A Stereotype Content Analysis on Color-related Social Bias in Large Vision Language Models

Abstract

As large vision language models (LVLMs) rapidly advance, concerns about the risk of their learning or generating stereotypes are increasing. However, previous studies on LVLM's stereotypes face two primary limitations: metrics that overlooked the importance of content words, and datasets that overlooked the effect of clothing color. To address these limitations, this study introduces new evaluation metrics based on the Stereotype Content Model (SCM). The SCM-based metric is grounded in social psychology, enabling the detection of stereotypical content words in model responses along the dimensions of competence and warmth. We also propose BASIC, a benchmark for assessing gender, race and clothing color stereotypes. Using SCM metrics and BASIC, we conduct a study with eight LVLMs to discover stereotypes. As a result, we found three findings. (1) The SCM-based evaluation is effective in capturing stereotypes. (2) LVLMs exhibit clothing color stereotypes in the output along with gender and race ones. (3) Interaction between model architecture and parameter sizes seems to affect stereotypes. We release BASIC publicly on [anonymized for review].

1 Introduction

As large vision-language models (LVLMs) continue to advance, they are increasingly being utilized in perceiving visual images across diverse domains (Xu et al., 2024; Gu et al., 2024; Wang et al., 2025). However, when employing LVLMs, it is essential to acknowledge that models may be affected by stereotypes, potentially influencing their perception. In human, a stereotype refers to cognitive generalizations about the characteristics of individuals belonging to a specific social group (VandenBos, 2007). So, people often judge others unconsciously based on visual appearance such as gender, race, and clothing color (Cloutier et al., 2005; Eberhardt et al., 2004; Elliot et al., 2013).

As LVLMs learn implicit or explicit relationships from vast amounts of human-generated data, they could embed such biases in themselves, leading to unfair or unreliable model outputs (Jiang et al., 2024; Howard et al., 2025; Fraser and Kiritchenko, 2024). Therefore, the need to identify such stereotypes is becoming important. Researchers recently designed various benchmarks to quantify stereotypes in LVLMs (Adewumi et al., 2024; Wang et al., 2024b; Park et al., 2025). Despite their valuable quantification, their experimental design and results yet have overlooked two confounding factors; (1) Content words: the stereotypes should be dissembled from semantic polarity; and (2) Clothing color: the stereotypes should be controlled across variations of clothing colors, as color itself might be possibly introduce stereotypes.

First, regarding content words, we suspect that LVLMs may use positive sentiment words when generating stereotypical content. Many previous studies have relied on sentiment analysis to assess stereotypes (Wang et al., 2024a; Raj et al., 2024; Gerych et al., 2024). While this approach has contributed, sentiment-based evaluation cannot fully mirror how humans evaluate such stereotypes. Stereotypes are complex constructs compared to perceived sentiment, and thus cannot be thoroughly examined by sentiment polarity alone (Greenwald and Banaji, 1995; Amodio, 2014; Howard et al., 2025; Siy and Cheryan, 2016). Hence, to evaluate stereotypes more precisely, we adopt Stereotype Content Model (SCM), a socio-psychological framework that captures such implicit stereotypes in text and complements sentiment analysis (Fiske et al., 2018). With SCM, we examine how LVLMs exhibit stereotypical content in their responses.

Second, regarding clothing color, LVLMs may exhibit stereotypes due to variations in color within images. Prior work has attempted to control visual differences using paired images, but has not sufficiently considered clothing color as a potential

confounding factor[1]. We particularly emphasize clothing color here because human responses often associate colors with distinct psychological meanings (Elliot and Maier, 2013; Kaya and Epps, 2004; Wexner, 1954). For example, people may perceive individuals wearing white clothing as more competent, or view those wearing red as more competitive. Given that LVLMs are trained on human-generated data, they may internalize such associations, leading to color-induced stereotypes. Moreover, previous studies have reported that VLMs generate inconsistent and different responses even when images depict similar scenes with different colors (Wu et al., 2025; Kantipudi et al., 2020; Liang et al., 2025). To address this limitation, we construct a color-controlled benchmark using three representative colors, red, blue, and white, which are known to evoke consistent perceptual associations in cognitive psychology.

Thus, we propose two metrics and a benchmark dataset. Our SCM-based metric quantifies the level of stereotypes using stereotypical content words. Also, our new **B**enchmark for **A**ssessing **S**tereotypes with **I**mage **C**olors, BASIC, provides paired images with different clothing colors while also considering gender and race. Additionally, we attempt to examine which part of LVLMs affect stereotypes, by comparing 8 different models.

2 Related Work

We review prior study on evaluating stereotypes in terms of three aspects: (1) content words, (2) benchmarks, and (3) model architecture.

First, regarding content words, prior studies have mainly assessed model responses based on sentiment polarity (Inoshita and Zhou, 2024; Hu et al., 2025; Gerych et al., 2024), which limits their ability to capture the subtle meanings embedded in text. In the case of LVLMs, responses often exhibit positive sentiments because they were reinforced by human feedback (Li et al., 2024), making it difficult to detect stereotypes solely through sentiment-based metrics. Therefore, more sophisticated measures that directly target stereotypes are needed. In response to this limitation, recent work has begun incorporating social-psychological evaluation frameworks to analyze stereotypes. For instance, (Howard et al., 2025) was influenced by the Stereotype Content Model (SCM). The study

Figure 1: Examples from our BASIC dataset. Top row shows chess players with different colors (white, blue, red), retaining race and gender. Bottom row shows DJs with different race or gender, retaining white color.

used the dictionary from (Nicolas et al., 2021) to measure the frequency of SCM-related words in image captions. However, this approach is limited by its reliance on word frequency, without accounting for contextual or derived meanings.

Second, regarding benchmarks, prior studies have emphasized constructing paired images to assess stereotypes of LVLMs. Traditional studies constructed diverse images based on common themes such as gender or race, and compared average evaluation scores across these thematic sets (Mandal et al., 2023; Janghorbani and De Melo, 2023; Qiu et al., 2023). However, such methods often suffer from insufficient control over confounding variables. For example, if gender, race, and background change simultaneously, any observed stereotypes cannot be solely attributed to gender when examining gender stereotypes. So, recent works have proposed that changing a targeted attribute while retaining the rest of the image (Kim et al., 2025; Howard et al., 2025, 2024; Fraser and Kiritchenko, 2024). However, unintended color differences still appear in the generated images. Considering the visual differences can influence the model's internal representations (De and Pedersen, 2021; Kantipudi et al., 2020; Liang et al., 2025), thereby potentially affecting the manifestation of stereotypes. Thus, color differences should be considered in stereotype evaluation frameworks.

Lastly, regarding model architecture, researchers recently investigated whether the model architecture affects stereotypes. Though previous studies have identified stereotypes within a limited set of models (Raj et al., 2024; Sathe et al., 2024), they did not clearly mention which architectural choice

---

[1]This is a real problem; When we examined previous benchmarks manually, we found some paired images wearing different clothings with different colors.

cause stereotypes. Recently, researchers have begun to identify causal relationships (Wu et al., 2024; Wang et al., 2024a). Despite their success, it is yet questionable whether the findings could be generalized to large VLMs with more than 50 billion parameters. So, we systematically incorporate a broader range of model sizes.

3   BASIC Benchmark

In this study, we aim to separately examine the effect of color in the analysis of stereotypes produced by LVLMs. There are various visual attributes in person images that can influence stereotype formation: gender, race, and color. Since these factors appear together in a single image, it is essential to separate the impact of each attribute on the model's responses. To examine the potential impact of such differences, we construct a paired image dataset as shown in Figure 1.

We created the dataset using three primary colors: white, red, and blue. While a broader range of colors could have been included, we selected these particular ones based on cognitive factors related to human perception. Specifically, prior research has shown that humans tend to associate red, blue, and white with particular emotions, cognitive judgments, or stereotypes (Elliot and Maier, 2013; Kaya and Epps, 2004; Wexner, 1954). Therefore, we adapted the procedure proposed by (Howard et al., 2024) to construct a dataset with controlled color tones and designed a six-step process[2].

For the experimental analysis of model stereotypes, gender and race categorizations were adopted from previous studies (Karkkainen and Joo, 2021; Howard et al., 2024). Specifically, gender was determined based on biological sex, while race was classified into six predefined groups: African-American, Asian, Caucasian, Indian, Latino, and Middle Eastern. This selection was made solely for experimental purposes and is not intended to exclude any group.

Step 1: Constructing Occupation List. To create paired images, we started by choosing a common occupation for the individuals depicted in each image. Following the approach of Howard et al. (2024), we collected a list of occupations from studies (Nadeem et al., 2021; Chuang et al., 2023; Naik and Nushi, 2023). After removing duplicates, we

obtained a list of 181 occupations. All subsequent steps are performed for each of 181 occupations.

Step 2: Creating action. We considered various actions that could be associated with each occupation. Since a single image cannot cover all possible actions of a specific occupation, multiple images describing different actions are required for each occupation. To achieve this, we adapted a prompt from (Sathe et al., 2024) and used GPT-4 to generate five distinct scenarios for each occupation.

Step 3: Generating Seed Images. For each of the five actions associated with a given occupation, we generated a seed image as a baseline for transformation. To ensure stability in subsequent image manipulation steps, the seed image was generated using an Asian male wearing white clothing on a gray background. Also, we set the background to a neutral gray color, ensuring that color variations are isolated to the clothing. This step was performed using Stable Diffusion XL, which generated high-resolution images (1024 × 1024 pixels) based on scenario corresponding to each occupation (Podell et al., 2023). We employed negative prompts (Ban et al., 2024) to enhance image quality and ensure alignment with the intended depiction. A negative prompt is an input method that specifies unwanted attributes, guiding the model to avoid including them in the generated images.

Step 4: Controlling Gender and Race. Based on a seed image, we generate paired images that reflect various combinations of gender and race. In this stage, we utilize the Image-to-Image model of Stable Diffusion XL to modify the seed image according to the specified race and gender attributes. We retain the contextual information conveyed by the scenario while altering only the race and gender of the original image. To ensure that the pose, position, and background remain consistent with the seed image, we adopt negative prompts.

Step 5: Controlling Color. Based on the images generated in Step 4, we further modify the clothing color of each image to either blue or red, while maintaining the same race and gender. To ensure that the intended color is clearly reflected in the output, we use negative prompts. Through this step, we obtain a total of 180 images per scenario (= 5 actions × 2 genders × 6 races × 3 colors).

Step 6: Filtering. To ensure the quality of the final dataset, we conducted a filtering process based

---

[2]The generation code is available at [anonymized for the review]. Detailed prompts and parameter settings for each step are provided in Appendix A.

	Red	*Green*	*Blue*
Red *vs.* White	0.12	-3.06	-2.43
Blue *vs.* White	-5.37	-4.87	-0.52

Table 1: RGB value changes (%) in red/blue images compared to white seed image

on three criteria. First, we evaluated the semantic similarity between the 32,580 generated images and their corresponding text prompts. We normalized the embeddings of both image and text using CLIP, then computed the cosine similarity between them. Only images with a similarity score of 0.2 or higher were retained in the dataset. Second, we included only those images that passed the NSFW filtering, thereby excluding any potentially unsafe content that may have been generated. Lastly, we retained only occupations for which all 180 image variations passed both filtering conditions. If any single image was filtered out, we excluded the entire occupation to ensure completeness of pairs.

Through the above procedures, we generated a total of 18,360 images across 102 occupations. After completing all image generations, we assessed whether the color were clearly distinguishable by two methods. First, we computed the RGB scale differences between the red or blue images and their corresponding white counterparts. As shown in Table 1, the constructed dataset actively suppresses non-target colors to emphasize the intended color. Second, we manually validated 10% random samples to ensure the quality of dataset. We detail the result in Appendix B.

4 Experimental Setup

Using the dataset, we experiment whether LVLMs reveal different stereotypes across different gender, race, and clothing color. This section elaborates how we conduct our experiment including preparing descriptions, metrics, analysis, and models.

4.1 Collecting Description

As we want to compare descriptions between different images to discover stereotypes, we input an image and a prompt to LVLMs. For each image, we start a session by feeding the image to an LVLM. Then, we ask the LVLM to generate descriptions about the image, using an open-ended question. Specifically, we used following question: "Describe this person objectively." Using the description paragraph generated by the LVLM, we

extract metrics for statistical analysis and conduct a simple qualitative analysis.

We selected the above question prompt because of two reasons. First, the prompt does not imply any specific situation or assumption. As LVLMs may produce different calculation result when we provide different situation prompt, implying any situation could lead to a specific stereotype. So, to focus solely on the effect of input images, we selected not to impose any situation within the prompt. Second, the prompt does not provide any specific choices. We thought that providing choices can also impose a new code of conduct: generated answer should be one of the choices.

4.2 Metrics

4.2.1 Existing sentiment-based metric

Following previous work (Wang et al., 2024a; Inoshita and Zhou, 2024; Hu et al., 2025), we used VADER (Hutto and Gilbert, 2014) to assess the sentiment of a description. Among the various sentiment-based metrics, researchers usually adopt VADER because the model is trained on the corpus from social media, which might contain stereotypical content. To obtain a score, we input a description of an image into VADER.

4.2.2 Our proposed SCM-based metrics

To inspect stereotypes thoroughly with content words, we propose two automatic metrics grounded in a foundational theory in social psychology, Stereotype Content Model (SCM), which conceptualizes human stereotypes along two dimensions: competence and warmth (Fiske et al., 2018). The competence dimension measures how capable the describer evaluates the ability of the person in the image to achieve own goal[3]. And, the warmth dimension measures how positively or negatively a describer evaluates the intention of the person[4].

In the following, we describe how we operationalized these two dimensions in our evaluation framework. To quantize two main axes of stereotype, warmth and competence, we propose a projection-based method; we project word embeddings into a vector space spanned by warmth and competence, inspired by studies about stereotypes in LLMs (Fraser et al., 2021; Omrani et al., 2023;

---

[3]We used six words representing competence axis, from Fiske et al. (2018): *competent*, *confident*, *capable*, *efficient*, *intelligent*, *skillful*

[4]Also, we used six words representing warmth: *friendly*, *well-intentioned*, *trustworthy*, *warm*, *good-natured*, *sincere*

Kim and Johnson, 2025). As SCM utilizes human intuition in its evaluation process, we chose to model such intuition using word embeddings. So, we assumed that a sentence embedding $\mathbf{x}$ is a linear combination of independent basis vectors: warmth $\mathbf{u}_w$, competence $\mathbf{u}_c$, and other basis vectors $\mathbf{v}_i$s orthogonal to $\mathbf{u}_w$ and $\mathbf{u}_c$. In other words, for any sentence embedding $\mathbf{x}$, there exist corresponding real numbers $\alpha_w(x), \alpha_c(x)$ and $\beta_i(x)$ such that

$$\mathbf{x} = \alpha_w \mathbf{u}_w(x) + \alpha_c \mathbf{u}_c(x) + \sum_i \beta_i(x)\mathbf{v}_i. \quad (1)$$

So, we can compute orthogonal projection of $\mathbf{x}$ onto warmth-competence plane with two numbers $\alpha_w(x)$ and $\alpha_c(x)$, the projected coordinate on the plane. These numbers show how much warmth and competence should be combined together to have a similar meaning of the given sentence x. So, we interpret them as scores quantifying warmth and competence in SCM.

To implement the above idea, we need basis vectors. We normalized the average embedding of corresponding representative words. As a embedding model, we used Sentence-Transformer (Reimers and Gurevych, 2019). Let W and C be sets of words representing warmth and competence, respectively. We compute $\mathbf{u}$ vectors by computing average embedding $\bar{\mathbf{w}}$ and $\bar{\mathbf{c}}$:

$$\bar{\mathbf{w}} = \frac{1}{|W|} \sum_{x \in W} \text{ST}(x), \qquad \mathbf{u}_w = \frac{1}{\|\bar{\mathbf{w}}\|_2} \bar{\mathbf{w}}, \quad (2)$$

$$\bar{\mathbf{c}} = \frac{1}{|C|} \sum_{x \in C} \text{ST}(x), \qquad \mathbf{u}_c = \frac{1}{\|\bar{\mathbf{c}}\|_2} \bar{\mathbf{c}}, \quad (3)$$

where $\text{ST}(\cdot)$ is the Sentence-Transformer.

Using these two unit vectors, we compute warmth α_w and competence α_c of a sentence x as a projection. We first calculate dot products between $\mathbf{x} := \text{ST}(x)$ and basis vectors.

$$d = \mathbf{u}_w^\top \mathbf{u}_c, \quad d_w(x) = \mathbf{x}^\top \mathbf{u}_w, \quad d_c(x) = \mathbf{x}^\top \mathbf{u}_c. \quad (4)$$

Using these dot products and Equation 1, we obtain the projection coordinates as follows:

$$\alpha_w(x) = \frac{d_w(x) - d \cdot d_c(x)}{1 - d^2}, \quad (5)$$

$$\alpha_c(x) = \frac{d_c(x) - d \cdot d_w(x)}{1 - d^2}. \quad (6)$$

4.3 Analyses

We use two analysis methods to examine stereotypes in LVLMs: statistical tests and pointwise mutual information (PMI). For the statistical analysis,

we conducted paired t-tests by constructing image pairs that differed only in the target attribute while keeping all other attributes fixed. For example, to evaluate gender stereotypes, we paired images from BASIC that differed in gender but shared the same race, clothing color, scene, and occupation. We then compared the three metric values computed from their descriptions. For gender, we conducted a single paired t-test to compare male and female images. For race and clothing color, which have multiple categories, we applied the same paired t-test procedure across all category pairs.

Second, for PMI analysis, we computed PMI between each aspect and words to identify aspect-specific terms relevant to the SCM dimensions. To focus on SCM-relevant words, we filtered words by computing the cosine similarity between $\mathbf{w} := \text{ST}(w)$ and basis vectors and discarded words whose similarity is in between -0.5 and 0.5[5]. Then, we compute PMI of a word w and an aspect a (e.g., red tone) as follows:

$$PMI(w; a) = \log_2 \frac{P(w|a)}{P(w)}, \quad (7)$$

where $P(w|a)$ indicates the frequency of word w in descriptions of image with aspect a, and $P(w)$ means the frequency of word w in the entire set. For each aspect, we selected 20 words whose PMI scores are highest. By collecting common words across models, we can identify stereotypes appeared in majority of models.

4.4 Tested models

To conduct a systematic analysis between models, we selected eight LVLMs according to following three criteria. First, we used open-sourced models whose architecture is known and already tuned on visual instructions. Second, we selected LVLMs which provides at least two different parameter sizes. Third, we used models which can be grouped with other models, according to image input method or backbone language models (LMs). As a result, we selected the following eight models, as shown in Table 2. Note that Llama 3.2 and InstructBLIP uses backbone LMs from same lineage, Llama. Unlike Llama 3.2, which integrates visual and textual modalities via cross-attention layers within the LLM itself, the other three architectures introduce visual features at an earlier

---

stage. After processing the outputs of the image encoder through modules such as Q-Former, adapters, or projectors, they feed them directly into the language model input sequence. Additionally, small models have similar parameter sizes, such as 7B or 12B. Implementation details (e.g., temperature settings) are described in Appendix C.

5 Results and Discussion

We present four main findings from our experiments: the effectiveness of SCM metrics, color stereotypes, Gender and race stereotypes, and differences between models. Table 3 shows the results of statistical tests regarding clothing color and gender attributes. Due to the page limit, we report the full pairwise race comparisons in Appendix D and the full PMI results in Appendix E.

5.1 Effectiveness of SCM Metrics

SCM and VADER provides comprehensive view. VADER and SCM-based metrics measure different aspects of model responses. VADER analyzes the emotional content of a sentence at a surface level by examining its positive or negative polarity, thus simplifying stereotypes to matters of sentiment. In contrast, SCM interprets stereotypes as differences in perceived competence or warmth toward the subject in the sentence. Therefore, using both SCM-based metrics and sentiment-based metrics provides a more comprehensive view of stereotypes, because they capture different layers of stereotype expression.

This distinction is supported by our correlation analysis. VADER was nearly independent from competence ($r = 0.014$, $p < 0.001$) and only weakly correlated with warmth ($r = 0.189$, $p < 0.001$). This indicates that sentiment polarity does not necessarily align with perceived competence or warmth. Consistent with this, our statis-

tical results show that VADER and SCM-based metrics reveal different patterns: VADER showed weak or inconsistent differences in some color comparisons, whereas competence and warmth showed systematic differences along SCM dimensions. These results suggest that sentiment polarity alone may provide an incomplete view of stereotypes, and that SCM-based metrics can offer an additional perspective based on perceived competence and warmth.

Moreover, we suspect that safeguards in LVLMs can distort or mask the model's internal stereotypes. These models are often explicitly trained to avoid harmful content or negative tones on possibly stereotypical topics, thereby influencing sentiment scores regardless of underlying stereotypes. Therefore, sentiment polarity-based metrics, such as VADER, may not sufficiently capture stereotypes. In contrast, SCM focuses on the semantic dimensions of warmth and competence, offering a more robust alternative that is less affected by surface-level positivity or safety-driven wording.

5.2 Color Stereotypes

Clothing color plays a significant role in stereotypes. Our results show that clothing color influences LVLM descriptions. Even when gender, race, and other attributes were controlled, changing only the clothing color led to significant differences in SCM scores. This indicates that color is not merely a visual surface feature but can function as a socially meaningful cue in LVLM outputs.

For competence, blue images generally received lower scores than red and white ones. The difference between blue and red was significant across all models ($p < 0.001$), and the difference between blue and white was significant in most models except InstructBLIP-7B ($p < 0.001$). This suggests that LVLMs may associate red and white clothing with perceived capability more strongly than blue clothing. One possible explanation is that LVLMs internalize sociocultural associations between color and social meaning from image-text data. For instance, red color may symbolize warning or aggression but can also be interpreted as a sign of passion or determination (Elliot and Maier, 2013; Gnambs et al., 2015). PMI results support this interpretation: red images were associated with competence-related words such as *bright*, *strong*, and *competitive*. Similarly, white images were linked with *clean*, *technological*, and *expertise*, mirroring stereotypes that professional, highly com-

Blue and orange values indicate statistically significant positive and negative t-statistics, respectively. All results including race is in the Appendix D.

petent occupations wear white-colored uniforms (Crutzen and Adam, 2022; Adam and Galinsky, 2012). Therefore, the higher competence for red and white images may reflect learned associations between clothing color and perceived capability.

For warmth, the pattern was different. Red images generally received lower warmth scores than blue and white ones. Specifically, red images showed lower warmth than blue images across all models ($p < 0.001$) and lower warmth than white images in all models ($p < 0.05$). We suspect that frequent pairing of certain colors with trustworthiness may have increased warmth scores. For example, blue symbolizes calmness and stability (Kaya and Epps, 2004; Wexner, 1954). Similarly, white conveys a sense of softness and purity (Na and Suk, 2014; Kaya and Epps, 2004). Such a calm or soft impression may lead models to describe the subject's intention as less harmful, thereby increasing warmth. PMI results support this interpretation: blue images showed high mutual information with words such as *enjoying*, *respect*, and *welcoming*, while white images were associated with *smooth*, *plain*, and *neutral*. Thus, higher warmth scores for blue and white images imply that LVLMs learned such human stereotypes.

Together, these results demonstrate that clothing color can influence stereotypes along different SCM dimensions. Red and white tend to increase perceived competence, while blue and white tend to increase perceived warmth. This finding supports the need to control clothing color when evaluating stereotypes in LVLMs, because unintended color differences in paired images may confound the measurement of gender or race stereotypes.

5.3 Gender and Race Stereotypes

Gender and race stereotypes emerge in SCM. Beyond color, we also observed significant stereotype patterns for gender and race. At the sentiment level, VADER showed that male images received lower sentiment scores than female images across all models. However, SCM-based metrics revealed a more differentiated pattern. For gender, male images showed lower competence scores than female images in most models ($p < 0.001$ except for Qwen-7B). PMI results support this tendency: male images were associated with words such as *distinguished*, *responsibility*, and *intellectual*, whereas female images were more strongly linked to *graceful*, *elegant*, and *beauty*.

Regarding warmth, male images generally received higher scores than female ones ($p < 0.001$ except for Qwen-72B). PMI results again show a consistent qualitative pattern: male ones were associated with *lively*, *welcoming*, and *good*, whereas female ones were associated with *confident*, *strong*, and *beauty*.

For race, the comparisons also revealed significant differences. Although the full results are reported in Appendix D, we illustrate some significant differences here. In VADER, sentiment scores also differed across racial groups, with Indian images generally receiving lower scores and Black images often receiving higher scores. In competence, Asian images generally received higher or comparable scores, while Indian and Middle Eastern images often received lower scores. In warmth, Asian and White images tended to receive lower scores, while Black and Middle Eastern images often received higher scores. These race-related patterns further support the usefulness of SCM metrics, because they reveal different stereotypes that cannot be reduced to sentiment polarity alone.

Overall, these results show that LVLMs exhibit stereotypes across gender and race. Rather than only asking whether a model response is positive or negative, SCM allows us to examine which type of social meaning is assigned to each group across multiple stereotype dimensions.

5.4 Differences between Models

Architecture do not independently explain stereotype levels. Our results also show that stereotype expression differs across models, but these differences cannot be explained by architecture or parameter size alone. Across the three metrics, different models showed different frequencies of significant stereotypes. For VADER, Pixtral-12B showed the highest frequency of significant stereotype tests. For competence, Pixtral-12B again showed the highest frequency. Meanwhile, for warmth, Llama-90B showed the highest.

However, these patterns do not form a simple architecture-level trend. Models with similar architectural properties did not necessarily show similar stereotype patterns. For example, Llama 3.2 and InstructBLIP share related Llama-family language model backbones, but they showed opposite trends when parameter size increased. Similarly, Pixtral and Qwen both introduce visual information as input tokens through vision encoder-based modules, but they also showed different patterns.

Parameter size also did not have a consistent independent effect. In the Llama and Qwen families, larger models tended to show more significant stereotypes in competence and warmth. In contrast, InstructBLIP and Pixtral often showed fewer significant stereotypes as model size increased. This suggests that scale interacts with model-specific

factors such as backbone language model, vision-language alignment strategy, training data, and safeguards. Therefore, we conclude that neither model architecture nor parameter size alone sufficiently explains stereotype expression in LVLMs. Instead, stereotypes appear to emerge from interactions among multiple model-specific factors.

6 Conclusion

In this paper, we introduced a comprehensive evaluation framework that adopts the SCM of social psychology and moves beyond sentiment-based assessments of stereotypes. We also presented BASIC, a novel benchmark designed to isolate and evaluate the role of clothing color in the formation of stereotypes by eight LVLMs.

Our empirical analysis revealed that color, alongside gender and race, significantly influences model outputs in terms of perceived competence and warmth. We demonstrated that SCM-based metrics provide a more nuanced and robust lens through which to capture stereotypical associations, compared to conventional sentiment measures that safeguard mechanisms may distort. Additionally, our cross-model comparisons suggest that neither architectural similarity nor parameter scale alone accounts for stereotypes. Instead, we observed complex interactions between model-specific factors that collectively shape the stereotypes.

These findings underscore two points: (1) the adoption of semantically informed evaluation methods when measuring stereotypes and (2) the need for more careful consideration of visual attributes such as color. While sentiment-based metrics have been widely used in prior work, they are often influenced by models' safety filters or general positivity, which may obscure the presence of stereotypes. SCM-based metrics capture structured dimensions of social perception, enabling a more precise and interpretable analysis. We also find that clothing color should not be treated as a mere background element, but rather as a socially meaningful visual cue that can influence model responses. We hope that BASIC and the SCM-based metrics will serve as practical and extensible tools for future research seeking to uncover, quantify, and ultimately mitigate the stereotype in LVLMs. As LVLMs continue to evolve and integrate into everyday applications, the ability to evaluate stereotypes across both linguistic and visual modalities will become increasingly essential in the research community.

Limitations

While our study presents SCM-based evaluation metrics and introduces BASIC, a benchmark developed to assess stereotypes in LVLMs, three limitations remain. First, our controlled design enables a focused analysis of clothing color, but it does not exhaust the broader space of visual attributes or higher-order attribute interactions. This study was designed to identify whether individual visual and social attributes produce systematic SCM-related shifts in LVLM outputs, providing a foundation for subsequent analyses of how these attributes jointly shape stereotype expression. We examined three clothing colors based on prior studies of human perception, but other colors (e.g., yellow or green) may produce different stereotype patterns. Beyond clothing color, visual elements such as facial expressions, brightness, or posture may also influence model outputs and interact with color stereotypes.

Second, our study prioritizes scalable and consistent evaluation across a large combinatorial dataset. We analyze approximately 140K generated responses from eight LVLMs across multiple race, gender, and clothing-color conditions, where reliable human validation would require balanced coverage across models and attribute combinations. Moreover, validating warmth and competence is not simply a matter of collecting intuitive preference ratings; it requires annotators to consistently distinguish between two theoretically grounded SCM dimensions and evaluate subtle stereotype-related signals in free-form model outputs. A small random annotation set could serve as a useful sanity check, but it would not fully establish whether the metric captures model-specific and attribute-specific variation across the full dataset. Future work could complement this scalable evaluation with carefully stratified human annotation.

Third, our findings only reveal a correlation between model architecture and stereotypes, not a causal relationship. Identifying causality would require controlling factors such as training data and safeguards, which typically necessitates pretraining from scratch and is prohibitively resource-intensive. We call for future work to uncover the architectural causes of stereotypes in LVLMs.

Ethical Considerations

For the selection of gender and race in BASIC benchmark, we acknowledge that there is a broader spectrum of gender and race beyond those considered in this study. As our aim is to experiment with LVLMs with various genders, races, and colored images, we made this selection solely for experimental purposes. We believe that our method can be easily generalizable to other gender and race groups because our method does not depend on specific gender or race groups. Also, we want to emphasize that we did not intend to exclude any other gender or race groups from the experiment.

The use of Large Language Models

We used AI assistance tools during the writing process of this manuscript. Specifically, we employed Grammarly for grammar checking, and GPT-4o for language polishing and improving clarity of expression. These tools were used for editorial purposes.

A Generation procedure of BASIC

Figure 2 shows the entire pipeline for generating BASIC benchmark. In this appendix, we provide detailed prompts and generation settings for each step.

A.1 Step 1: Constructing Occupation List

Table 4 lists all 102 occupations used in our image generation experiments. These professions were selected to cover a diverse range of domains including medicine, engineering, arts, public service, and manual labor, enabling robust analysis across various social roles.

A.2 Step 2: Creating action

We used the following prompts for generating actions for each occupation.

System prompt:

```
You are an NLP assistant whose
purpose is to generate prompts in
a specific format.
```

User prompt:

```
Generate 20 prompts in the given
format for the given occupation:
{TARGET_OCCUPATION}       Each
prompt should be in the format "A
<occupation> doing <action>" with
no more than 20 words per prompt.
Each prompt has a different,
gender-neutral, simple-to-sketch
<action> that is relevant to
the given occupation.  Choose
actions that make it easy to
guess occupation of <subject>
ONLY from <action>. Output one
prompt on each line. Do NOT print
ANY additional information.
```

A.3 Step 3: Generating Seed Images

For each pair of occupation and prompt, we first create a single seed portrait of an Asian man wearing pure-white attire. Generation is performed

Figure 2: Process of Image Generation in BASIC

with the Stable Diffusion XL text-to-image pipeline (`stabilityai/stable-diffusion-xl-base-1.0, fp16`) on one of two NVIDIA A6000 GPUs, using 50 inference steps, a guidance scale of 9.0, and a resolution of 1024 × 1024.

We designed the prompts to control for three key attributes: **occupation**, **clothing color**, and **demographic traits** (race and gender). The template prompt for generating seed image is as follows:

```
Asian       man,     {OCCUPA-
TION_PROMPT},    wearing    pure
white clothes, gray background,
professional photography, high
detail, high quality
```

For example, a prompt for doctor is as follows:

```
Asian   man,   a   confident   and
professional doctor standing in
a  hospital  corridor,  wearing
pure white clothes, completely
white outfit, gray background,
professional photography, high
detail, high quality
```

To reduce visual noise and confounds, we applied a consistent negative prompt for all generations to avoid low quality or undesired attributes:

```
poor  quality,  low  resolution,
bad   anatomy,   worst   quality,
disfigured,    different   pose,
different  background,  colored
clothes, any color except white
```

A.4 Step 4: Controlling Gender and Race

After creating the seed image, the seed image is then passed to the Stable Diffusion XL Image-to-Image pipeline (`stabilityai/stable-diffusion-xl-base-1.0`) with strength parameter of 0.7. To generate the remaining 11 race-gender combinations in the Cartesian product {Asian, Black, Indian, Latino, Middle Eastern, White} × {man, woman}, we applied the pipeline for 11 times, except for Asian male images. Inspired by previous work (Howard et al., 2024), we also used the same terms Black/White to represent African-American/Caucasian people. This yields 12 white-clothing images per occupation.

We slightly modified the prompt used in Step 3 and used it as prompts for generation. We replaced 'Asian' and 'man' with placeholders **race** and **gender**, as follows:

```
{RACE}  {GENDER},  {PROFES-
SION_PROMPT},    wearing   pure
white clothes, gray background,
professional  photography,  high
detail, high quality
```

We used the same negative prompts to reduce visual noise and confounds, as in Step 3.

A.5 Step 5: Controlling Color

Each of the 12 white images is then converted to blue and red images. We used the same image-to-image pipeline as in Step 4, with different hyperparameters: we set strength as 0.8 and guidance

Astronaut	Audiologist	Blacksmith	Bricklayer

Real-estate Developer	Receptionist	Roofer	Scientist
Security Guard	Soldier	Telemarketer	Tennis Player
Veterinarian	Waiter		

Table 4: Full list of 102 occupations used in our dataset

as 11. Similar to Step 4, we slightly modified our prompts as follows, by introducing a placeholder of **clothing color**.

> *{RACE} {GENDER}, {PROFES-SION_PROMPT}*, wearing *{CLOTH-ING_COLOR}*, gray background, professional photography, high detail, high quality

Also, as color-aware negative prompts can prevent leakage into unwanted colors, we modified negative prompts as follows:

> poor quality, low resolution, bad anatomy, worst quality, disfigured, different pose, different background, colored clothes, any color except *{TAR-GET_COLOR}*

A.6 Step 6: Filtering

As a result, we obtain 36 images per occupation and its scene (or action). We then applied filtering for ensuring semantic similarity and avoiding NSFW. For both filtering, we used CLIP (openai/clip-vit-base-patch32).

B Human Validation

To ensure the quality and appropriateness of the generated dataset, we conducted a human valida-tion on 10% pairs randomly sampled from the en-tire dataset. Two of the authors independently an-notated each paired dataset. Specifically, this val-idation examined (1) whether the images appro-priately reflect the intended manipulation (gender, color, and race), and (2) whether non-target visual elements are held constant across each pair.

B.1 Assessment of Intended Attributes

To evaluate whether each target attribute was clearly manifested in the images, we evaluated im-age groups corresponding to gender (2 conditions per a group of images), color (3 conditions), and race (6 conditions). We asked the following ques-tion:

> Do these images manifest the intended difference in (gender/color/race) in a way that is attributable to that factor?

Evaluators rated each group using 5-point Lik-ert scale: from strongly appropriate (5 points) to strongly inappropriate (1 point). As shown in Ta-ble 5, evaluators mostly agreed that the images successfully manifested the conditions.

	Average Score	Cohen's κ
Gender	4.92 ($\pm$ 0.27)	0.54
Color	4.23 ($\pm$ 0.78)	0.79
Race	4.79 ($\pm$ 0.41)	0.70

Table 5: Average scores and Cohen's kappa (κ) for human evaluation of intended attribute reflection

	Average Score	Cohen's κ
Gender	4.07 ($\pm$ 0.57)	0.64
Color	4.09 ($\pm$ 0.53)	0.60
Race	4.08 ($\pm$ 0.52)	0.55

Table 6: Average scores and Cohen's kappa (κ) for human evaluation of visual consistency

B.2 Assessment of Visual Consistency

To verify that only the intended attribute was manipulated while all other elements remained consistent, we evaluated the consistency of non-target visual elements (e.g., background, pose) across each image group. We asked the following question:

```
Aside from (gender/color/race),
do these images show consistency
in other visual aspects?
```

Evaluators rated each group using 5-point Likert scale: from strongly consistent (5 points) to strongly inconsistent (1 point). As shown in Table 6, evaluators moderately agreed that the generated images showed high consistency regarding other visual aspects.

C Experimental Setup

We called eight LVLMs with following methods. For Llama, Qwen, and Pixtral models, we used OpenRouter API[6] for generating responses. In total, our experiment consumed over 160 million tokens, costing around USD 350. For InstructBLIP, we called `transformers` library: `salesforce/instructblip-vicuna-7b` and `salesforce/instructblip-vicuna-13b`. All experiments were conducted in a Python 3.10.16 environment with `diffusers` 0.25.1,

---

[6]https://openrouter.ai

`transformers` 4.49.0, `scipy` 1.15.1, and `torch` 2.1.2.

Also, we set the following parameters to ensure reproducibility of our experiment when the models allow setting these parameters. For temperature, we used 0 for deterministic response. For maximun number of tokens in generation, we used 1024.

D Detailed Result on race

Tables from 7 to 9 show the detailed results of race.

VADER: Stereotype levels were found to differ significantly across race. In most models, the result shows that Indian received the lowest scores (row 6, 10, 14, 16), followed by four race attributes with comparable scores: Middle Eastern, Asian, Latino, and White. Black consistently scored the highest (row 5, 10-13). For instance, the difference between Black and Indian was statistically significant (row 10; $p < 0.05$ except for Qwen 7B)

Competence: Regarding race, we observed a higher frequency of competence-related stereotypes compared to VADER. Moreover, stereotype levels differed significantly across race. In most models, the result shows that Indian and Middle Eastern groups showed the lowest values. Latino, Black and White showed higher score than those two. Lastly, Asian received the highest or comparable scores to White. For instance, Asian showed higher competence than Indian (row 10; $p < 0.001$ except for Qwen 7B) and Middle Eastern (row 19; $p < 0.001$ for all). PMI result revealed a similar phenomenon; Asians were associated with high competence words such as PRECISE, SUITABLE, PREPARED. Also, Indian and Eastern were associated with high competence words such as INTRICATE.

Warmth: Regarding Race, we observed a higher frequency of stereotypes in warmth compared to VADER. Moreover, stereotype levels differed significantly across race. In most models, the result shows that Asian and White showed the lowest scores, followed by Latino and Indian. Black and Middle Eastern received the highest scores. For instance, Asian received lower scores (row 5-9), whereas Middle Eastern received relatively higher scores (row 8, 15, 17, 19). PMI result revealed a similar phenomenon; Middle Eastern were associated with high warm words such as FRIENDLY, STYLISH, ACTIVELY.
