Do We Really Need to Approach the Entire Pareto Front in Many-Objective Bayesian Optimisation?

Abstract

Many-objective optimisation, a subset of multi-objective optimisation, involves optimisation problems with more than three objectives. As the number of objectives increases, the number of solutions needed to adequately represent the entire Pareto front typically grows substantially. This makes it challenging, if not infeasible, to design a search algorithm capable of effectively exploring the entire Pareto front. This difficulty is particularly acute in the Bayesian optimisation paradigm, where sample efficiency is critical and only a limited number of solutions (often a few hundred) are evaluated. Moreover, after the optimisation process, the decision-maker eventually selects just one solution for deployment, regardless of how many high-quality, diverse solutions are available. In light of this, we argue an idea that under a very limited evaluation budget, it may be more useful to focus on finding a single solution of the highest possible quality for the decision-maker, rather than aiming to approximate the entire Pareto front as existing many-/multi-objective Bayesian optimisation methods typically do. Bearing this idea in mind, this paper proposes a single point-based multi-objective search framework (SPMO) that aims to improve the quality of solutions along a direction that leads to a good tradeoff between objectives. Within SPMO, we present a simple acquisition function, called expected single-point improvement (ESPI), working under both noiseless and noisy scenarios. We show that ESPI can be optimised effectively with gradient-based methods via the sample average approximation (SAA) approach and theoretically prove its convergence guarantees on acquisition optimisation under the SAA. We also empirically demonstrate that the proposed SPMO is computationally tractable and outperforms state-of-the-arts on a wide range of benchmark and real-world problems.

1 Introduction

Multi-objective optimisation problems (MOPs) (Emmerich & Deutz, 2018; Zheng & Wang, 2024) involve scenarios where multiple objectives need to be optimised simultaneously. Unlike single-objective optimisation problems which typically have a single optimal solution, in MOPs there is a set of optimal solutions known as Pareto optimal solutions. The corresponding points in the objective space form what is known as the Pareto front. In general, a multi-objective optimisation algorithm aims to generate a set of solutions that well approximate the Pareto front, from which the decision-maker chooses a solution to deploy based on their preferences.

In modern applications, optimisation is becoming increasingly complex, with a growing number of requirements and objectives that need to be considered at the same time (Matrosov et al., 2015; Hierons et al., 2020; Lin et al., 2025). Taking the car cab design as an example, there are up to nine objectives to be optimised (Deb & Jain, 2013), including cabin space, fuel efficiency, acceleration time, and road noise at various speeds. This has given rise to a new research topic, many-objective optimisation, focusing on MOPs involving more than three objectives (Ishibuchi et al., 2008; Li et al., 2015a).

At the same time, many real-world multi-/many-objective optimisation problems are black-box and costly in terms of solution evaluation. This is evident across a range of fields, including chemistry (Park et al., 2018; Shields et al., 2021; Dunlap et al., 2023), materials science (Liang et al., 2021; Low et al., 2024; Peng et al.,

2025), and transportation (Deb & Jain, 2013; Jain & Deb, 2013a; Cheaitou & Cariou, 2019; Deb et al., 2009). For example, in vehicle design optimisation, it can take about 20 hours to evaluate a vehicle design (Youn et al., 2004; Daulton et al., 2021). To tackle such problems, multi-objective Bayesian optimisation (MOBO) is a very effective approach (Garnett, 2023), along with other alternatives (e.g., surrogate-assisted evolutionary algorithms (Jin, 2011; Liang et al., 2024)). Over the past decades, a variety of effective MOBO methods have emerged, including scalarisation-based methods (Knowles, 2006; Paria et al., 2020; Lin et al., 2022) which convert a multi-objective problem into a number of single-objective problems, and Pareto-based methods which consider Pareto dominance relations over objectives (Daulton et al., 2020; Emmerich et al., 2006; Tu et al., 2022). Most works aim to find a good approximation of the entire Pareto front.

However, with the increase of the objective number, the number of solutions needed to adequately represent the problem's Pareto front typically grows substantially. For example, for a 10-objective problem, it normally needs 220 points (i.e., $\binom{12}{3}$) even if only three divisions on each objective are considered (Das & Dennis, 1998). This difficulty is especially pronounced in Bayesian optimisation, where often only a few hundred solutions can be generated and evaluated. With such a limited budget, it is highly unlikely for an optimisation algorithm to reach or even be close to the Pareto front. On top of that, after the optimisation process, the decision-maker eventually selects just one solution to deploy, regardless of how many high-quality, diverse solutions are provided.

Given the above, this paper argues an idea that under a very limited evaluation budget, it may be more useful to focus on finding a single solution of the highest possible quality for the decision-maker, rather than aiming to approximate the entire Pareto front. That is, we may not need to care about diversifying solutions to represent the entire Pareto front, but focus on improving the quality of a single solution. Figure 1 illustrates this idea in a bi-objective case. As can be seen from the figure, in contrast to aiming for a set of diversified solutions which existing MOBO methods typically do (Li et al., 2025a; Lin et al., 2022), our method aims for a single solution with better convergence (i.e., closer to the Pareto front). Although it may yield a worse *hypervolume* (HV) value (Zitzler & Thiele, 1999) compared to the diverse solution set obtained by existing methods, it may be more likely to be chosen by the decision-maker as it achieves a more favourable trade-off among the objectives.

Figure 1: An illustration of our idea in a bi-objective case, in comparison with existing methods that aim to search for the entire Pareto front. The red points represent (nondominated) solutions that existing methods may obtain, and the blue point represents what our method aims for. It can be seen that the red points are much more diversified, hence, as a whole, having a better hypervolume (HV) value (Zitzler & Thiele, 1999). However, the blue point has better convergence (i.e., closer to the Pareto front) than any single red point, which may be more likely to be preferred by the decision-maker.

Bearing this idea in mind, this paper proposes a single point-based multi-objective search framework, called SPMO. The contributions of this work can be summarised as follows.

- We propose a novel MOBO search framework that does not aim to approximate the entire Pareto front, but rather focuses on improving the quality of solutions along a single direction that leads to a good tradeoff between objectives.

- Within SPMO, we present a simple acquisition function, called Expected Single-Point Improvement (ESPI). We show that ESPI can be optimised effectively with gradient-based methods via the sample average approximation (SAA) approach from Balandat et al. (2020) and also theoretically prove its theoretical convergence guarantees on acquisition optimisation under the SAA.

- We consider both noiseless and noisy cases, resulting in two versions of the proposed ESPI.

- We verify SPMO through an extensive experimental study, including in comparison with various state-of-the-arts, under both sequential and batch optimisation settings, through sensitivity analysis, with different metrics embedded, and on a range of benchmark and real-world problems.

2 Background and Related Work

2.1 Background

Many-Objective Optimisation. Many-objective optimisation, a subset of multi-objective optimisation, refers to an optimisation scenario having more than three objectives to be considered. Without loss of generality, this paper considers the problem of minimising a vector-valued function: $\boldsymbol{f}(\boldsymbol{x}) : \mathcal{X} \to \mathbb{R}^m$, where $\boldsymbol{x} \in \mathcal{X}$ ($\mathcal{X} \subset \mathbb{R}^d$) and m is the number of objectives. In multi-/many-objective optimisation, a solution $\boldsymbol{x}_1$ is said to dominate $\boldsymbol{x}_2$, denoted by $\boldsymbol{x}_1 \prec \boldsymbol{x}_2$, if $\forall i \in \{1, ..., m\}$, $f_i(\boldsymbol{x}_1) \leq f_i(\boldsymbol{x}_2)$ and $\exists j \in \{1, ..., m\}$, $f_j(\boldsymbol{x}_1) < f_j(\boldsymbol{x}_2)$. If a solution $\boldsymbol{x}_1 \in \mathcal{X}$ is not dominated by any other solution, then $\boldsymbol{x}_1$ is said to be Pareto optimal. The collection of Pareto optimal solutions of a problem is called the Pareto set, and its mapping to the objective space is called Pareto front.

Bayesian Optimisation (BO). BO is a sample-efficient global optimisation approach that builds a probabilistic surrogate, typically a Gaussian process (GP), and uses an acquisition function $\alpha : \mathcal{X} \to \mathbb{R}$ to decide which points to evaluate. In this work, we model each objective with an independent Gaussian process $f_i \sim \mathcal{GP}(m_i(\boldsymbol{x}), k_i(\boldsymbol{x}, \boldsymbol{x}'))$, where $m_i(\boldsymbol{x}) : \mathcal{X} \to \mathbb{R}$ is the ith mean function, and $k_i(\cdot, \cdot) : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ is the ith covariance function. Given n observed points $\mathcal{D} = \{(\boldsymbol{x}^{(t)}, \boldsymbol{y}^{(t)})\}_{t=1}^n$ where $\boldsymbol{y}^{(t)} = \boldsymbol{f}(\boldsymbol{x}^{(t)}) + \boldsymbol{\zeta}^{(t)}$ and the noise $\boldsymbol{\zeta}^{(t)} \sim \mathcal{N}(\boldsymbol{0}, \text{diag}(\boldsymbol{\sigma}_\zeta^2))$, the posterior distribution of the ith objective at a new location $\boldsymbol{x}$ is a Gaussian distribution: $f_i(\boldsymbol{x})|\mathcal{D} \sim \mathcal{N}(\mu_i(\boldsymbol{x}), \sigma_i^2(\boldsymbol{x}))$ where $\mu_i(\boldsymbol{x})$ and $\sigma_i^2(\boldsymbol{x})$ are the posterior mean and variance at $\boldsymbol{x}$, respectively. Detailed expressions of the posterior mean and variance are given in Appendix A.

2.2 Related Work

Over the past decades, various MOBO methods have been proposed (Konakovic Lukovic et al., 2020; Daulton et al., 2022a). They can be loosely divided into scalarisation-based and Pareto-based methods. In scalarisation-based methods (Knowles, 2006; Paria et al., 2020), a multi-objective problem is converted into a number of single-objective problems (Chugh, 2020). Hence, one can leverage acquisition functions (Lai & Robbins, 1985) from single-objective BO to decide which point to evaluate. For instance, ParEGO (Knowles, 2006), TS-TCH (Paria et al., 2020), and Pareto set learning (PSL) (Lin et al., 2022) use expected improvement (EI) (Jones et al., 1998), Thompson sampling (TS) (Thompson, 1933), and upper confidence bound (UCB) (Lai & Robbins, 1985), respectively. In contrast, Pareto-based methods consider Pareto dominance relations over objectives and directly solve a multi-objective problem without converting it into a number of single-objective subproblems (Emmerich et al., 2006; Tu et al., 2022). A popular idea is to use HV as maximising the HV value is equivalent to finding the entire Pareto front (Shang et al., 2020). Expected hypervolume improvement (EHVI) is commonly used in MOBO (Couckuyt et al., 2014; Daulton et al., 2020; 2021). Another idea is to leverage information theory to guide exploration toward regions likely contributing to the Pareto front. For instance, joint entropy search (JES) (Tu et al., 2022) selects points that maximise the joint information gain for optimal inputs (i.e., the approximated Pareto set) and outputs (i.e., the approximated Pareto front). All of the above methods aim to approach the entire Pareto front.

It is worth noting that, similar to our approach, a few studies do not attempt to approximate the entire Pareto front. Some methods instead target a specific region of the front, such as the central area (Gaudrie et al., 2018; 2020; Binois et al., 2020). Another line of work incorporates decision-maker preferences by dynamically adjusting the target region based on elicited or updated preferences during optimisation (Abdolshah et al., 2019; Astudillo & Frazier, 2020; Ozaki et al., 2024; Ip et al., 2025). In contrast, our method mainly assumes no prior knowledge of decision-maker preferences and seeks to identify a high-quality trade-off solution across objectives. A more detailed discussion of related work can be found in Appendix C.

Algorithm 1: Single Point-based Multi-Objective (SPMO) Framework

---

Input: $\boldsymbol{f}$: Expensive black-box problem with m objectives; T: Maximum number of evaluations;
$\quad\quad g$: Metric that measures the quality of a single point; α: Acquisition function;
$\quad\quad \mathcal{D} := \{(\boldsymbol{x}^{(t)}, \boldsymbol{y}^{(t)})\}_{t=1}^{n_0}$: Initial observed solutions.

1 for $t = n_0 + 1 : T$ **do**

2 $\quad$ $GPs \leftarrow$ Train $\mathcal{GP}s(\mathcal{D})$ $\quad\quad\quad\quad\quad\quad\quad\quad$ // Train m Gaussian process models

3 $\quad$ $\boldsymbol{x}^{(t)} \leftarrow \arg\max_{\boldsymbol{x} \in \mathcal{X}} \alpha(\boldsymbol{x}; g, GPs)$ $\quad\quad$ // Maximise the acquisition function based
$\quad\quad\quad\quad\quad\quad\quad\quad\quad\quad\quad\quad\quad\quad\quad\quad\quad\quad\quad$ on the single-point quality metric $g(\cdot)$

4 $\quad$ $\boldsymbol{y}^{(t)} \leftarrow \boldsymbol{f}(\boldsymbol{x}^{(t)}) + \boldsymbol{\zeta}^{(t)}$ $\quad\quad\quad\quad\quad\quad$ // Evaluate the solution $\boldsymbol{x}^{(t)}$

5 $\quad$ $\mathcal{D} \leftarrow \mathcal{D} \cup \{(\boldsymbol{x}^{(t)}, \boldsymbol{y}^{(t)})\}$ $\quad\quad\quad\quad\quad\quad$ // Augment the observed solutions

Output: $\mathcal{D}$: Observed solutions.

---

3 The Proposed Method

In this section, we first give the proposed MOBO framework. We then present the considered acquisition function (called ESPI), which is based on a simple distance-based metric. We note that analytically solving ESPI is not feasible, and thus consider its Monte Carlo approximation. Lastly, we consider ESPI under noisy cases, namely noisy ESPI (NESPI), and also its MC approximation.

Single Point-based Multi-Objective (SPMO) Framework. Algorithm 1 gives the procedure of the proposed SPMO framework. As can be seen, SPMO is very similar to a standard MOBO algorithm, except for the step of maximising the acquisition function based on a single-point quality metric (line 3). In principle, any metric that can reflect the quality of a solution in achieving a good trade-off between objectives can be adopted. This includes distance-based, scalarisation-based, and HV-based metrics, such as the weighted sum and augmented Tchebycheff (Miettinen, 1999) with a fixed weight vector (e.g., $(\frac{1}{m}, \ldots, \frac{1}{m}) \in \mathbb{R}^m$ in the m-objective case), as well as the HV of a single solution. Here, we use a simple distance-based metric as the default choice, and compare it with different metrics in our experiments (Section 6; details in Appendix F.5).

Single-Point Improvement (SPI). We consider the distance of solutions to a utopian point: $g(\boldsymbol{f}(\boldsymbol{x}), \boldsymbol{z}^*) = \|\boldsymbol{f}(\boldsymbol{x}) - \boldsymbol{z}^*\| = \sqrt{\sum_{i=1}^{m}(f_i(\boldsymbol{x}) - z_i^*)^2}$, where m denotes the number of objectives, and $\boldsymbol{z}^* = (z_1^*, z_2^*, \ldots, z_m^*)$ is a utopian point, i.e., $z_i^* \leq \min_{\boldsymbol{x} \in \mathcal{X}} f_i(\boldsymbol{x})$. In many real-world cases, the utopian value of an objective can be loosely estimated, for example, by assuming idealised conditions such as zero cost, time or error (Branke et al., 2008). In our experimental evaluation, we perform a sensitivity analysis on the choice of the utopian point, and it shows that substantially different settings can yield consistent results.

We first consider noiseless cases, i.e., $\bar{\boldsymbol{y}}^{(t)} = \boldsymbol{f}(\bar{\boldsymbol{x}}^{(t)})$. Let $\bar{\mathcal{D}} = \{(\bar{\boldsymbol{x}}^{(t)}, \bar{\boldsymbol{y}}^{(t)})\}_{t=1}^{n}$ be n observed points and $\bar{X} = \{\bar{\boldsymbol{x}}^{(t)}\}_{t=1}^{n}$ be the set of all the observed decision vectors in $\bar{\mathcal{D}}$. For any point $\boldsymbol{x} \in \mathcal{X}$, we define the single-point improvement (SPI) as:

$$I_{SP}(\boldsymbol{f}(\boldsymbol{x}); g^*, \boldsymbol{z}^*, \bar{\mathcal{D}}) = \max\Big(0, \, g^* - \|\boldsymbol{f}(\boldsymbol{x}) - \boldsymbol{z}^*\|\Big), \tag{1}$$

where $g^* = \min_{\boldsymbol{x} \in \bar{X}} g(\boldsymbol{f}(\boldsymbol{x}), \boldsymbol{z}^*)$.

Expected Single-Point Improvement (ESPI). We now present ESPI to account for the posterior distribution $p(\boldsymbol{f}|\bar{\mathcal{D}})$. Suppose that we independently model each objective f_i as a Gaussian process based on $\bar{\mathcal{D}}$. Then, the posterior of each f_i at a new location $\boldsymbol{x}$ is a Gaussian random variable, i.e., $f_i(\boldsymbol{x})|\bar{\mathcal{D}} \sim \mathcal{N}(\mu_i(\boldsymbol{x}), \sigma_i^2(\boldsymbol{x}))$, where $f_1, \ldots, f_m$ are mutually independent Gaussians. Let $\eta_i := f_i - z_i^*$. Then we obtain $\eta_i \sim \mathcal{N}(\mu_i(\boldsymbol{x}) - z_i^*, \sigma_i^2(\boldsymbol{x}))$ which is a Gaussian as well. The proposed ESPI is defined as:

$$\begin{aligned}
\alpha_{\text{ESPI}}(\boldsymbol{x}) &= \mathbb{E}\big[I_{SP}(\boldsymbol{f}(\boldsymbol{x}); g^*, \boldsymbol{z}^*, \bar{\mathcal{D}})\big] \\
&= \mathbb{E}_{p(\boldsymbol{\eta})}\big[\max(0, \, g^* - \|\boldsymbol{\eta}\|)\big]
\end{aligned} \tag{2}$$

An illustration of ESPI in a bi-objective case is given in Figure 6 of Appendix B for aiding understanding. Note that the integral in Eq. 2 cannot be solved analytically as it involves the distribution of $\|\boldsymbol{\eta}\|$, whose PDF and

---

151 CDF have no closed-form expressions and are typically computed via numerical methods (Imhof, 1961; Ruben,
152 1962; Das, 2025). Hence, we use the MC integration with samples from the posterior $\tilde{\boldsymbol{f}}_t(\boldsymbol{x}) \sim p(\boldsymbol{f}(\boldsymbol{x})|\bar{\mathcal{D}})$ for
153 $t = 1, \ldots, N$ to estimate Eq. 2:

$$\alpha_{\text{ESPI}}(\boldsymbol{x}) \approx \hat{\alpha}_{\text{ESPI}}(\boldsymbol{x}) = \frac{1}{N} \sum_{t=1}^{N} I_{SP}(\tilde{\boldsymbol{f}}_t(\boldsymbol{x})|g^*, \boldsymbol{z}^*, \bar{\mathcal{D}}) \tag{3}$$

154 **Noisy Expected Single-Point Improvement (NESPI).** In the real world, it is not uncommon to
155 encounter an optimisation problem with noises: $\boldsymbol{y}^{(t)} = \boldsymbol{f}(\boldsymbol{x}^{(t)}) + \boldsymbol{\zeta}^{(t)}$, where $\boldsymbol{\zeta}^{(t)} \sim \mathcal{N}(\boldsymbol{0}, \text{diag}(\boldsymbol{\sigma}_\zeta^2))$. In noisy
156 cases, simply using the observed best distance g^* may adversely affect the optimisation performance. Here,
157 we present an extension of ESPI, i.e., noisy ESPI (NESPI). Let $\mathcal{D} = \{(\boldsymbol{x}^{(t)}, \boldsymbol{y}^{(t)})\}_{t=1}^n$ be n observed points
158 and $X = \{\boldsymbol{x}^{(t)}\}_{t=1}^n$ be the set of all the observed decision vectors in $\mathcal{D}$. By considering the uncertainty in the
159 function values at X, the proposed NESPI is defined as:

$$\alpha_{\text{NESPI}}(\boldsymbol{x}) = \int \alpha_{\text{ESPI}}(\boldsymbol{x}|\hat{g}^*) p(\boldsymbol{f}|\mathcal{D}) d\boldsymbol{f} \tag{4}$$

160 where $\hat{g}^*$ denotes the smallest distance to the utopian point over $\boldsymbol{f}(X)$. Note that in noiseless cases, NESPI is
161 equivalent to ESPI. Additionally, ESPI and NESPI can be naturally extended to the parallel (batch) setting
162 by using sequential greedy approximation (Balandat et al., 2020).

163 Like in the noiseless case, the integral in Eq. 4 is also analytically intractable but can be approximated
164 using the MC integration. Let $\tilde{\boldsymbol{f}}_t(\boldsymbol{x}) \sim p(\boldsymbol{f}(\boldsymbol{x})|\mathcal{D})$ for $t = 1, \ldots, N$ be samples from the posterior, and let
165 $\hat{g}^* = \min_{\boldsymbol{x} \in X} \|\tilde{\boldsymbol{f}}_t(\boldsymbol{x}) - \boldsymbol{z}^*\|$ be the smallest distance to utopian point over the previously evaluated points
166 under the sampled function $\boldsymbol{f}^{\tilde{(t)}}(\boldsymbol{x})$. Then, $\alpha_{\text{NESPI}} \approx \frac{1}{N} \sum_{t=1}^N \alpha_{\text{ESPI}}(\boldsymbol{x}|\hat{g}^*, \boldsymbol{z}^*, \mathcal{D})$. Using the MC integration,
167 the inner expectation in α_{NESPI} can be computed simultaneously using samples from the joint posterior
168 $\tilde{\boldsymbol{f}}_t(\boldsymbol{x}, X) \sim p(f(\boldsymbol{x}, X)|\mathcal{D})$ over $\boldsymbol{x}$ and X:

$$\alpha_{\text{NESPI}}(\boldsymbol{x}) \approx \hat{\alpha}_{\text{NESPI}}(\boldsymbol{x}) = \frac{1}{N} \sum_{t=1}^{N} I_{SP}(\tilde{\boldsymbol{f}}_t; \hat{g}^*, \boldsymbol{z}^*, \mathcal{D}) \tag{5}$$

4 Optimising ESPI and NESPI

170 Having presented the MC estimators of ESPI and NESPI, we are now ready to optimise them.

171 **Differentiability.** The MC estimators of ESPI and NESPI ($\hat{\alpha}_{\text{ESPI}}(\boldsymbol{x})$ in Eq. 3 and $\hat{\alpha}_{\text{NESPI}}(\boldsymbol{x})$ in Eq. 5)
172 are differentiable with respect to $\boldsymbol{x}$. We are able to automatically compute exact gradients of the MC
173 estimators of ESPI and NESPI ($\nabla_{\boldsymbol{x}} \hat{\alpha}_{\text{ESPI}}(\boldsymbol{x})$ and $\nabla_{\boldsymbol{x}} \hat{\alpha}_{\text{NESPI}}(\boldsymbol{x})$) by leveraging the auto-differentiation in
174 modern computational frameworks. This facilitates efficient gradient-based optimisation of ESPI and NESPI.

175 **SAA Convergence Results.** The sample average approximation (SAA) approach (Kleywegt et al., 2002),
176 which addresses stochastic optimisation problems by using the MC simulation, has gained increasing popularity
177 and has become a standard technique in BO for optimising MC-based acquisition functions (Balandat et al.,
178 2020). By fixing the base samples, the SAA yields a deterministic acquisition function which enables using
179 (quasi-) higher-order optimisation algorithms to obtain fast convergence rates for acquisition optimisation.
180 We now give the theoretical convergence guarantees on acquisition optimisation under the SAA.

181 **Theorem 4.1.** *Suppose that $\mathcal{X}$ is compact and $\boldsymbol{f}$ has a multi-output GP prior whose mean and covariance*
182 *functions are continuously differentiable. Let $\alpha_{ESPI}^* := \max_{\boldsymbol{x} \in \mathcal{X}} \alpha_{ESPI}(\boldsymbol{x})$ denote the maximum of ESPI,*
183 *$S^* := \arg\max_{\boldsymbol{x} \in \mathcal{X}} \alpha_{ESPI}(\boldsymbol{x})$ denote the set of maximisers of α_{ESPI}, $\hat{\alpha}_{ESPI}^N(\boldsymbol{x})$ denote the deterministic function*
184 *via the base samples $\{\epsilon^{(t)}\}_{t=1}^N \sim \mathcal{N}(0, I_m)$. Suppose $\hat{\boldsymbol{x}}_N^* \in \arg\max_{\boldsymbol{x} \in \mathcal{X}} \hat{\alpha}_{ESPI}^N(\boldsymbol{x})$, then*

185 *(1) $\hat{\alpha}_{ESPI}^N(\hat{\boldsymbol{x}}_N^*) \to \alpha_{ESPI}^*$ a.s.*

186 *(2) $d(\hat{\boldsymbol{x}}_N^*, S^*) \to 0$ a.s., where $d(\hat{\boldsymbol{x}}_N^*, S^*) := \inf_{\boldsymbol{x} \in S^*} \|\hat{\boldsymbol{x}}_N^* - \boldsymbol{x}\|$.*

The proof of the theorem is given in Appendix D.1. This theorem indicates that one is able to optimise the MC estimator of the acquisition function ESPI to obtain a solution that converges almost surely to the optimal solution of the original acquisition function. For the noisy case NESPI, the theorem of the theoretical convergence guarantees on acquisition optimisation under the SAA (Theorem D.1), together with its proof, is provided in Appendix D.2.

5 Experimental Design

Compared Methods. To evaluate the proposed SPMO, we consider eight MOBO methods. These include one baseline method (Sobol (Sobol, 1967)), five methods that aim to approximate the entire Pareto front, and two methods that aim at the trade-off region of the Pareto front. The five methods consist of three scalarisation-based methods, ParEGO (Knowles, 2006) (along with its noisy variant NParEGO (Daulton et al., 2021)), TS-TCH (Paria et al., 2020), and PSL (Lin et al., 2022), and two Pareto-based methods, EHVI (Daulton et al., 2020) (along with its noisy variant NEHVI (Daulton et al., 2021)), and JES (Tu et al., 2022). For methods that do not aim at the entire Pareto front, we consider TS-TCH (Paria et al., 2020) with fixed weights, denoted as TS-TCH$^+$, and C-EHVI (Gaudrie et al., 2018; 2020). TS-TCH$^+$ uses equal weights to search for a good trade-off solution, and C-EHVI prefers the central region of the Pareto front. We would like to see whether these two methods are competitive with our method for identifying a well-balanced solution. For all EI-based methods, i.e., ParEGO, NParEGO, EHVI, NEHVI, C-EHVI and SPMO, we use the log version as suggested by Ament et al. (2023). Note that we only consider NESPI in this work, as it is equivalent to ESPI under noiseless cases.[1]

Benchmarks and Real-World Problems. For benchmark problems, we first choose two most widely scalable functions, DTLZ1 and DTLZ2 (Deb et al., 2005). However, their Pareto fronts are rather homogeneous, i.e., with a simplex shape. We then include their inverted versions, i.e., inverted DTLZ1 and inverted DTLZ2 (Deb & Jain, 2013). These problems do not include the one with convex Pareto fronts nor different objective scales. We thus add convex DTLZ2 and scaled DTLZ2 (Jain & Deb, 2013a). We also give the results of other DTLZ problems which have different features (e.g., degenerate and disconnected Pareto fronts) (Deb et al., 2005; Cheng et al., 2017) in Appendix F.1; those problems are widely used in many-objective optimisation (Deb & Jain, 2013; Li et al., 2014b;a; 2015b). Each problem is considered with 3, 5 and 10 objectives, following the practice in Deb & Jain (2013); Jain & Deb (2013a); Li et al. (2014a), and tested under both noiseless and noisy cases. We also consider three well-studied real-world problems (Tanabe & Ishibuchi, 2020), i.e., car side impact design (CSI) (Jain & Deb, 2013a), water resource planning (WRP) (Ray et al., 2001), and car cab design (Deb & Jain, 2013). CSI and WRP are noise-free problems with four and six objectives, respectively. The car cab design problem has nine objectives and involves four stochastic variables (out of the total seven variables) that introduce noise into the optimisation process, making it a natural noisy optimisation problem. For the other problems without noise, to make their noise cases, we use the additive zero-mean Gaussian noise with a standard deviation of 0.1, as suggested in Hernandez-Lobato et al. (2016); Jiang & Li (2025b). The details of the problem formulations are given in Appendix E.3.

Performance Metrics. The proposed method aims to find a single trade-off solution between objectives which has a high chance of being favoured by the decision-maker, and therefore requires the use of appropriate metrics to fairly evaluate our method (Li & Yao, 2019; Li et al., 2022). As such, we first consider two single-point-based metrics, i.e., the distance-based metric used in the proposed method (reported as log-distance for better visualisation) and the HV-based metric (Zitzler & Thiele, 1999), which measures the HV contribution of a solution. Note that the distance-based metric is used in the normalised objective space. We expect that our method performs well on the distance-based metric as we directly optimise it. Notably, we are not certain whether our method performs best on the single-point HV since we do not directly optimise it. On the other hand, since most of the compared methods aim to achieve a good approximation of the entire Pareto front, we also consider the HV of the whole (nondominated) solution set obtained. It is expected that our method performs poorly, compared to other methods since we only optimise one point, rather than maximising the HV of the whole set (see Figure 1). For the reference point of the two HV metrics, we followed the practice

---

[1]Although NEHVI is equivalent to EHVI under noiseless cases, the wall time of NEHVI is much higher than EHVI (see Table 28). Hence we consider EHVI and NEHVI under noiseless and noisy cases, respectively.

Table 1: Results of the distance-based metric (log distance) obtained by the SPMO and the peer methods on the benchmark problems with 5 objectives and the two real-world problems on 30 runs. The method with the best mean is highlighted in bold. The symbols "+", "∼" and "−" indicate that the method is statistically worse than, equivalent to and better than our SPMO, respectively.

Figure 2: Trajectories of the distance-based metric (log distance) obtained by the nine methods on the benchmark problems with 5 objectives and the two real-world problems. Each coloured line represents the mean metric value on 30 independent runs (after the initial samples, represented by the dashed grey line).

in Ishibuchi et al. (2018); Balandat et al. (2020); Chugh (2020); Daulton et al. (2020) (see detailed settings in Appendix E.2).

Budget and Statistical Validation. For all the methods, we allow a maximum of 200 evaluations, following the practice in Daulton et al. (2020; 2021); Konakovic Lukovic et al. (2020). To enable statistical comparisons, each optimisation was repeated 30 times. We use the Wilcoxon rank-sum test (Wilcoxon, 1992) at a significance level of $\alpha = 0.05$ and Holm-Bonferroni correction (Holm, 1979) to see if our method differs significantly from each peer method.

6 Experimental Results

We first report the results under noiseless cases, then under noisy cases and under batch settings. Next, we perform the sensitivity analysis of the utopian point used. Then, we compare the proposed framework working with different single-point metrics, e.g., the distance-based, weighted sum-based, Tchebycheff-based, and HV-based. We further investigate the performance of these metrics when preference information is available. Lastly, we give the acquisition optimisation wall time for all the algorithms.

Noiseless Cases. We begin our evaluation by considering the distance metric, for which we expect good performance obtained by our SPMO. Table 1 shows the results of SPMO and the peer methods on the benchmark problems with five objectives and the two real-world problems. Unsurprisingly, as can be seen from the table, our method significantly outperforms the other methods on all the problems. In addition, to understand the anytime performance, Figure 2 presents the trajectories of the distance-based metric obtained

Figure 3: Trajectories of the HV of the best solution (in terms of its HV value) obtained by the SPMO and the peer methods on the benchmark problems with 5 objectives and the two real-world problems. Each coloured line represents the mean metric value on 30 independent runs.

Figure 4: Spider chart of the best solution (in terms of its HV) obtained by the nine methods on the inverted DTLZ1 problem with 5 objectives in a typical run. Each axis in the spider chart represents one objective. Here, the objective values are multiplied by −1 in this minimisation problem, such that a solution with a larger area indicates better quality.

by the nine methods. As seen, SPMO demonstrates a clear advantage over the other methods, obtaining a better convergence rate from the very beginning.

We now compare the methods by the HV metric of a single solution. Table 2 shows the results of the best solution (in terms of its HV value) obtained by SPMO and the peer methods. As can be seen, SPMO is still very competitive, performing best on all the problems except DTLZ2, where EHVI obtains the best HV. In addition, to evaluate the anytime behaviour, Figure 3 presents the trajectories of the HV of the best solution obtained by the nine methods. The results indicate that SPMO generally outperforms the other methods and converges faster from the early stages of the optimisation process. To get a sense of what such a best-HV solution looks like, we use a spider chart to plot the solution on the five-objective inverted DTLZ1 problem in Figure 4. As seen, the solution of SPMO has the largest area, and it actually Pareto dominates the solutions of the other methods (i.e., better or at least equal on all five objectives).

Lastly, we consider the HV results of all the solutions obtained by the compared methods (Table 3). Interestingly, although SPMO does not aim to approximate the entire Pareto front, it still gets fairly good

Table 3: The HV of all the solutions obtained by the SPMO and the peer methods on the benchmark problems with five objectives and the two real-world problems on 30 independent runs. The method with the best mean HV is highlighted in bold. The symbols "+", "∼", and "−" indicate that a method is statistically worse than, equivalent to, and better than SPMO, respectively.

Figure 5: *Left:* Violin plots of the HV values of the best solution (with respect to its HV) obtained by all the methods on the car cab design problem in 30 independent runs. *Right:* The objective values (normalised and multiplied by −1) of the best solution (with the highest HV) obtained by each method on the cab design problem in a typical run.

results, outperforming the other methods on at least 3 out of the 7 problems. One explanation for this is that within very tight budget, searching for improving convergence of solutions may play a bigger part than searching for improving diversity, thus contributing more to the HV value.

For simplicity, we here only show the results of the benchmark problems with five objectives. Results on 3- and 10-objective problems can be found in Appendix F.1. A general pattern is that as the number of objectives increases, the advantages of SPMO become more pronounced. On the 3-objective problems, the differences between SPMO and the peer methods in terms of the two single-point metrics are relatively small, whereas on the 10-objective problems, the gaps in both metrics become substantially larger (see Figures 7 and 8 in the Appendix). Regarding the HV of all evaluated solutions, SPMO statistically outperforms the peer methods on at least 2 and 5 out of the 6 problems on the 3-objective and 10-objective cases, respectively.

Noisy Cases. We compare the proposed SPMO with the peer methods on the seven noisy benchmark and real-world problems. The results (the distance-based metric, two HV metrics, and convergence trajectories) are given in Appendix F.2. Like in the noiseless setting, SPMO significantly outperforms the peer methods on all the problems with respect to the single-point metrics (distance and HV). Regarding the HV of all the (nondominated) solutions obtained, SPMO achieves the best performance on the majority of the problems. Figure 5 shows the spider chart of the best solution (with respect to its HV) obtained by each algorithm in a typical run on the 9-objective car cab design problem. The violin plot of their HV values in 30 independent runs is given in the left panel for reference. As can be seen, the solution of SPMO is the best or close to the best on most of the objectives (except the first objective), thus having a clearly larger area.

Batch Setting. Previously, we considered the case in the sequential setting, where solutions are evaluated sequentially. Now we want to see if the proposed method works in the batch setting. Here, the batch size q is set to 5, a commonly used value (Lin et al., 2022; Jiang & Li, 2025b). As can be seen in Tables 14–16 and Figures 17–19 (Appendix F.3), similar to the results in the sequential setting, SPMO generally performs best.

On the single-point metrics, it achieves the smallest distance on all the problems and the highest HV on 5 out of the 6 problems (except on DTLZ2). As for the HV of all evaluated solutions, SPMO obtains the best HV on two problems and takes the second or third places on the remaining ones. This indicates that prioritising convergence is also very useful for many-objective problems in batch settings.

Sensitivity Analysis. A parameter needed in the proposed method is the utopian point. In our experiment, we set it to be the vector consisting of the best value on each objective (i.e., the problem's ideal point). However, in real life, the ideal point is usually unknown before the optimisation. Hence, we would like to investigate how much different utopian points affect the performance. In this context, we consider three other settings based on the problem's true ideal point. The first one is slightly better than the ideal point, i.e., with a difference of 0.01, the second is fairly better than the ideal point (i.e. 0.1), and the last one is significantly better than the ideal point (i.e. 1.0). The results are given in Appendix F.4.1. As can be seen, interestingly, SPMO with the three lower utopian points with different levels performs better than or at least equivalently to SPMO with our current setting. This indicates that 1) using the ideal point in the proposed method may not be the best choice (though it performs better than the other MOBO methods), and 2) SPMO's performance is robust to the choice of the utopian point and a liberal estimate is sufficient to achieve good results, e.g., considering zero cost in real-world cases.

Previously, we investigated SPMO using different utopian points based on the problem's true ideal point. However, in real-world applications, one may have very little knowledge about the optimisation problem. To further examine a more practical setting, we consider dynamically setting the utopian point based only on the observed solutions during optimisation. We consider four settings, where the observed objective values are first normalised and the utopian point is then set to $(-0.1, \ldots, -0.1)$, $(-0.2, \ldots, -0.2)$, $(-0.5, \ldots, -0.5)$, and $(-1.0, \ldots, -1.0)$, respectively. The results are reported in Appendix F.4.2. Overall, the dynamic settings achieve comparable performance to the setting using the problem's true ideal point. Moreover, using a more optimistic dynamic utopian point, e.g., $(-1.0, \ldots, -1.0)$, can even lead to better performance.

Comparison of Single-Point Metrics within SPMO. In the proposed SPMO framework, we employ a distance metric (i.e., the distance of a solution to the utopian point). It is worth noting that different metrics can be adopted provided that they can reflect the quality of a solution in achieving a good trade-off between objectives. We now consider three other well-known metrics, weighted sum, Tchebycheff scalarisation, and single-point HV, denoted by SPMO_{ws}, SPMO_{Tch}, and SPMO_{hv}, respectively. The equal weights $(\frac{1}{m}, \ldots, \frac{1}{m})$ are used in SPMO_{ws} and SPMO_{Tch}. The reference point of SPMO_hv is set to 1.1 times the observed Pareto front, since using a fixed reference point (e.g., $(1.1, \ldots, 1.1)$ for DTLZ2) can lead to zero acquisition values when no candidate solution dominates the reference point. We compare these four variants of SPMO. The results (given in Appendix F.5) show that SPMO (using the distance metric, denoted as SPMO_{dist}) performs in general better than SPMO_{ws}, SPMO_{Tch}, and SPMO_{hv}. It achieves the best statistical results on all the problems in terms of the HV of the best solution. It is interesting to see that SPMO_hv, which optimises the single-point hypervolume, performs relatively poorly. One possible reason for this is that the reference point constructed during the search may not be reliable when the optimisation focuses on only one solution rather than the whole solution set. As for the HV of all the solutions, SPMO_{dist} performs best on inverted DTLZ1 and convex DTLZ2, but performs relatively poorly on inverted DTLZ2 and CSI. A possible explanation is that other variants (e.g., SPMO_{hv}) have slower convergence and can be better in exploring different solutions, and thus perform better on relatively easy-to-converge problems.

Incorporating Preference Information into SPMO. Previously, we focused on the preference-free setting, where no prior knowledge of the decision maker's preferences is available. However, SPMO can naturally incorporate preference information into its single-point metrics. We extend the four metrics introduced above, i.e., SPMO_{dist}, SPMO_{ws}, SPMO_{Tch}, and SPMO_{hv}, to the preference-based setting. Given a weight vector $\boldsymbol{w}$, a preference-based distance metric can be defined as $\|\boldsymbol{w} \odot (\boldsymbol{y} - \boldsymbol{z})\|_2$, where $\odot$ denotes element-wise multiplication. Weighted-sum and Tchebycheff scalarisation can incorporate preference information directly through a weight vector. Regarding the single-point HV metric, given a reference point $\boldsymbol{r}$, preference-based single-point HV can be defined as $\prod_{i=1}^{m} \max(w_i(y_i - r_i), 0)$.

We consider a very different weight vector from the previous equal weights; that is $\boldsymbol{w} = (0.1, 0.2, \ldots, 0.1m)$ for an m-objective problem. Note that these weights will be normalised by their sum, i.e., $\boldsymbol{w} \leftarrow \boldsymbol{w} / \sum_{i=1}^{m} w_i$, to ensure that their sum is equal to 1.0. Similar to the previous comparison, we use the preference-based distance metric and preference-based single-point HV as the performance metrics. The results are given in Appendix F.6. As shown in the results, SPMO_{dist} generally performs better than the other variants. It obtains the best results on 6 out of the 7 problems in terms of the preference-based distance metric. Regarding preference-based single-point HV, SPMO_{dist} obtains the best results on 4 out of the 7 problems. Overall, the distance-based metric remains a robust choice.

Acquisition Optimisation Wall Time. Lastly, we present the wall time for optimising the acquisition function (i.e., determining a solution to be evaluated). The results (Appendix F.7) show that our method is among the fastest algorithms. When the number of objectives is 3 or 5, the time of all the methods is acceptable with a maximum of 98 seconds. As the number of objectives increases to 10, hypervolume-based methods become very expensive. For example, EHVI and NEHVI take about half an hour and more than 3 hours, respectively.[2] Note that although PSL takes only several minutes based on the initial samples, the hypervolume computation can take up to one day for a single evaluation when the number of non-dominated solutions becomes large in the 10-objective case. The proposed SPMO method shows high computational efficiency, achieving the lowest time requirement in four out of the six instances.

7 Discussion

7.1 Beyond Approximating the Entire Pareto Front in Many-Objective Optimisation

In general, multi-objective optimisation algorithms aim to generate a set of solutions that well approximates the entire Pareto front. However, the required number of solutions to well approximate the entire Pareto front could be exponentially large with respect to the number of objectives. This difficulty is particularly acute when the evaluation budget is very limited. Hence this work proposes the SPMO framework to find a single high-quality trade-off solution without approximating the entire Pareto front. Along the same lines, some methods in literature target a specific region of the front, such as the central region (Gaudrie et al., 2018; 2020; Binois et al., 2020), though they do not aim for a single trade-off solution.

Another related direction is to identify a small set of representative solutions that collectively cover many objectives (Ding et al., 2024; Liu et al., 2024; Li et al., 2025b; Lin et al., 2025; Liu et al., 2025; Maus et al., 2025). Note that most of these methods are developed for general many-objective optimisation rather than Bayesian optimisation, but they share the similar motivation of avoiding full Pareto-front approximation. These representative solutions complement one another so that each objective is well represented by at least one solution in the set, e.g., using sum-of-minimum (Ding et al., 2024), Tchebycheff set scalarisation (Lin et al., 2025), and optimal transport between objectives and solutions (Li et al., 2025b). Liu et al. (2025) refines and extends this idea as a conditional set-optimization problem, i.e., the few-for-many problem, and Maus et al. (2025) further extend this idea to the Bayesian optimisation setting. Together with our work, these studies suggest a trend in many-objective optimisation: moving beyond full Pareto-front approximation towards identifying a single trade-off solution or a small set of representative solutions. Note that this differs from the archiving process in evolutionary multi-objective optimisation, where an archive is maintained to preserve a small representative set of Pareto optimal solutions for presentation to the decision-maker (though the algorithm may generate many Pareto optimal solutions) (Li et al., 2024b). Instead, the objective here is to generate only a small number of solutions given the expensiveness of the optimisation problem.

7.2 The Distance-to-Utopian Metric

In the proposed SPMO framework, we employ a distance metric (i.e., the distance of a solution to the utopian point). One reason for using the distance-to-utopian metric is that it naturally favours a single well-balanced trade-off solution. Minimising this distance favours a solution that is jointly close to the best attainable value

---

[2]Wall time is measured based on the initial samples. Due to the exponentially increasing computational complexity with objectives, EHVI, NEHVI, and PSL are evaluated only for problems with objectives $m \leq 6$.

of each objective, rather than being extremely good in one objective but poor in others. Such a distance-based metric is also widely used as a utility function in multi-criteria decision making, e.g., TOPSIS (Hwang & Yoon, 1981) and compromise programming (Zeleny, 1973).

Note that we have considered three other well-known metrics in the experiments, i.e., weighted sum, Tchebycheff scalarisation, and single-point HV. The results show that SPMO with the distance-to-utopian metric generally performs better than these alternatives. This suggests the effectiveness of the distance-based method under the SPMO framework. In addition, it is worth noting that we also reported the single-point HV as an additional evaluation metric, alongside the distance metric, to validate the effectiveness of the considered distance-based SPMO. The results show a consistent trend across these two single-point metrics: methods that perform well under the distance-to-utopian metric also tend to perform well under single-point HV (see Tables 1 and 2).

8 Conclusion

This work presented a multi-objective BO framework that aims to find a single trade-off solution of the highest possible quality with respect to multiple objectives, rather than seeking to explore their entire Pareto front. We theoretically proved the convergence guarantees on acquisition optimisation under the SAA and empirically verified the proposed framework through extensive experiments, including on noiseless/noisy and sequential/batch cases, by sensitivity analysis, with different metrics for the acquisition function, and on a range of benchmark and real-world problems. A noticeable limitation of the proposed framework is that it focuses on finding a single trade-off point, thus failing to capture the information about the entire Pareto front; it thus may be less useful for certain applications where such information is valuable (e.g., the ranges and nadir point of the Pareto front). A detailed discussion of its applicability is provided in Appendix G. However, notably, the proposed framework showed its competitiveness against existing state-of-the-arts with respect to even the quality of the whole solution set (through HV of all solutions, see Table 3). Future work includes studying and enhancing the scalability of the proposed methods (i.e., in higher-dimensional search space) and extending their applicability to other scenarios, e.g., multi-fidelity optimisation (see Appendix H for more details).

Appendix to:

Do We Really Need to Approach the Entire Pareto Front in Many-Objective Bayesian Optimisation?

A Multi-objective Bayesian Optimisation (MOBO)

MOBO consists of two main steps, i.e., training m Gaussian process models based on the observed solutions and optimising an acquisition function $\alpha(\boldsymbol{x}) : \mathcal{X} \to \mathbb{R}$ to select a solution for evaluation. In this work, we model each objective with an independent Gaussian process $f_i \sim \mathcal{GP}(m_i(\boldsymbol{x}), k_i(\boldsymbol{x}, \boldsymbol{x}'))$, where $m_i(\boldsymbol{x}) : \mathcal{X} \to \mathbb{R}$ is the ith mean function, and $k_i(\cdot, \cdot) : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ is the ith covariance function. We use the notation $K(\text{A}, \text{B})$ to represent the covariance matrix at all pairs of solutions in set A and in set B. Given n observed solutions $\mathcal{D} = \{(\boldsymbol{x}^{(t)}, \boldsymbol{y}^{(t)})\}_{t=1}^n$ where $\boldsymbol{y}^{(t)} = \boldsymbol{f}(\boldsymbol{x}^{(t)}) + \boldsymbol{\zeta}^{(t)}$ and the noise $\boldsymbol{\zeta}^{(t)} \sim \mathcal{N}(0, \text{diag}(\boldsymbol{\sigma}_\zeta^2))$, the posterior distribution of ith objective at a new location $\boldsymbol{x}$ is a Gaussian distribution:

$$p(f_i(\boldsymbol{x})|\mathcal{D}) \sim \mathcal{N}(\mu_i(\boldsymbol{x}), \sigma_i^2(\boldsymbol{x})) \tag{6}$$

$$\mu_i(\boldsymbol{x}) = K(\boldsymbol{x}, X)(K(X, X) + \sigma_{\zeta_i}^2 \mathbf{I})^{-1} Y_i \tag{7}$$

$$\sigma_i^2(\boldsymbol{x}) = K(\boldsymbol{x}, \boldsymbol{x}) - K(\boldsymbol{x}, X)((K(X, X) + \sigma_{\zeta_i}^2 \mathbf{I})^{-1} K(X, \boldsymbol{x}) \tag{8}$$

where $\mu_i(\boldsymbol{x})$ and $\sigma_i^2(\boldsymbol{x})$ are the mean and variance at $\boldsymbol{x}$, respectively; $X = (\boldsymbol{x}^{(1)}, \dots, \boldsymbol{x}^{(n)}) \in \mathbb{R}^{n \times d}$ and $Y_i = (y_i^{(1)}, \dots, y_i^{(n)}) \in \mathbb{R}^n$ are the matrix of evaluated solutions and the corresponding vector of y values, respectively; $\sigma_{\zeta_i}^2$ is the variance of the observation noise $\zeta_i \sim \mathcal{N}(0, \sigma_{\zeta_i}^2)$, and corresponds to the i-th diagonal entry of the noise covariance matrix $\text{diag}(\boldsymbol{\sigma}_\zeta^2)$;

B Illustrative Example of ESPI

To help understand the proposed ESPI, an illustration of ESPI in a bi-objective case is shown in Figure 6. In this example, the utopian point is denoted by the black star, while the red dots represent the nondominated solutions from the current dataset. A new candidate point, whose objective values are yet to be observed, is shown as the blue dot. The red dotted line indicates the shortest Euclidean distance g^* from the utopian point to the existing nondominated set. In contrast, the blue dotted line represents the distance from the new point to the utopian point. When a new point lies within the shaded blue region and is closer to the utopian point, the improvement $I_{SP}(\cdot)$ is higher.

C Extended Related Work

Over the last two decades, a variety of BO methods have been proposed to tackle expensive multi-objective optimisation problems (Jeong & Obayashi, 2005; Bautista, 2009; Svenson, 2011; Svenson & Santner, 2016; Zuluaga et al., 2016; Zhan et al., 2017; Picheny et al., 2019; Belakaria et al., 2020b; Malkomes et al., 2021; Park et al., 2023; Ngo et al., 2025). Most of them aim to identify a good approximation of the entire Pareto front (Keane, 2006; Svenson, 2011; Parr, 2013; Zuluaga et al., 2013; Ahmadianshalchi et al., 2024). To do so, some studies convert a multi-objective problem into multiple single-objective problems by a scalarisation function (e.g., random augmented Tchebycheff scalarisation). They then optimise acquisition functions from single-objective BO to determine the next evaluation point(s) (Knowles, 2006; Zhao & Zhang, 2023). In these studies, different acquisition functions are employed, such as expected improvement (EI) (Jones et al., 1998) in Knowles (2006); Zhang et al. (2010); Namura et al. (2017); Chugh (2020), Thompson

Figure 6: Illustration of the proposed expected single-point improvement (ESPI) in a bi-objective space. The figure shows the utopian point (black star), nondominated points in the current dataset $\mathcal{D}^n$ (red dots), and a new candidate point whose true objective values are not yet observed (blue dot). The dashed arc represents the current best Euclidean distance from the utopian point to the nondominated set, denoted as g^* (red dotted line). The blue dotted line represents the distance from the new candidate point to the utopian point $\boldsymbol{z}^*$, which may improve upon the current best distance g^*. When a new point lies within the shaded blue region and is closer to the utopian point, the improvement $I_{SP}(\cdot)$ is higher.

sampling (TS) (Thompson, 1933) in Paria et al. (2020); Zhang & Golovin (2020), and upper confidence bound (UCB) (Lai & Robbins, 1985) in Paria et al. (2020); Zhang & Golovin (2020); Li et al. (2024a).

The remaining studies directly optimise multi-objective problems by considering the definition of optimality in multi-objective optimisation, i.e., the Pareto dominance relation. A representative approach is to use HV since maximising the HV value is equivalent to finding the entire Pareto front (Ponweiser et al., 2008; Couckuyt et al., 2014; Daulton et al., 2020; 2021; Renganathan & Carlson, 2025; Bhatija et al., 2025). Along this line, expected hypervolume improvement (EHVI) is widely considered (Emmerich et al., 2006; Daulton et al., 2023; Qing et al., 2023; Yang et al., 2019b;a; Deng et al., 2025) as it is a natural extension of the EI for multi-objective optimisation. Another idea is to leverage information theory to guide exploration toward regions likely contributing to the Pareto front. Such methods focus on improving the posterior of optimal inputs (i.e., the approximated Pareto set) (Garrido-Merchán et al., 2023; Garrido-Merchán & Hernández-Lobato, 2019; Hernandez-Lobato et al., 2016), optimal outputs (i.e., the approximated Pareto front) (Belakaria et al., 2019; 2021; Suzuki et al., 2020), or both of them (Tu et al., 2022).

That said, there do exist a few studies that do not aim to identify the entire Pareto front. Among them, some attempt to use decision-maker preferences to guide the search towards specific region(s) (Abdolshah et al., 2019; Astudillo & Frazier, 2020; Ozaki et al., 2024; Ip et al., 2025). Such methods typically adjust the target region by eliciting or updating decision-maker preferences during optimisation. Another attempt is to directly target certain region(s) of the Pareto front, without an assumption that decision-maker preferences can be available or elicited (Gaudrie et al., 2018; 2020; Binois et al., 2020). For example, Gaudrie et al. (2018; 2020) propose the Centred Expected Hypervolume Improvement (C-EHVI) by dynamically adjusting the reference point using the Kalai-Smorodinsky equilibrium (also used in Binois et al. (2020)) to approach the central part of the Pareto front, regardless of whether the central region contains best trade-off solutions, even if the central region is of relatively low quality (e.g., on a rather concave front). In contrast, our proposed approach searches for a good trade-off solution, which may not lie in the intermediate region, but can often be interpreted as a "knee" point on the Pareto front. C-EHVI is more relevant to our study, and we have thus included it in our experimental comparison.

D Theoretical Results

D.1 Proof of Theorem 4.1.

We consider the setting from Balandat et al. (2020, Section D.5). Let $\epsilon^{(t)} \sim \mathcal{N}(0, I_m)$.[3] Using the reparameterisation trick, we can write the posterior at $\boldsymbol{x}$ as

$$\bar{\boldsymbol{f}}_t(\boldsymbol{x}, \epsilon^{(t)}) = \bar{\mu}(\boldsymbol{x}) + \bar{L}(\boldsymbol{x})\epsilon^{(t)}$$

---

[3]Theorem 4.1 can be extended to handle non-iid base samples from a family of quasi-Monte Carlo methods as in Balandat et al. (2020).

where $\bar{\mu}(\boldsymbol{x}) : \mathbb{R}^d \to \mathbb{R}^m$ is the multi-output GP's posterior mean; $\bar{L}(\boldsymbol{x}) \in \mathbb{R}^{m \times m}$ is a root decomposition (often a Cholesky decomposition) of the multi-output GP's posterior covariance $\bar{K} \in \mathbb{R}^{m \times m}$; and $\epsilon^{(t)} \in \mathbb{R}^m$. Let

$$\bar{A}(\boldsymbol{x}, \epsilon^{(t)}) = \max\left(0, \, g^* - \|\bar{\boldsymbol{f}}_t(\boldsymbol{x}, \epsilon^{(t)}) - \boldsymbol{z}^*\|\right)$$

where $g^* = \min_{\boldsymbol{x} \in \bar{X}} g(\boldsymbol{f}(\boldsymbol{x}), \boldsymbol{z}^*)$ and $\boldsymbol{z}^* = (z_1^*, z_2^*, \ldots, z_m^*)$ is the utopian point. Following [Balandat et al.](2020, Theorem 3), we need to show that there exists an integrable function $\ell : \mathbb{R}^m \mapsto \mathbb{R}$ such that for almost every $\epsilon^{(t)}$ and all $\boldsymbol{x}, \boldsymbol{y} \in \mathcal{X} \subset \mathbb{R}^d$,

$$|\bar{A}(\boldsymbol{x}, \epsilon^{(t)}) - \bar{A}(\boldsymbol{y}, \epsilon^{(t)})| \leq \ell(\epsilon^{(t)})\|\boldsymbol{x} - \boldsymbol{y}\|. \tag{9}$$

Let

$$\begin{aligned}
\bar{A}(\boldsymbol{x}, \epsilon^{(t)}) &= \max\left(0, \, g^* - \|\bar{\boldsymbol{f}}_t(\boldsymbol{x}, \epsilon^{(t)}) - \boldsymbol{z}^*\|\right) \\
&= \frac{1}{2}\left(g^* - \|\bar{\boldsymbol{f}}_t(\boldsymbol{x}, \epsilon^{(t)}) - \boldsymbol{z}^*\| + |g^* - \|\bar{\boldsymbol{f}}_t(\boldsymbol{x}, \epsilon^{(t)}) - \boldsymbol{z}^*\||\right).
\end{aligned}$$

Hence we obtain,

$$\begin{aligned}
&\left|\bar{A}(\boldsymbol{x}, \epsilon^{(t)}) - \bar{A}(\boldsymbol{y}, \epsilon^{(t)})\right| \\
&= \left|\frac{1}{2}\left(\|\bar{\boldsymbol{f}}_t(\boldsymbol{y}, \epsilon^{(t)}) - \boldsymbol{z}^*\| - \|\bar{\boldsymbol{f}}_t(\boldsymbol{x}, \epsilon^{(t)}) - \boldsymbol{z}^*\|\right) + \frac{1}{2}\left(|g^* - \|\bar{\boldsymbol{f}}_t(\boldsymbol{x}, \epsilon^{(t)}) - \boldsymbol{z}^*\|| - |g^* - \|\bar{\boldsymbol{f}}_t(\boldsymbol{y}, \epsilon^{(t)}) - \boldsymbol{z}^*\||\right)\right|.
\end{aligned}$$

Let $I_1 := \|\bar{\boldsymbol{f}}_t(\boldsymbol{y}, \epsilon^{(t)}) - \boldsymbol{z}^*\| - \|\bar{\boldsymbol{f}}_t(\boldsymbol{x}, \epsilon^{(t)}) - \boldsymbol{z}^*\|$ and $I_2 := |g^* - \|\bar{\boldsymbol{f}}_t(\boldsymbol{x}, \epsilon^{(t)}) - \boldsymbol{z}^*\|| - |g^* - \|\bar{\boldsymbol{f}}_t(\boldsymbol{y}, \epsilon^{(t)}) - \boldsymbol{z}^*\||$. Hence

$$\left|\bar{A}(\boldsymbol{x}, \epsilon^{(t)}) - \bar{A}(\boldsymbol{y}, \epsilon^{(t)})\right| \leq \frac{1}{2}|I_1| + \frac{1}{2}|I_2|.$$

We observe that

$$\begin{aligned}
|I_1| &= \left|\|\bar{\boldsymbol{f}}_t(\boldsymbol{y}, \epsilon^{(t)}) - \boldsymbol{z}^*\| - \|\bar{\boldsymbol{f}}_t(\boldsymbol{x}, \epsilon^{(t)}) - \boldsymbol{z}^*\|\right| \\
&\leq \|\bar{\boldsymbol{f}}_t(\boldsymbol{y}, \epsilon^{(t)}) - \bar{\boldsymbol{f}}_t(\boldsymbol{x}, \epsilon^{(t)})\| \\
&= \|\bar{\mu}(\boldsymbol{y}) + \bar{L}(\boldsymbol{y})\epsilon^{(t)} - (\bar{\mu}(\boldsymbol{x}) + \bar{L}(\boldsymbol{x})\epsilon^{(t)})\| \\
&\leq \|\bar{\mu}(\boldsymbol{y}) - \bar{\mu}(\boldsymbol{x})\| + \|(\bar{L}(\boldsymbol{y}) - \bar{L}(\boldsymbol{x}))\epsilon^{(t)}\|.
\end{aligned}$$

Since $\mathcal{X}$ is compact, and $\bar{\mu}$ and $\bar{L}$ have uniformly bounded gradients, they are Lipschitz. There exist $C_{\mu_1}, C_{L_1} < \infty$ such that

$$\begin{aligned}
|I_1| &\leq \|\bar{\mu}(\boldsymbol{y}) - \bar{\mu}(\boldsymbol{x})\| + \|(\bar{L}(\boldsymbol{y}) - \bar{L}(\boldsymbol{x}))\epsilon^{(t)}\| \\
&\leq \ell_{I_1}(\epsilon^{(t)})\|\boldsymbol{x} - \boldsymbol{y}\|
\end{aligned}$$

where $\ell_{I_1}(\epsilon^{(t)}) := C_{\mu_1} + C_{L_1}\|\epsilon^{(t)}\|$. Furthermore,

$$\begin{aligned}
|I_2| &= \left||g^* - \|\bar{\boldsymbol{f}}_t(\boldsymbol{x}, \epsilon^{(t)}) - \boldsymbol{z}^*\|| - |g^* - \|\bar{\boldsymbol{f}}_t(\boldsymbol{y}, \epsilon^{(t)}) - \boldsymbol{z}^*\||\right| \\
&\leq \left|\|\bar{\boldsymbol{f}}_t(\boldsymbol{x}, \epsilon^{(t)}) - \boldsymbol{z}^*\| - \|\bar{\boldsymbol{f}}_t(\boldsymbol{y}, \epsilon^{(t)}) - \boldsymbol{z}^*\|\right| \\
&\leq \|\bar{\boldsymbol{f}}_t(\boldsymbol{x}, \epsilon^{(t)}) - \bar{\boldsymbol{f}}_t(\boldsymbol{y}, \epsilon^{(t)})\| \\
&= \|\bar{\mu}(\boldsymbol{x}) + \bar{L}(\boldsymbol{x})\epsilon^{(t)} - (\bar{\mu}(\boldsymbol{y}) + \bar{L}(\boldsymbol{y})\epsilon^{(t)})\| \\
&\leq \|\bar{\mu}(\boldsymbol{x}) - \bar{\mu}(\boldsymbol{y})\| + \|(\bar{L}(\boldsymbol{x}) - \bar{L}(\boldsymbol{y}))\epsilon^{(t)}\|.
\end{aligned}$$

Since $\mathcal{X}$ is compact, and $\bar{\mu}$ and $\bar{L}$ have uniformly bounded gradients, they are Lipschitz. There exist $C_{\mu_2}, C_{L_2} < \infty$ such that

$$|I_2| \leq \ell_{I_2}(\epsilon^{(t)}) \|\boldsymbol{x} - \boldsymbol{y}\|$$

where $\ell_{I_2}(\epsilon^{(t)}) := C_{\mu_2} + C_{L_2} \|\epsilon^{(t)}\|$. Hence

$$
\begin{aligned}
\left| \bar{A}(\boldsymbol{x}, \epsilon^{(t)}) - \bar{A}(\boldsymbol{y}, \epsilon^{(t)}) \right| &\leq \frac{1}{2} |I_1| + \frac{1}{2} |I_2| \\
&\leq \frac{1}{2} \ell_{I_1}(\epsilon^{(t)}) \|\boldsymbol{x} - \boldsymbol{y}\| + \frac{1}{2} \ell_{I_2}(\epsilon^{(t)}) \|\boldsymbol{x} - \boldsymbol{y}\| \\
&= \frac{1}{2} (\ell_{I_1}(\epsilon^{(t)}) + \ell_{I_2}(\epsilon^{(t)})) \|\boldsymbol{x} - \boldsymbol{y}\|.
\end{aligned}
$$

Hence

$$\left| \bar{A}(\boldsymbol{x}, \epsilon^{(t)}) - \bar{A}(\boldsymbol{y}, \epsilon^{(t)}) \right| \leq \ell(\epsilon^{(t)}) \|\boldsymbol{x} - \boldsymbol{y}\|$$

where $\ell(\epsilon^{(t)}) := (C_{\mu_1} + C_{\mu_2}) + (C_{L_1} + C_{L_2}) \|\epsilon^{(t)}\|$. Note that $\ell(\epsilon^{(t)})$ is integrable because all absolute moments exist for the Gaussian distribution. Since this satisfies the criteria for Theorem 3 in Balandat et al. (2020), the theorem holds for ESPI.

D.2 Theorem D.1 and Its Proof

Theorem D.1. *Suppose that $\mathcal{X}$ is compact and that $\boldsymbol{f}$ has a multi-output GP prior with continuously differentiable mean and covariance functions. Let $X = \{\boldsymbol{x}^{(t)}\}_{t=1}^n$ be the set of observed decision vectors in $\mathcal{D}$, $\alpha_{NESPI}^* := \max_{\boldsymbol{x} \in \mathcal{X}} \alpha_{NESPI}(\boldsymbol{x})$ denote the maximum of NESPI, $S^* := \arg\max_{\boldsymbol{x} \in \mathcal{X}} \alpha_{NESPI}(\boldsymbol{x})$ denote the set of maximisers of α_{NESPI}, $\hat{\alpha}_{NESPI}^N(\boldsymbol{x})$ denote the deterministic acquisition function via the base samples $\{\epsilon^{(t)}\}_{t=1}^N \sim \mathcal{N}(0, I_{(n+1)m})$. Suppose that $\hat{\boldsymbol{x}}_N^* \in \arg\max_{\boldsymbol{x} \in \mathcal{X}} \hat{\alpha}_{NESPI}^N(\boldsymbol{x})$, then*

(1) $\hat{\alpha}_{NESPI}^N(\hat{\boldsymbol{x}}_N^*) \to \alpha_{NESPI}^*$ a.s.,

(2) $d(\hat{\boldsymbol{x}}_N^*, S^*) \to 0$ a.s., where $d(\hat{\boldsymbol{x}}_N^*, S^*) := \inf_{\boldsymbol{x} \in S^*} \|\hat{\boldsymbol{x}}_N^* - \boldsymbol{x}\|$.

Proof of Theorem D.1. Let $X := [(\boldsymbol{x}^{(1)})^T, \ldots, (\boldsymbol{x}^{(n)})^T]^T \in \mathbb{R}^{nd}$ be the n observed points; $\boldsymbol{x}^{(n+1)} \in \mathcal{X} \subset \mathbb{R}^d$ be a candidate point; and $\epsilon^{(t)} \in \mathbb{R}^{(n+1)m}$ with $\epsilon^{(t)} \sim \mathcal{N}(0, I_{(n+1)m})$. Let $\tilde{\boldsymbol{f}}_t(X, \boldsymbol{x}^{(n+1)}) := [\tilde{\boldsymbol{f}}_t(\boldsymbol{x}^{(1)}), \ldots, \tilde{\boldsymbol{f}}_t(\boldsymbol{x}^{(n)}), \tilde{\boldsymbol{f}}_t(\boldsymbol{x}^{(n+1)})]$ denote the tth sample of the corresponding objectives, so that we can write the posterior via the reparameterisation trick as:

$$\boldsymbol{f}_t(X, \boldsymbol{x}^{(n+1)}, \epsilon^{(t)}) = \mu(X, \boldsymbol{x}^{(n+1)}) + L(X, \boldsymbol{x}^{(n+1)}) \epsilon^{(t)}$$

where $\mu(X, \boldsymbol{x}^{(n+1)}) : \mathbb{R}^{(n+1)d} \to \mathbb{R}^{(n+1)m}$ is the multi-output GP's posterior mean; $L(X, \boldsymbol{x}^{(n+1)}) \in \mathbb{R}^{(n+1)m \times (n+1)m}$ is a root decomposition of the multi-output GP's posterior covariance $K \in \mathbb{R}^{(n+1)m \times (n+1)m}$. Let $\boldsymbol{f}^{(m)}(\boldsymbol{x}^{(i)}, \epsilon^{(t)}) := S_i \left(\mu(X, \boldsymbol{x}^{(n+1)}) + L(X, \boldsymbol{x}^{(n+1)}) \epsilon^{(t)} \right)$, where $\boldsymbol{f}^{(m)}(\boldsymbol{x}^{(i)}, \epsilon^{(t)}) \in \mathbb{R}^m$ represents the posterior at point $\boldsymbol{x}^{(i)}$ and $S_i \in \mathbb{R}^{m \times (n+1)m}, i = 1, \ldots, n+1$ is the selector matrix used to extract the corresponding element for the $\boldsymbol{x}^{(i)}$. Let

$$A(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)}; X) = \max \left(0, \hat{g}_t^*(X) - \|\boldsymbol{f}^{(m)}(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)}) - \boldsymbol{z}^*\| \right).$$

Let $\hat{g}_t^*(X) := \min_{\boldsymbol{x}_{obs} \in \{\boldsymbol{x}^{(i)}\}_{i=1}^n} \|\boldsymbol{f}_t^{(m)}(\boldsymbol{x}_{obs}, \epsilon^{(t)}) - \boldsymbol{z}^*\|$, hence we obtain:

$$A(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)}; X) = \max \left(0, \min_{\boldsymbol{x}_{obs} \in \{\boldsymbol{x}^{(i)}\}_{i=1}^n} \|\boldsymbol{f}^{(m)}(\boldsymbol{x}_{obs}, \epsilon^{(t)}) - \boldsymbol{z}^*\| - \|\boldsymbol{f}^{(m)}(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)}) - \boldsymbol{z}^*\| \right).$$

Following Balandat et al. (2020, Theorem 3), we need to show that there exists an integrable function $\ell : \mathbb{R}^{(n+1)m} \mapsto \mathbb{R}$ such that for almost every $\epsilon^{(t)}$ and all $\boldsymbol{x}^{(n+1)}, \boldsymbol{y}^{(n+1)} \in \mathcal{X} \subset \mathbb{R}^d$,

$$|A(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)}; X) - A(\boldsymbol{y}^{(n+1)}, \epsilon^{(t)}; X)| \le \ell(\epsilon^{(t)}) \|\boldsymbol{x}^{(n+1)} - \boldsymbol{y}^{(n+1)}\|. \tag{10}$$

Let

$$A(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)}; X) = \max\left(0, \hat{g}_t^*(X) - \|\boldsymbol{f}^{(m)}(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)}) - \boldsymbol{z}^*\|\right)$$
$$= \frac{1}{2}\left(\hat{g}_t^*(X) - \|\boldsymbol{f}^{(m)}(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)}) - \boldsymbol{z}^*\| + \left|\hat{g}_t^*(X) - \|\boldsymbol{f}^{(m)}(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)}) - \boldsymbol{z}^*\|\right|\right).$$

Hence we obtain

$$\left|A(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)}; X) - A(\boldsymbol{y}^{(n+1)}, \epsilon^{(t)}; X)\right|$$
$$= \left|\frac{1}{2}\left(\|\boldsymbol{f}^{(m)}(\boldsymbol{y}^{(n+1)}, \epsilon^{(t)}) - \boldsymbol{z}^*\| - \|\boldsymbol{f}^{(m)}(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)}) - \boldsymbol{z}^*\|\right)\right.$$
$$\left. + \frac{1}{2}\left(\left|\hat{g}_t^*(X) - \|\boldsymbol{f}^{(m)}(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)}) - \boldsymbol{z}^*\|\right| - \left|\hat{g}_t^*(X) - \|\boldsymbol{f}^{(m)}(\boldsymbol{y}^{(n+1)}, \epsilon^{(t)}) - \boldsymbol{z}^*\|\right|\right)\right|.$$

Let $I_1' := \|\boldsymbol{f}^{(m)}(\boldsymbol{y}^{(n+1)}, \epsilon^{(t)}) - \boldsymbol{z}^*\| - \|\boldsymbol{f}^{(m)}(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)}) - \boldsymbol{z}^*\|$ and $I_2' := \left|\hat{g}_t^*(X) - \|\boldsymbol{f}^{(m)}(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)}) - \boldsymbol{z}^*\|\right| - \left|\hat{g}_t^*(X) - \|\boldsymbol{f}^{(m)}(\boldsymbol{y}^{(n+1)}, \epsilon^{(t)}) - \boldsymbol{z}^*\|\right|$. Hence

$$\left|A(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)}; X) - A(\boldsymbol{y}^{(n+1)}, \epsilon^{(t)}; X)\right| \le \frac{1}{2}|I_1'| + \frac{1}{2}|I_2'|.$$

We observe that

$$|I_1'| = \left|\|\boldsymbol{f}^{(m)}(\boldsymbol{y}^{(n+1)}, \epsilon^{(t)}) - \boldsymbol{z}^*\| - \|\boldsymbol{f}^{(m)}(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)}) - \boldsymbol{z}^*\|\right|$$
$$\le \|\boldsymbol{f}^{(m)}(\boldsymbol{y}^{(n+1)}, \epsilon^{(t)}) - \boldsymbol{f}^{(m)}(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)})\|$$
$$= \|\mu^{(m)}(\boldsymbol{y}^{(n+1)}) + L^{(m)}(\boldsymbol{y}^{(n+1)})\epsilon^{(t)} - (\mu^{(m)}(\boldsymbol{x}^{(n+1)}) + L^{(m)}(\boldsymbol{x}^{(n+1)})\epsilon^{(t)})\|$$
$$\le \|\mu^{(m)}(\boldsymbol{y}^{(n+1)}) - \mu^{(m)}(\boldsymbol{x}^{(n+1)})\| + \|(L^{(m)}(\boldsymbol{y}^{(n+1)}) - L^{(m)}(\boldsymbol{x}^{(n+1)}))\epsilon^{(t)}\|$$

Since $\mathcal{X}$ is compact, and $\mu^{(m)}$ and $L^{(m)}$ have uniformly bounded gradients, they are Lipschitz. There exist $C_{\mu_1}', C_{L_1}' < \infty$ such that

$$|I_1'| \le \|\mu^{(m)}(\boldsymbol{y}^{(n+1)}) - \mu^{(m)}(\boldsymbol{x}^{(n+1)})\| + \|(L^{(m)}(\boldsymbol{y}^{(n+1)}) - L^{(m)}(\boldsymbol{x}^{(n+1)}))\epsilon^{(t)}\|$$
$$\le \ell_{I_1'}(\epsilon^{(t)})\|\boldsymbol{x}^{(n+1)} - \boldsymbol{y}^{(n+1)}\|.$$

where $\ell_{I_1'}(\epsilon^{(t)}) := C_{\mu_1}' + C_{L_1}'\|\epsilon^{(t)}\|$. Furthermore,

$$|I_2'| = \left|\left|\hat{g}_t^*(X) - \|\boldsymbol{f}^{(m)}(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)}) - \boldsymbol{z}^*\|\right| - \left|\hat{g}_t^*(X) - \|\boldsymbol{f}^{(m)}(\boldsymbol{y}^{(n+1)}, \epsilon^{(t)}) - \boldsymbol{z}^*\|\right|\right|$$
$$\le \left|\|\boldsymbol{f}^{(m)}(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)}) - \boldsymbol{z}^*\| - \|\boldsymbol{f}^{(m)}(\boldsymbol{y}^{(n+1)}, \epsilon^{(t)}) - \boldsymbol{z}^*\|\right|$$
$$\le \|\boldsymbol{f}^{(m)}(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)}) - \boldsymbol{f}^{(m)}(\boldsymbol{y}^{(n+1)}, \epsilon^{(t)})\|$$
$$= \|\mu^{(m)}(\boldsymbol{x}^{(n+1)}) + L^{(m)}(\boldsymbol{x}^{(n+1)})\epsilon^{(t)} - (\mu^{(m)}(\boldsymbol{y}^{(n+1)}) + L^{(m)}(\boldsymbol{y}^{(n+1)})\epsilon^{(t)})\|$$
$$\le \|\mu^{(m)}(\boldsymbol{x}^{(n+1)}) - \mu^{(m)}(\boldsymbol{y}^{(n+1)})\| + \|(L^{(m)}(\boldsymbol{x}^{(n+1)}) - L^{(m)}(\boldsymbol{y}^{(n+1)}))\epsilon^{(t)}\|$$

Since $\mathcal{X}$ is compact, and $\mu^{(m)}$ and $L^{(m)}$ have uniformly bounded gradients, they are Lipschitz. There exist $C_{\mu_2}', C_{L_2}' < \infty$ such that

$$|I_2'| \le \ell_{I_2'}(\epsilon^{(t)})\|\boldsymbol{x}^{(n+1)} - \boldsymbol{y}^{(n+1)}\|$$

909 where $\ell_{I'_2}(\epsilon^{(t)}) := C'_{\mu_2} + C'_{L_2}\|\epsilon^{(t)}\|$. Hence

$$
\begin{aligned}
\left| A(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)}; X) - A(\boldsymbol{y}^{(n+1)}, \epsilon^{(t)}; X) \right| &\leq \frac{1}{2}|I'_1| + \frac{1}{2}|I'_2| \\
&\leq \frac{1}{2}\ell_{I'_1}(\epsilon^{(t)})\|\boldsymbol{x}^{(n+1)} - \boldsymbol{y}^{(n+1)}\| + \frac{1}{2}\ell_{I'_2}(\epsilon^{(t)})\|\boldsymbol{x}^{(n+1)} - \boldsymbol{y}^{(n+1)}\| \\
&= \frac{1}{2}(\ell_{I'_1}(\epsilon^{(t)}) + \ell_{I'_2}(\epsilon^{(t)}))\|\boldsymbol{x}^{(n+1)} - \boldsymbol{y}^{(n+1)}\|
\end{aligned}
$$

910 Hence

$$
\left| A(\boldsymbol{x}^{(n+1)}, \epsilon^{(t)}) - A(\boldsymbol{y}^{(n+1)}, \epsilon^{(t)}) \right| \leq \ell(\epsilon^{(t)})\|\boldsymbol{x}^{(n+1)} - \boldsymbol{y}^{(n+1)}\|
$$

911 where $\ell(\epsilon^{(t)}) := (C'_{\mu_1} + C'_{\mu_2}) + (C'_{L_1} + C'_{L_2})\|\epsilon^{(t)}\|$. Note that $\ell(\epsilon^{(t)})$ is integrable because all absolute moments
912 exist for the Gaussian distribution. Since this satisfies the criteria for Theorem 3 in Balandat et al. (2020),
913 the theorem holds for NESPI. It is worth noting that Theorems 4.1 and D.1 readily extend to the batch
914 setting.

915 It can be shown that the gradient of $\hat{\alpha}_{\mathrm{ESPI}}(\boldsymbol{x})$ or $\hat{\alpha}_{\mathrm{NESPI}}(\boldsymbol{x})$ is an unbiased estimator of the true gradient of
916 α_{ESPI} or α_{NESPI}, though it is not necessary for the SAA approach (Daulton et al., 2021).

E Experiment Settings

E.1 Implementation details

919 All experiments were conducted using Python 3.12, with all methods developed on the open-source Python
920 framework BoTorch (Balandat et al., 2020), which builds on GPyTorch (Gardner et al., 2018) for Gaussian
921 process modelling and PyTorch (Paszke et al., 2019) for automatic differentiation. The computational studies
922 were performed on a Red Hat Enterprise Linux 8.8 system, operating on a 64-bit x86 CPU architecture. The
923 computing cluster utilised Intel Xeon Platinum 8360Y processors running at 2.40 GHz.

924 The code for ParEGO, NParEGO, TS-TCH, EHVI, NEHVI, and JES is available at `https://github.com/`
925 `pytorch/botorch`. Specifically, we implement ParEGO and NParEGO based on the implementation provided
926 by BoTorch.[4] We implement TS-TCH based on the implementation provided by BoTorch.[5] We implement
927 EHVI and NEHVI based on the implementation provided by BoTorch.[6] We implement JES based on the
928 implementation provided by BoTorch.[7]

929 The data and code are available at `https://github.com/ChaoJiang52/SPMO`.

E.2 Method Details

931 For all the methods, we set the same $2(d+1)$ points from a scrambled Sobol sequence and allow a maximum
932 of 200 evaluations, following the practice in Daulton et al. (2020; 2021); Konakovic Lukovic et al. (2020). All
933 the methods use $N = 128$ Monte Carlo samples.

934 For ParEGO (Knowles, 2006) and its noisy variant NParEGO (Daulton et al., 2021), we employ random
935 scalarisations, whereby a weight vector $\boldsymbol{w} \in \mathbb{R}^m$ is generated from the unit simplex. The augmented
936 Tchebycheff scalarisation function is applied, defined as $g(\boldsymbol{y}) = \max_i(w_i y_i) + \alpha \sum_i(w_i y_i)$. Log expected
937 improvement and noisy log expected improvement are used as the acquisition functions in ParEGO and
938 NParEGO, respectively, as recommended in Ament et al. (2023). In the batch setting, q distinct weight
939 vectors are sampled, and the acquisition function is optimised sequentially for each.

940 For TS-TCH (Paria et al., 2020), similarly to ParEGO, we employ random scalarisations by using the
941 augmented Tchebycheff scalarisation function. After converting to single-objective optimisation problem,

Table 4: Reference points of the six benchmark problems used for hypervolume computation in EHVI and NEHVI, as well as for performance evaluation. Note that the referents points of the two real-world problems, i.e., car side impact design and car cab design, are set to $(1.1, ..., 1.1) \in \mathbb{R}^m$ in the normalised objective space following the practice in Tanabe & Ishibuchi (2020) the utopian and nadir points are available at `https://github.com/ryojitanabe/reproblems/tree/master/ideal_nadir_points`).

Problem	Reference point	Suggested by
DTLZ1	$(400.0, ..., 400.0) \in \mathbb{R}^m$	Balandat et al. (2020); Chugh (2020)
DTLZ2	$(1.1, \ldots, 1.1) \in \mathbb{R}^m$	Balandat et al. (2020); Daulton et al. (2020); Ishibuchi et al. (2018)
Inverted DTLZ1	$(400.0, \ldots, 400.0) \in \mathbb{R}^m$	Chugh (2020); Ishibuchi et al. (2018)
Inverted DTLZ2	$(1.1, \ldots, 1.1) \in \mathbb{R}^m$	Ishibuchi et al. (2018)
Convex DTLZ2	$(1.1, \ldots, 1.1) \in \mathbb{R}^m$	Ishibuchi et al. (2018)
Scaled DTLZ2	$(1.1 * 2^0, \ldots, 1.1 * 2^m) \in \mathbb{R}^m$	Ishibuchi et al. (2018)
DTLZ3	$(10000.0, \ldots, 10000.0) \in \mathbb{R}^m$	Balandat et al. (2020)
DTLZ4	$(1.1, \ldots, 1.1) \in \mathbb{R}^m$	Balandat et al. (2020)
DTLZ5	$(10.0, \ldots, 10.0) \in \mathbb{R}^m$	Balandat et al. (2020)
DTLZ6	$(10.0, \ldots, 10.0) \in \mathbb{R}^m$	Balandat et al. (2020)
DTLZ7	$(15.0, \ldots, 15.0) \in \mathbb{R}^m$	Balandat et al. (2020)

Thompson sampling is used as the acquisition function. We draw a sample from the joint posterior over a discrete set of $1000d$ points sampled from a scrambled Sobol sequence, suggested by Daulton et al. (2020). In the batch setting, q distinct weight vectors are sampled, and the acquisition function is optimised sequentially for each.

For EHVI (Daulton et al., 2020) and its noisy variant NEHVI (Daulton et al., 2021), the reference point is predefined, following the practice in Daulton et al. (2020); Yang et al. (2019b). Table 4 lists the reference points used for each problem in the experimental evaluation. The logarithmic variants of both acquisition functions are employed, as recommended in Ament et al. (2023). In the batch setting, the sequential greedy optimisation strategy is adopted. It is worth noting that in this study, EHVI and NEHVI are evaluated only on problems with 3 and 5 objectives, as the acquisition optimisation wall time becomes prohibitively high when the number of objectives increases to 10 (see Table 28).

For C-EHVI (Gaudrie et al., 2018; 2020), the Kalai-Smorodinsky equilibrium is used to determine the reference point of HV. The logarithmic variant of the acquisition functions is employed, as recommended in Ament et al. (2023).

For joint entropy search (JES), we use $S = 10$ Monte Carlo samples and $p = 10$ number of Pareto optimal points, according to Tu et al. (2022). In the batch setting, the sequential greedy optimisation strategy is adopted.

For all the problems, we normalise the input variables and standardise the objective values before training Gaussian processes. We assume an independent surrogate model for each objective, using a constant mean function and a Matérn 5/2 ARD kernel. We optimise all acquisition functions by using the L-BFGS-B, with up to 200 iterations.

E.3 Problem Details

The details of the benchmark problems and real-world problems are given in the following.

DTLZ1. DTLZ1 is a scalable benchmark problem from Deb et al. (2005), which is defined as:

$$f_1(\boldsymbol{x}) = \frac{1}{2}x_1 x_2 \cdots x_{m-1}(1 + g(\boldsymbol{x}_m)),$$

$$f_2(\boldsymbol{x}) = \frac{1}{2}x_1 x_2 \cdots (1 - x_{m-1})(1 + g(\boldsymbol{x}_m)),$$

$$\vdots$$

$$f_{m-1}(\boldsymbol{x}) = \frac{1}{2}x_1(1 - x_2)(1 + g(\boldsymbol{x}_m)),$$

$$f_m(\boldsymbol{x}) = \frac{1}{2}(1 - x_1)(1 + g(\boldsymbol{x}_m)),$$

$$\text{s.t.} \quad 0 \le x_i \le 1, \quad \text{for } i = 1, 2, \ldots, d.$$

where $g(\boldsymbol{x}_m) = 100\left(|\boldsymbol{x}_m| + \sum_{x_i \in \boldsymbol{x}_m}(x_i - 0.5)^2 - \cos(20\pi(x_i - 0.5))\right)$ and $\boldsymbol{x}_m$ is the last $d - m + 1$ variables.

DTLZ2. DTLZ2 is a scalable benchmark problem from Deb et al. (2005), which is defined as:

$$f_1(\boldsymbol{x}) = (1 + g(\boldsymbol{x}_m))\cos(x_1\pi/2)\cdots\cos(x_{m-2}\pi/2)\cos(x_{m-1}\pi/2),$$
$$f_2(\boldsymbol{x}) = (1 + g(\boldsymbol{x}_m))\cos(x_1\pi/2)\cdots\cos(x_{m-2}\pi/2)\sin(x_{m-1}\pi/2),$$
$$f_3(\boldsymbol{x}) = (1 + g(\boldsymbol{x}_m))\cos(x_1\pi/2)\cdots\sin(x_{m-2}\pi/2),$$

$$\vdots$$

$$f_m(\boldsymbol{x}) = (1 + g(\boldsymbol{x}_m))\sin(x_1\pi/2),$$
$$s.t. \quad 0 \le x_i \le 1, \quad \text{for } i = 1, 2, \ldots, d.$$

where $g(\boldsymbol{x}_m) = \sum_{x_i \in \boldsymbol{x}_m}(x_i - 0.5)^2$ and $\boldsymbol{x}_m$ is the last $d - m + 1$ variables.

Inverted DTLZ1. Inverted DTLZ1 is a variant of DTLZ1 (Jain & Deb, 2013a), which is defined as:

$$f_i(\boldsymbol{x}) = 0.5 \cdot (1 + g(\boldsymbol{x}_m)) - f_i^{\text{DTLZ1}}(\boldsymbol{x}), \quad i = 1, \ldots, m$$

where $g(\boldsymbol{x}_m)$ is the same function as used in DTLZ1, $f_i^{\text{DTLZ1}}(\boldsymbol{x})$ denotes the ith objective of the original DTLZ1 formulation.

Inverted DTLZ2. Inverted DTLZ2 is a variant of DTLZ2 (Jain & Deb, 2013b), which is defined as:

$$f_i(\boldsymbol{x}) = 1 + g(\boldsymbol{x}_m) - f_i^{\text{DTLZ2}}(\boldsymbol{x}), \quad i = 1, \ldots, m$$

where $g(\boldsymbol{x}_m)$ is the same function as used in DTLZ2, $f_i^{\text{DTLZ2}}(\boldsymbol{x})$ denotes the ith objective of the original DTLZ2 formulation.

Convex DTLZ2. Convex DTLZ2 is a variant of DTLZ2 (Deb & Jain, 2013), which is defined as:

$$f_i(\boldsymbol{x}) = (f_i^{\text{DTLZ2}}(\boldsymbol{x}))^4, \quad i = 1, \ldots, m - 1$$
$$f_m(\boldsymbol{x}) = (f_m^{\text{DTLZ2}}(\boldsymbol{x}))^2$$

where $f_i^{\text{DTLZ2}}(\boldsymbol{x})$ denotes the ith objective of the original DTLZ2 formulation. This problem convert the original concave problem to convex problem.

Scaled DTLZ2. Scaled DTLZ2 is a variant of DTLZ2, which is defined as:

$$f_i(\boldsymbol{x}) = 2^{i-1} \cdot f_i^{\text{DTLZ2}}(\boldsymbol{x}), \quad i = 1, \ldots, m$$

where $f_i^{\text{DTLZ2}}(\boldsymbol{x})$ denotes the ith objective of the original DTLZ2 formulation. This benchmark problem is used to see whether an algorithm can deal with problems with different scales of different objectives.

DTLZ3–DTLZ7. DTLZ3–DTLZ7 are scalable multi-objective benchmark problems. Their mathematical formulations are provided in Deb et al. (2005).

According to the original paper (Deb et al., 2005), the dimensionality d of DTLZ1 and its variant (i.e., inverted DTLZ1) is $m + 4$, the dimensionality d of DTLZ2-6 and their variants (i.e., inverted DTLZ2, convex DTLZ2, and scaled DTLZ2) is $m + 9$, and the dimensionality d of DTLZ7 is $m + 19$.

Car Side Impact Design (CSI). The car side-impact problem aims to minimise vehicle weight while satisfying safety constraints related to occupant injury and structural response (Jain & Deb, 2013a). It involves $m = 4$ objectives with $d = 7$ variables, which are based on a surrogate model that is fit to data collected from a simulator. The mathematical formulations are given as follows:

$$
\begin{aligned}
f_1(\boldsymbol{x}) &= 1.98 + 4.9x_1 + 6.67x_2 + 6.98x_3 + 4.01x_4 + 1.78x_5 + 10^{-5}x_6 + 2.73x_7 \\
f_2(\boldsymbol{x}) &= 4.72 - 0.5x_4 - 0.19x_2x_3 \\
f_3(\boldsymbol{x}) &= 0.5\left(V_{\mathrm{MBP}}(\boldsymbol{x}) + V_{\mathrm{FD}}(\boldsymbol{x})\right) \\
f_4(\boldsymbol{x}) &= -\sum_{i=1}^{10} \max\left(g_i(\boldsymbol{x}), 0\right)
\end{aligned}
$$

where the constraint functions $g_i(\boldsymbol{x})$ are defined as:

$$
\begin{aligned}
g_1(\boldsymbol{x}) &= 1 - 1.16 + 0.3717x_2x_4 + 0.0092928x_3 \\
g_2(\boldsymbol{x}) &= 0.32 - 0.261 + 0.0159x_1x_2 + 0.06486x_1 + 0.019x_2x_7 - 0.0144x_3x_5 - 0.0154464x_6 \\
g_3(\boldsymbol{x}) &= 0.32 - 0.214 - 0.00817x_5 + 0.045195x_1 + 0.0135168x_1 - 0.03099x_2x_6 \\
&\quad + 0.018x_2x_7 - 0.007176x_3 - 0.023223x_3 + 0.00364x_5x_6 + 0.018x_2^2 \\
g_4(\boldsymbol{x}) &= 0.32 - 0.74 + 0.61x_2 + 0.031296x_3 + 0.031872x_7 - 0.227x_2^2 \\
g_5(\boldsymbol{x}) &= 32 - 28.98 - 3.818x_3 + 4.2x_1x_2 - 1.27296x_6 + 2.68065x_7 \\
g_6(\boldsymbol{x}) &= 32 - 33.86 - 2.95x_3 + 5.057x_1x_2 + 3.795x_2 + 3.4431x_7 - 1.45728 \\
g_7(\boldsymbol{x}) &= 32 - 46.36 + 9.9x_2 + 4.4505x_1 \\
g_8(\boldsymbol{x}) &= 4 - f_2(\boldsymbol{x}) \\
g_9(\boldsymbol{x}) &= 9.9 - V_{\mathrm{MBP}}(\boldsymbol{x}) \\
g_{10}(\boldsymbol{x}) &= 15.7 - V_{\mathrm{FD}}(\boldsymbol{x})
\end{aligned}
$$

with volume terms defined as:

$$
\begin{aligned}
V_{\mathrm{MBP}}(\boldsymbol{x}) &= 10.58 - 0.674x_1x_2 - 0.67275x_2 \\
V_{\mathrm{FD}}(\boldsymbol{x}) &= 16.45 - 0.489x_3x_7 - 0.8435x_6x_7.
\end{aligned}
$$

The search space is defined as:

$$
\begin{aligned}
x_1 &\in [0.5, 1.5], \\
x_2 &\in [0.45, 1.35], \\
x_3, x_4 &\in [0.5, 1.5], \\
x_5 &\in [0.875, 2.625], \\
x_6, x_7 &\in [0.4, 1.2].
\end{aligned}
$$

Water Resource Planning (WRP). The water resource planning problem (Ray et al., 2001) aims to minimise the costs and expected losses associated with an urban storm drainage system. It involves $m = 6$ objectives with $d = 3$ variables, where the first five objectives correspond to the drainage network cost, storage facility cost, treatment facility cost, expected flood damage cost, and expected economic loss due to flooding,

respectively. The sixth objective is defined as the total constraint violation. The mathematical formulations are given as follows:

$$f_1(\boldsymbol{x}) = 106780.37(x_2 + x_3) + 61704.67$$
$$f_2(\boldsymbol{x}) = 3000x_1$$
$$f_3(\boldsymbol{x}) = \frac{305700 \times 2289x_2}{(0.06 \times 2289)^{0.65}}$$
$$f_4(\boldsymbol{x}) = 250 \times 2289 \exp(-39.75x_2 + 9.9x_3 + 2.74)$$
$$f_5(\boldsymbol{x}) = 25 \left(\frac{1.39}{x_1 x_2} + 4940x_3 - 80 \right)$$
$$f_6(\boldsymbol{x}) = \sum_{i=1}^{7} \max\left(g_i(\boldsymbol{x}), 0\right).$$

where the constraint functions $g_i(\boldsymbol{x})$ are defined as:

$$g_1(\boldsymbol{x}) = \frac{0.00139}{x_1 x_2} + 4.94x_3 - 0.08 - 1$$
$$g_2(\boldsymbol{x}) = \frac{0.000306}{x_1 x_2} + 1.082x_3 - 0.0986 - 1$$
$$g_3(\boldsymbol{x}) = \frac{12.307}{x_1 x_2} + 49408.24x_3 + 4051.02 - 50000$$
$$g_4(\boldsymbol{x}) = \frac{2.098}{x_1 x_2} + 8046.33x_3 - 696.71 - 16000$$
$$g_5(\boldsymbol{x}) = \frac{2.138}{x_1 x_2} + 7883.39x_3 - 705.04 - 10000$$
$$g_6(\boldsymbol{x}) = 0.417x_1 x_2 + 1721.26x_3 - 136.54 - 2000$$
$$g_7(\boldsymbol{x}) = \frac{0.164}{x_1 x_2} + 631.13x_3 - 54.48 - 550.$$

The search space is defined as:

$$x_1 \in [0.01, 0.45],$$
$$x_2, x_3 \in [0.01, 0.10].$$

Car Cab Design. This vehicle performance optimisation problem involves $m = 9$ objectives with $d = 7$ variables, relating to aspects such as car roominess, fuel economy, acceleration time, and road noise at various speeds (Deb & Jain, 2013). The problem includes 7 decision variables and 4 stochastic variables, which are based on a surrogate model that is fit to data collected from a simulator, defined as:

$$f_1(\boldsymbol{x}) = 1.98 + 4.9x_1 + 6.67x_2 + 6.98x_3 + 4.01x_4 + 1.75x_5 + 10^{-5}x_6 + 2.73x_7$$

$$f_2(\boldsymbol{x}) = [1.16 - 0.3717x_2x_4 - 0.00931x_2x_{10} - 0.484x_3x_9 + 0.01343x_6x_{10}]_+$$

$$f_3(\boldsymbol{x}) = \left[\frac{1}{0.32} \left(\begin{matrix} 0.261 - 0.0159x_1x_2 - 0.188x_1x_8 - 0.019x_2x_7 + 0.0144x_3x_5 + 0.8757x_5x_{10} \\ + 0.08045x_6x_9 + 0.00139x_8x_{11} + 0.00001575x_{10}x_{11} \end{matrix} \right) \right]_+$$

1005   where $[\cdot]_+$ denotes $\max(0, \cdot)$ and the search space is defined as:

$$x_1 \in [0.5,\ 1.5],$$
$$x_2 \in [0.45,\ 1.35],$$
$$x_3,\ x_4 \in [0.5,\ 1.5],$$
$$x_5 \in [0.875,\ 2.625],$$
$$x_6,\ x_7 \in [0.4,\ 1.2].$$

1006   The four stochastic variables are defined as:

$$x_8 \sim \mathcal{N}(0.345,\ 0.006^2),$$
$$x_9 \sim \mathcal{N}(0.192,\ 0.006^2),$$
$$x_{10},\ x_{11} \sim \mathcal{N}(0,\ 10^2).$$

F Additional Experimental Results

F.1 Noiseless Cases

In this section, we present the results on the noiseless problems, including DTLZ1 and DTLZ2, their four variants with 3 and 10 objectives, and the two real-world problems. Tables 5, 6 and 7 show the distance-based metric (log distance), the HV of the best solution (in terms of its HV value) and the HV of all evaluated solutions obtained by the SPMO and the peer methods on the six noiseless problems, respectively. Figures 7, 8 and 9 present the violin plots, illustrating the distributions of the corresponding results reported in Tables 5, 6, and 7, respectively. In addition, Figure 10 presents the trajectories of the distance metric obtained by each method on the noiseless problems with 3 and 10 objectives. Figure 11 presents the trajectories of the HV of the best solution obtained by each method on the noiseless problems with 3 and 10 objectives. Figure 12 presents the trajectories of the HV of all evaluated solutions obtained by each method on the noiseless problems. Note that the results of the HV of all evaluated solutions are reported every 10 evaluations due to the high computational cost of HV calculation. We also give the results of the problems DTLZ3–DLTZ7 with 5 objectives, shown in Tables 8, 9 and 10.

Table 5: Results of the distance-based metric (log distance) obtained by the SPMO and the peer methods on the noiseless problems with 3 objectives (**top**) and 10 objectives (**bottom**) on 30 independent runs. The method with the best mean is highlighted in bold. The symbols "+", "∼" and "−" indicate that the method is statistically worse than, equivalent to and better than our SPMO, respectively.

F.2 Noisy Cases

In this section, we present the results on the noisy problems. Tables 11, 12 and 13 show the distance-based metric (log distance), the HV of the best solution (in terms of its HV value) and the HV of all evaluated solutions obtained by the SPMO and the peer methods, respectively. Figures 13, 14 and 15 present the violin plots, illustrating the distributions of the corresponding results reported in Tables 11, 12 and 13, respectively. Figure 16 shows trajectories of the distance metric, the HV of the best solution, and the HV of all evaluated solutions obtained by the SPMO and the peer methods.

Table 11: Results of the distance-based metric (log distance) obtained by the SPMO and the peer methods on the noisy problems with 5 objectives on 30 independent runs. The method with the best mean is highlighted in bold. The symbols "+", "∼" and "−" indicate that the method is statistically worse than, equivalent to and better than our SPMO, respectively.

Figure 13: Violin plots of the distance-based metric (log distance) obtained by the six methods on the noisy problems with five objectives. Each violin represents the distribution of the distance-based metric obtained by a method over 30 independent runs.

Figure 14: Violin plots of the HV of the best solution (in terms of its HV value) obtained by the six methods on the noisy problems with five objectives. Each violin represents the distribution of maximum HV values obtained by a method over 30 independent runs.

Figure 15: Violin plots of the HV of all evaluated solutions obtained by the six methods on the noisy problems with five objectives. Each violin represents the distribution of maximum HV values obtained by a method over 30 independent runs.

(a) Trajectories of the distance metric.

(b) Trajectories of the HV of the best solution.

(c) Trajectories of the HV of all evaluated solutions.

Figure 16: Trajectories of the distance metric, the HV of the best solution, and the HV of all evaluated solutions obtained by the SPMO and the peer methods. Each coloured line represents the mean metric value on 30 independent runs. Note that we report the HV of all evaluated solutions every 10 evaluations due to the high computational complexity of HV calculation.

F.3 Batch Setting

We compare the proposed SPMO with the peer methods in the batch setting where the batch size q is set to 5 (a commonly used value (Lin et al., 2022)). Tables 14, 15 and 16 show the distance-based metric (log distance), the HV of the best solution (in terms of its HV value) and the HV of all evaluated solutions obtained by the SPMO and the peer methods, respectively. Figures 17, 18 and 19 present the violin plots, illustrating the distributions of the corresponding results reported in Tables 14, 15 and 16, respectively. Figure 20 shows trajectories of the distance metric, the HV of the best solution, and the HV of all evaluated solutions obtained by the SPMO and the peer methods.

Table 14: Results of the distance-based metric (log distance) obtained by the SPMO and the five peer methods with a batch size $q = 5$ on the problems with 5 objectives on 30 independent runs. The method with the best mean is highlighted in bold. The symbols "+", "∼" and "−" indicate that the method is statistically worse than, equivalent to and better than our SPMO, respectively.

Note that we report the HV of all evaluated solutions every 10 evaluations due to the high computational complexity of HV calculation.

F.4 Sensitivity analysis

F.4.1 Utopian Points Based on the True Ideal Point.

In this section, we conduct a sensitivity analysis to assess the effect of different utopian points. We consider three different settings based on the problem's true ideal point. The first one is slightly better than the ideal point, i.e., with a difference of 0.01, the second is fairly better than the ideal point (i.e. 0.1), and the last one is significantly better than the ideal point (i.e. 1.0). Tables 17, 18 and 19 show the distance-based metric (log distance), the HV of the best solution (in terms of its HV value), and the HV of all evaluated solutions obtained by the SPMO with four different utopian points, respectively. Figures 21, 22 and 23 present the violin plots, illustrating the distributions of the corresponding results reported in Tables 17, 18 and 19, respectively. Figure 24 shows trajectories of the distance metric, the HV of the best solution, and the HV of all evaluated solutions obtained by the SPMO with four different utopian points.

Table 17: Results of the distance-based metric (log distance) obtained by the SPMO with four different utopian points on the problems with five objectives on 30 independent runs. The method with the best mean is highlighted in bold. The symbols "+", "∼" and "−" indicate that the method is statistically worse than, equivalent to and better than SPMO (current), respectively.

F.4.2 Utopian Points Based on Observed Solutions based on the observed solutions.

Previously, we investigated SPMO using different utopian points based on the problem's true ideal point. However, there may exist situations in the real world where one may have very little knowledge about the optimisation problem. To further examine a more practical setting, we consider dynamically setting the utopian point based only on the observed solutions during optimisation. We consider four settings, where the observed objective values are first normalised and the utopian point is then set to $(-0.1, \ldots, -0.1)$, $(-0.2, \ldots, -0.2)$, $(-0.5, \ldots, -0.5)$, and $(-1.0, \ldots, -1.0)$, respectively. These variants are denoted as $\text{SPMO}_{dynamic\_0.1}$, $\text{SPMO}_{dynamic\_0.2}$, $\text{SPMO}_{dynamic\_0.5}$, and $\text{SPMO}_{dynamic\_1.0}$, respectively. Tables 20, 21 and 22 show the distance-based metric (log distance), the HV of the best solution (in terms of its HV value), and the HV of all evaluated solutions obtained by the SPMO with four different utopian points, respectively. Figures 25, 26 and 27 present the violin plots, illustrating the distributions of the corresponding results reported in Tables 20, 21 and 22, respectively. Figure 28 shows trajectories of the distance metric, the HV of the best solution, and the HV of all evaluated solutions obtained by the SPMO with five different utopian points.

Each coloured line represents the mean metric value on 30 independent runs. Note that we report the HV of all evaluated solutions every 10 evaluations due to the high computational complexity of HV calculation.

F.5 Comparison of Single-Point Metrics within SPMO

In the proposed SPMO framework, we employ a distance metric (i.e., the distance of a solution to the utopian point), denoted as SPMO_{dist}. However, different metrics can be adopted provided that they can reflect the quality of a solution in achieving a good trade-off between objectives. We now consider three other well-known metrics, weighted sum, Tchebycheff scalarisation, and single-point HV, denoted by SPMO_{ws}, SPMO_{Tch}, and SPMO_{hv}, respectively. The equal weights $(\frac{1}{m}, \ldots, \frac{1}{m})$ are used in SPMO_{ws} and SPMO_{Tch}. The reference point of SPMO_{hv} is set to 1.1 times the observed Pareto front, since using a fixed reference point (e.g., $(1.1, \ldots, 1.1) \in \mathbb{R}^m$ for DTLZ2) can lead to zero acquisition values when no candidate solution dominates the reference point. Here, we compare these four variants of SPMO, i.e., SPMO_{dist}, SPMO_{Tch}, SPMO_{ws}, and SPMO_{hv}. Tables 23, 24 and 25 show the distance-based metric (log distance), the HV of the best solution (in terms of its HV value) and the HV of all evaluated solutions obtained by the SPMO with four different single-point metrics, respectively. Figures 29, 30 and 31 present the violin plots, illustrating the distributions of the corresponding results reported in Tables 23, 24 and 25, respectively. Figure 32 shows trajectories of the distance metric, the HV of the best solution, and the HV of all evaluated solutions obtained by each method.

Table 23: Results of the distance-based metric (log distance) obtained by the SPMO using four different single-point metrics on the problems with five objectives on 30 independent runs. The method with the best mean is highlighted in bold. The symbols "+", "~" and "−" indicate that the method is statistically worse than, equivalent to and better than our SPMO (i.e., SPMO_{dist}), respectively.

Figure 31: Violin plots of the HV of all evaluated solutions obtained by the SPMO using four different single-point metrics on the problems with five objectives. Each violin represents the distribution of maximum HV values obtained by a method over 30 independent runs.

(a) Trajectories of the distance metric.

(b) Trajectories of the HV of the best solution.

(c) Trajectories of the HV of all evaluated solutions.

Figure 32: Trajectories of the distance metric, the HV of the best solution, and the HV of all evaluated solutions obtained by the SPMO with four different single-point metrics. Each coloured line represents the mean metric value on 30 independent runs. Note that we report the HV of all evaluated solutions every 10 evaluations due to the high computational complexity of HV calculation.

F.6 Incorporating Preference Information into SPMO.

Previously, we focused on the preference-free setting, where no prior knowledge of the decision maker's preferences is available. However, SPMO can naturally incorporate preference information into its single-point metrics. We extend the four metrics introduced above, i.e., SPMO_{dist}, SPMO_{ws}, SPMO_{Tch}, and SPMO_{hv}, to the preference-based setting. Given a weight vector $\boldsymbol{w}$, a preference-based distance metric can be defined as $\|\boldsymbol{w} \odot (\boldsymbol{y} - \boldsymbol{z})\|_2$, where $\odot$ denotes element-wise multiplication. Weighted-sum and Tchebycheff scalarisation can incorporate preference information directly through a weight vector. Regarding the single-point HV metric, given a reference point $\boldsymbol{r}$, preference-based single-point HV can be defined as $\prod_{i=1}^{m} \max(w_i(y_i - r_i), 0)$.

For an m-objective problem, the weight vector is set to $\boldsymbol{w} = (0.1, 0.2, \ldots, 0.1m)$ and is normalised by its sum, i.e., $\boldsymbol{w} \leftarrow \boldsymbol{w} / \sum_{i=1}^{m} w_i$. Similar to the previous comparison, we use the preference-based distance metric and preference-based single-point HV as the performance metrics. Tables 26 and 27 show the weighted log distance and the preference-based single-point HV obtained by the SPMO with three different single-point metrics, respectively. Figures 33 and 34 present the violin plots, illustrating the distributions of the corresponding results reported in Tables 26 and 27, respectively. Figure 35 shows trajectories of the preference-based distance metric and the preference-based single-point HV of the best solution obtained by each method.

Table 26: Results in terms of the preference-based distance metric (log distance) obtained by SPMO with four different single-point metrics. The method with the best mean is highlighted in bold. The symbols "+", "∼" and "−" indicate that the method is statistically worse than, equivalent to and better than our SPMO (i.e., SPMO_{dist}), respectively.

Each coloured line represents the mean metric value on 30 independent runs (after the initial Sobol samples, represented by the dashed grey line).

F.7 Acquisition Wall Time

Table 28 presents the mean acquisition optimisation wall time of the eight methods. As shown, when the number of objectives is 3 or 5, the time of all the methods is acceptable with a maximum of 98 seconds. As the number of objectives increases to 10, hypervolume-based methods become very expensive. For example, EHVI and NEHVI take about half an hour and more than 3 hours, respectively. Note that although PSL takes only several minutes based on the initial samples, the hypervolume computation can take a day for a single evaluation when the number of non-dominated solutions becomes large. The proposed SPMO method shows high computational efficiency, achieving the lowest time requirement in four out of the six instances.

Table 28: Mean acquisition optimisation wall time in seconds based on the $2(d+1)$ initial Sobol samples on DTLZ1 problems with $m = 3, 5, 10$ objectives, where $d = m + 4$, over 30 runs. Experiments are conducted using a CPU (Intel Xeon CPU Platinum 8360Y @ 2.40 GHz) and a GPU (NVIDIA A100). Note that N/A means the wall time of NEHVI on DTLZ1 with 10 objectives exceeds 3 hours.

G Applicability of the Proposed SPMO

In conventional multi-objective optimisation, algorithms are designed to approximate the entire Pareto front, so that a decision-maker can later select a preferred solution based on their own preferences. This is the ideal situation, as a well-represented Pareto front provides the most comprehensive view of the possible trade-offs (Jiang & Li, 2025a). However, under tight evaluation budgets - especially when many objectives are involved - it is often unrealistic, if not impossible, to obtain a good approximation of the Pareto front. In such settings, the decision-maker may benefit more from receiving a well-balanced solution that is close to the Pareto front, rather than a well-distributed solution set far from the front. The proposed SPMO framework is designed for this purpose: instead of spreading search effort across the whole front, it directs the optimisation towards a well-balanced solution. With a focused search effort, the obtained solution is often closer to the front, and thus has a higher likelihood of being selected by the decision-maker.

It is worth pointing out that if the optimisation problem under consideration is extremely simple (e.g., smooth, unimodal landscape with a very limited search space), on which finding a good representation of the entire Pareto front is possible under tight budgets, then our approach may not be desirable. Moreover, exploring the Pareto front can help decision-makers better understand the optimisation problem and facilitate the elicitation or refinement of their preferences. In such cases, our framework is not applicable.

H Extensions

The preceding discussion has addressed multi-objective optimisation problems in which evaluations are performed either sequentially or in batches, under both noiseless and noisy scenarios. However, not all multi-objective settings conform to these scenarios. To accommodate a broader class of problems, we propose several extensions that enable the methodology to handle more optimisation scenarios.

High-Dimensional Bayesian Optimisation (HDBO). High-dimensional black-box optimisation problems are highly challenging and frequently encountered in a wide range of applications. The dimensionality may range from tens to a billion (González-Duque et al., 2024; Papenmeier et al., 2023; Santoni et al., 2024; Wang et al., 2016; Hoang et al., 2025). To tackle such optimisation problems, various HDBO methods have been proposed (Binois & Wycoff, 2022; Chen et al., 2024; Nayebi et al., 2019; Wang et al., 2018; 2016; Xu et al., 2025). They can loosely be categorised into four classes (Santoni et al., 2024), i.e., variable selection (Eriksson & Jankowiak, 2021), additive models (Delbridge et al., 2020; Han et al., 2021; Wang et al.,

2018; Ziomek & Ammar, 2023), embeddings (Antonov et al., 2022; Letham et al., 2020; Raponi et al., 2020), and trust regions (Daulton et al., 2022b; Diouane et al., 2023; Eriksson et al., 2019). However, recent studies show that standard Gaussian processes without the above techniques can perform well in high-dimensional spaces (Hvarfner et al., 2024; Papenmeier et al., 2025; Xu et al., 2025; Jiang et al., 2026) and suggest that the main issue in high-dimensional BO is the gradient vanishing. Our work can be naturally extended to the high-dimensional setting by mitigating the gradient vanishing issue (Papenmeier et al., 2025; Xu et al., 2025).

Multi-Fidelity Bayesian Optimisation (MFBO). In many real-world optimisation scenarios, the evaluation is often available at multiple fidelity levels, where increasing fidelity typically leads to improved accuracy at the expense of higher computational cost. Many MFBO methods have been proposed to tackle such optimisation problems (Belakaria et al., 2020a; Kandasamy et al., 2017; Li et al., 2020; Moss et al., 2021; Song et al., 2019; Takeno et al., 2020; Wu et al., 2020; Zhang et al., 2017). Our proposed SPMO can be potentially extended to the multi-fidelity setting by integrating prior techniques, e.g., building multiple surrogate models of different levels of fidelity.
