0.1 | 0.075 | 0.075 |
| | $\beta$ | 0.1 | 0.1 | 0.075 | 0.075 |
| | $\eta$ | 0.3 | 0.3 | 0.25 | 0.25 |
| | *Epochs/Glances* | 5 | 10 | 2 | 10 |
| LA-MAML | $\alpha_0$ | 0.1 | 0.1 | 0.1 | 0.1 |
| | $\eta$ | 0.3 | 0.3 | 0.3 | 0.3 |
| | *Epochs/Glances* | 10 | 10 | 2 | 10 |

in the buffer. For Tiny-Imagenet, we split the validation set into *val* and *test* splits, since the labels in the actual test set are not released.

## E. Baselines

On the MNIST benchmarks, we compare our algorithm against the baselines used in (Riemer et al., 2019), which are as follows:

- Online: A baseline for the LLL setup, where a single network is trained one example at a time with SGD.

- EWC (Kirkpatrick et al., 2017): Elastic Weight Consolidation is a regularisation based method which constraints the weights important for the previous tasks to avoid catastrophic forgetting.

- GEM (Lopez-Paz & Ranzato, 2017): Gradient Episodic Memory does constrained optimisation by solving a quadratic program on the gradients of new and replay samples, trying to make sure that these gradients do not alter the past tasks' knowledge.

- MER (Riemer et al., 2019): Meta Experience Replay samples i.i.d data from a replay memory to meta-learn model parameters that show increased gradient alignment between old and current samples. We evaluate against this baseline in the LLL setup.

On the real-world visual classification datasets, we carry out experiments on GEM, MER along with:-

- ER: Experience Replay uses a small replay buffer to store old data using reservoir sampling. This stored data is then replayed again along with the new data samples.

- IID: Network gets the data from all tasks in an independent and identically distributed manner, thus bypassing the issue of catastrophic forgetting completely.

- iCARL (Rebuffi et al., 2017): iCarl is from the family of class incremental learners, which learns to classify images in the metric space. It prevents catastrophic forgetting by using a memory of exemplar samples to perform distillation from the old network weights.

- A-GEM (Chaudhry et al., 2019): Averaged Gradient Episodic Memory proposed to project gradients of the new task to a direction such as to avoid interference with respect to the average gradient of the old samples in the buffer.

- Meta-BGD: Bayesian Gradient Descent (Zeno et al., 2018) proposes training a bayesian neural network for CL where the learning rate for the parameters (the means) are derived from their variances. We construct this baseline by equipping C-MAML with bayesian training, where each parameter in $\theta$ is now sampled from a gaussian distribution with a certain mean and variance. The inner-loop stays as in C-MAML(constant LR), but the magnitude of the meta-update to the parameters in $\theta$ is now influenced by their associated variances. The variance updates themselves have a closed form expression which depends on $m$ monte-carlo samples of the *meta-loss*, thus implying $m$ forward passes of the inner-and-outer loops (each time with a newly sampled $\theta$) to get $m$ meta-gradients.
