Detecting and Filtering Unsafe Training Data via Data Attribution with Denoised Representation

Abstract

Large language models (LLMs) are highly sensitive to even small amounts of unsafe training data, making effective detection and filtering essential for trustworthy model development. Current state-of-the-art (SOTA) detection approaches primarily rely on moderation classifiers, which require significant computation overhead for training and are limited to predefined taxonomies. In this work, we explore data attribution approaches that measure the similarity between individual training samples and a small set of unsafe target examples, based on data representations such as hidden states or gradients. We identify a key limitation in existing methods: unsafe target texts contain both critical tokens that make them unsafe and neutral tokens (e.g., stop words or benign facts) that are necessary to form fluent language, and the latter of which makes the overall representations "noisy" for the purpose of detecting unsafe training data. To address this challenge, we propose Denoised Representation Attribution (DRA), a novel representation-based data attribution approach that denoises training and target representations for unsafe data detection. Across tasks of filtering jailbreaks and detecting gender bias, the proposed approach leads to significant improvement for data attribution methods, outperforming SOTA methods that are mostly based on moderation classifiers.

1 Introduction

Large Language Models (LLMs) are known to exhibit various unsafe behaviors, including toxicity, stereotyping, privacy leaks, and ethical violations (Wang et al., 2024a). A primary source of these issues is unsafe training data (Jiang et al., 2024; Chen et al., 2024). For instance, inherent biases or toxic content in training data can lead to harmful responses (Jiang et al., 2024; Ouyang et al., 2022), while deliberate training-time attacks, such as adversarial prompts or injected backdoors, can be used to bypass safety alignments (Chen et al., 2024; Zou et al., 2023; Li et al., 2024b). Consequently, identifying and removing these unsafe training instances is critical for mitigating risks and building safer LLMs.

Existing methods for detecting and filtering unsafe training data typically rely on moderation classifiers. Online API tools, such as the Perspective API [1] and OpenAI's Moderation API (Markov et al., 2023), focus on certain predefined toxicity taxonomies, struggling to generalize to nuanced and emerging unsafe artifacts beyond these predefined taxonomies (Weber et al., 2025). Fine-tuned detection models, including Llama-Guard-3-8B (Llama Team, 2024) and Wildguard (Han et al., 2024), require significant time and resources for additional data collection and training. Moreover, these moderation classifiers primarily flag stylistically unsafe data in a model-agnostic way, without accounting for how individual training samples actually influence the model. As a result, they fail to capture the true training impact of unsafe data and are less effective for enhancing model safety through retraining.

Another line of research focuses on filtering training data by measuring data representation similarity with a set of unsafe model responses. These methods are appealing because they do not require additional labeled data and can be flexibly applied across diverse forms of unsafe model outputs. The core hypothesis is that unsafe training data exhibit higher similarity to unsafe model outputs. Prior work has explored model hidden states, for example, LARF (Li et al., 2025) and RepSim (Pezeshkpour et al., 2021), as well as gradient-based similarity (Xia et al., 2024). These methods are widely adopted in the data attribution literature (Deng et al., 2025) to quantify the influence of training data on target data (Pruthi et al., 2020).

---

[1] https://www.perspectiveapi.com/

However, existing representation-based methods typically measure similarity between training samples and target unsafe examples using representations averaged over all tokens in each sample. This naive averaging introduces a key limitation: not all token representations contribute equally to detecting unsafe data. Unsafe texts often contain only a few critical tokens that account for the unsafe semantics while the majority of tokens (e.g., stop words or neutral phrases) are benign and contribute to linguistic fluency or neutral factual information. As a result, the averaged representations are "noisy", obscuring the true signal needed to identify unsafe training data.

To address this limitation, we propose Denoised Representation Attribution (DRA), a novel representation-based data attribution method for unsafe training data detection and filtering. DRA denoises the training and target representations in two steps. First, motivated by the optimal linear detector in signal detection theory (Stanislaw and Todorov, 1999), DRA centers and whitens the data representations so spurious high-variance dimensions often irrelevant to the unsafeness are downweighted. Second, DRA applies a simple *leave-target-out* surrogate to select most informative hidden dimensions of the representations for unsafe training data detection. This two-step procedure leads to denoised representations that are more effective to detect unsafe training samples.

We validate our proposed approach through experiments on both jailbreaking and gender bias scenarios. Experimental results demonstrate that our method consistently outperforms state-of-the-art detection approaches across different model architectures, increasing average detection AUPRC by up to 63.3%. Moreover, when retraining models on data filtered by our method, we decrease average ASR (Attack Success Rate) by up to 39.9% , confirming the effectiveness of our approach in mitigating unsafe training data.

2 Related Work

2.1 Sources of Unsafe Training Data in LLMs

Recent studies (Yi et al., 2024; Qi et al., 2023) reveal that malicious fine-tuning can severely compromise safety alignment, even with limited exposure to unsafe data. Unfortunately, current online fine-tuning services are inadequate at detecting these unsafe training data, leaving LLMs vulnerable to potential exploitation (Qi et al., 2023).

Unsafe data may also emerge from synthetic training data generation. For instance, Wang et al. (2022) generate samples by conditioning LLMs on specific keywords and target labels, while Wang et al. (2023) synthesize fine-tuning data from LLM-generated responses. However, as recent safety research (Wang et al., 2024a) indicates, even highly aligned models like GPT-4 and GPT-3.5 exhibit unsafe behaviors, suggesting that synthetic data can introduce significant risks.

In addition, inherent biases in training data pose challenges that current detection methods are not equipped to handle. Studies have shown that gender bias in training data can lead LLMs to develop skewed assumptions about occupations (Kotek et al., 2023), while cognitive biases during training undermine model reliability in high-stakes decisions (Itzhak et al., 2024; Echterhoff et al., 2024).

The diverse source of unsafe training data highlights the need for more flexible and adaptable detection methods. Current moderation classifiers, often designed for specific content moderation tasks, are insufficient for addressing the complexity and variability of unsafe data in training pipelines.

2.2 Unsafe Training Data Detection in LLMs

Existing efforts to detect unsafe training data primarily focus on content moderation classifiers. For example, online moderation tools such as OpenAI's Moderation API (Markov et al., 2023) are developed to detect harmful content. Recently, there has been growing efforts in developing LLM-based classifiers. One line of research has explored fine-tuning open-source LLMs on specifically curated safety dataset to develop moderation classifiers. Examples of such classifiers include Llama-Guard-3-8B (Llama Team, 2024), Wildguard (Han et al., 2024), Aegis-Guard (Ghosh et al., 2024), and ShieldGemma (Zeng et al., 2024). Another line of research focuses on leveraging LLMs directly as judges for unsafe data detection (Franco et al., 2023; Li et al., 2024a). For instance, Safety-Analyst (Li et al., 2024a) proposes using LLMs to generate "harm-benefit" tree for interpretable content moderation.

Beyond safety classifiers, other approaches rely on representation-based similarity for unsafe data detection. For example, BEBC (Zheng et al., 2024) employs fine-tuned BERT embeddings for content moderation, while gradient-based methods such as GradSafe (Xie et al., 2024) estimate similarity with respect to safety-critical parameters. More

broadly, gradient-similarity methods can be seen as a form of data attribution (Koh and Liang, 2020), which quantify the influence of individual training samples on model outputs. These attribution-based perspectives are particularly useful for detecting unsafe data, as such data often exert disproportionate influence on unsafe behaviors, making them distinguishable from the broader benign dataset. Although influence estimation can be computationally intensive, recent gradient-similarity approaches (Xia et al., 2024; Kwon et al., 2024) provide more efficient alternatives, making them better suited for scaling to large models.

However, prior work such as GradSafe and BEBC primarily focus on prompt filtering, whereas in training data detection the training label is also important, since it drives model behavior during training. Naively extending these methods to the training data setting yields suboptimal results, as noise in model responses manifests as degraded detection performance (Jiao et al., 2025). In this context, our methods enable efficient and principled denoising and dimension selection techniques for representation-based detection. Our approach enhances detection performance and fosters safer model developments.

3 Unsafe Training Data Detection and Filtering

In this section, we formally define the task of unsafe training data detection, introduce a framework for quantifying the sensitivity of representation-based detection methods, and present our proposed Denoised Representation Attribution (DRA) approach for improving detection effectiveness. We also describe how this detection method can be used to filter unsafe data for safer downstream model training.

3.1 Problem Setup: Representation-Based Unsafe Training Data Detection

Consider a training dataset with a mixture of *benign* and *unsafe* data:

$$\mathcal{D}_{\text{train}} = \mathcal{D}_{\text{benign}} \cup \mathcal{D}_{\text{unsafe}},$$

where $\mathcal{D}_{\text{benign}}$ refers to the benign dataset that is safe to train on while $\mathcal{D}_{\text{unsafe}}$ is the unsafe training dataset that could lead to unsafe model behaviors. In real world scenarios, the training dataset often consists of only a small portion of unsafe data, and the membership of $\mathcal{D}_{\text{benign}}$ and $\mathcal{D}_{\text{unsafe}}$ is unknown.

The goal of *unsafe training data detection* is to identify a subset of training data points in $\mathcal{D}_{\text{train}}$ that are mostly likely to be unsafe.

In addition, we assume access to a (small) target dataset $\mathcal{D}_{\text{target}}$ that consists of unsafe model outputs. In practice, these examples may be flagged by users or collected via red teaming.

Representation-based detection. For any $z \in \mathcal{D}_{\text{train}} \cup \mathcal{D}_{\text{target}}$, let h be the mapping from the data point z to its representation $h(z) \in \mathbb{R}^m$ (e.g., hidden states or gradients). Then we define $B = \{h(z) \mid z \in \mathcal{D}_{\text{benign}}\}, U = \{h(z) \mid z \in \mathcal{D}_{\text{unsafe}}\}$, and $Q = \{h(z) \mid z \in \mathcal{D}_{\text{target}}\}$, which are respectively the set of data representations for $\mathcal{D}_{\text{benign}}, \mathcal{D}_{\text{unsafe}}$, and $\mathcal{D}_{\text{target}}$. The set of data representations for $\mathcal{D}_{\text{train}}$ is then $X = B \cup U$.

A common paradigm in prior work (Xie et al., 2024; Xia et al., 2024; Li et al., 2025) is to assign each training representation $x \in X$ ($x \in \mathbb{R}^m$) a *detection score* based on its similarity to an aggregated target representation $\mu_Q = \text{Agg}(Q) \in \mathbb{R}^m$ (e.g., $\text{Agg}(Q) = \frac{1}{|Q|} \sum_{q \in Q} q$). Training samples with the highest detection scores are then flagged as unsafe. Formally, the score is typically defined as the inner product

$$s_{\mu_Q}(x) = \langle x, \mu_Q \rangle.$$

In LLMs, both the training representation x and the aggregated target representation μ_Q encode rich semantic information, much of which is irrelevant to the unsafeness of the samples. For the purpose of detecting unsafe training data, both representations are therefore noisy.

Goal. Our study aims to quantify the *sensitivity* of the detection score s_{μ_Q}, and develop better representation-based detection measures.

3.2 Sensitivity of the Detection Score

We frame the problem of detecting unsafe training data in the language of *signal detection theory* (Stanislaw and Todorov, 1999): the unsafe training data act as the *signal* to be distinguished from a much larger background of benign data constituting the *noise*. The sensitivity of such detection can be quantified by the classical *discriminability index*, $d' = \frac{\mu_{\text{signal}} - \mu_{\text{noise}}}{\sigma_{\text{noise}}}$, which depends on the means ($\mu_.$) and standard deviations ($\sigma_.$) of a given detection measure for the signal and noise distributions, and reflects how well the two distributions can be separated.

By applying this formulation to the detection score s_{μ_Q} in our problem, we obtain the following sensitivity measure for detecting signal samples U from noise samples X[2] using s_{μ_Q}:

$$
\begin{aligned}
d'(s_{\mu_Q}) &= \frac{\mathbb{E}_{u \sim U}[s_{\mu_Q}(u)] - \mathbb{E}_{x \sim X}[s_{\mu_Q}(x)]}{\sqrt{\mathrm{Var}_{x \sim X}[s_{\mu_Q}(x)]}} \\
&= \frac{\langle \mu_U - \mu_X, \mu_Q \rangle}{\sqrt{\mu_Q^\top \Sigma_X \mu_Q}},
\end{aligned} \tag{1}
$$

where μ_U and μ_X are the mean of U and X, and $\Sigma_X = \mathrm{Cov}(X) \in \mathbb{R}^{m \times m}$ is the covariance of X. It is worth noting that under certain technical assumptions, the discriminability index d' is monotonic with respect to AUROC and AUPRC (Stanislaw and Todorov, 1999). Thus d' can be viewed as a theoretically grounded surrogate of these widely used evaluation metrics for unsafe data detection, while additionally admitting a natural decomposition that enables fine-grained analysis of the representation-based detection.

3.3 Improving the Detection Score by Denoising Representations

Given the discriminability index d', our goal is to develop a representation-based detection score s that achieves a higher $d'(s)$.

Optimal linear detection score. We consider the family of *linear detection scores*, $s_w(x) = \langle x, w \rangle$, for any linear weights $w \in \mathbb{R}^m$. There is a classical result (Poor, 2013) in signal detection theory about the optimal linear detection score as stated below.

Lemma 3.1 (Optimal Linear Detection Score)
For any $w \in \mathbb{R}^m$, denoting $\Delta = \mu_U - \mu_X$, then

$$
\begin{aligned}
d'(s_w) &= \frac{\langle \Delta, w \rangle}{\sqrt{w^\top \Sigma_X w}} = \frac{\langle \Sigma_X^{-1/2} \Delta, \Sigma_X^{1/2} w \rangle}{\|\Sigma_X^{1/2} w\|} \\
&\leq \|\Sigma_X^{-1/2} \Delta\|,
\end{aligned}
$$

with equality achieved for optimal $w^* \propto \Sigma_X^{-1} \Delta$.

However, note that this theoretically optimal linear weight w^* is infeasible to compute, as it depends on μ_U, which is unknown due to the unavailability of the unsafe dataset $\mathcal{D}_{\mathrm{unsafe}}$.

Plug-in detection score. In practice, under the hypothesis that the mean μ_Q from the target dataset aligns well with μ_U, we propose to set $\hat{w} = \Sigma_X^{-1}(\mu_Q - \mu_X)$, which gives us a *plug-in detection score* $s_{\hat{w}}$ as an estimate of the optimal linear detection score s_{w^*}.

Intuitively, compared to the raw score $s_{\mu_Q}(x) = \langle x, \mu_Q \rangle$, the plug-in score

$$
\begin{aligned}
s_{\hat{w}}(x) &= \langle x, \Sigma_X^{-1}(\mu_Q - \mu_X) \rangle \\
&= \langle \Sigma_X^{-1/2}(x - \mu_X), \Sigma_X^{-1/2}(\mu_Q - \mu_X) \rangle + c,
\end{aligned}
$$

is a *Mahalanobis* correlation (up to a constant c independent of x): it first *centers* both train and target representations by the background mean μ_X to remove global content common to almost all training points, then *whitens* by $\Sigma_X^{-1/2}$ to suppress the high-variance dimensions of the data representation, since the dominant dimensions could correspond to topics or styles instead of the unsafeness.

Dimension selection via leave-target-out discriminability index. For LLMs, the data representation dimension size m can be very large. Even with the denoising step described above, the representations could still contain too much irrelevant information. Since dimension selection is essentially a subset selection problem, the task becomes challenging when m is large. We further propose to conduct a dimension selection to select the most informative hidden dimensions in the representation for unsafe training data detection.

Specifically, given the eigen decomposition of $\Sigma_X = V \Lambda V^\top$, we will select a subset of eigenvectors $V_I \in \mathbb{R}^{m \times |I|}$ indexed by indices $I \subseteq \{1, 2, \ldots, m\}$. Let $\Pi_I = V_I V_I^\top$ be the projection matrix for the space spanned by V_I. We define a detection score restricted to the selected dimensions I as following:

$$
s_I(x) = \langle \Pi_I \Sigma_X^{-1/2}(x - \mu_X), \ \Pi_I \Sigma_X^{-1/2}(\mu_Q - \mu_X) \rangle.
$$

A natural criterion for selecting the dimensions I is to maximize the discriminability index applied to s_I:

$$
d'(s_I) = \frac{\mathbb{E}_{u \sim U}[s_I(u)] - \mathbb{E}_{x \sim X}[s_I(x)]}{\sqrt{\mathrm{Var}_{x \sim X}[s_I(x)]}}.
$$

However, since $d'(s_I)$ depends on U, it is infeasible to compute. Again, we utilize the trick of approximating U from the ground truth unsafe training

---

[2]Strictly speaking, the noise samples are B. Under the assumption that $|U|$ is much smaller than $|B|$, the empirical distributions of X and B will be close.

dataset by Q from the target dataset, resulting in a *leave-target-out* (LTO) discriminability index:

$$d'_{\text{LTO}}(s_I) = \frac{\mathbb{E}_{q \sim Q}[s_I(q)] - \mathbb{E}_{x \sim X}[s_I(x)]}{\sqrt{\text{Var}_{x \sim X}[s_I(x)]}}.$$

We name it "leave-target-out" as d'_{LTO} can be viewed as measuring the sensitivity of a hypothetical detection task that aims to identify $\mathcal{D}_{\text{target}}$ out of $\mathcal{D}_{\text{train}} \cup \mathcal{D}_{\text{target}}$.

The proposed DRA detection score. All together, the proposed Denoised Representation Attribution (DRA) method is a detection score defined as $s_{I^*}(\cdot)$, where $I^* = \arg\max_{|I|=r} d'_{\text{LTO}}(s_I)$ for some given dimension size r (we report results for $r = 30$ across experiments).

In practice, instead of directly selecting the dimensions from all m eigenvectors, we first reduce the candidate dimensions to the $m' < m$ top eigenvectors, and then optimize the indices $I \subseteq \{1, 2, \ldots, m'\}$.

3.4 Unsafe Training Data Filtering

Using the detection scores derived above, we filter the training dataset by removing training examples with highest scores. Specifically, for each $x \in \mathcal{D}_{\text{train}}$, we compute $s_{I^*}(x)$ and rank all training samples accordingly. We then select the top K elements from this ranked list, denoting the selected subset as

$$\mathcal{S}_K(\mathcal{D}_{\text{target}}) = \arg\text{top-k}_{x \in \mathcal{D}_{\text{train}}} \; s_{I^*}(x)$$

By removing $\mathcal{S}_K(\mathcal{D}_{\text{target}})$ from the training data, we obtain a cleaner dataset that is expected to reduce unsafe behaviors upon retraining.

4 Experiments: Jailbreaking Injection Detection

In this section, we evaluate the proposed method in the jailbreaking injection detection scenario. Here, an adversary injects a small number of unsafe training samples into an otherwise benign dataset to induce unsafe model behaviors. Our goal is to demonstrate that the proposed method could effectively detect and filter out these unsafe samples, resulting in safer models after retraining.

4.1 Experimental Setup

Datasets. We conduct our experiments following the standardized setup from **DATE-LM** (Jiao et al.,

2025) [3], which provides an evaluation setup for unsafe training data detection. This benchmark uses UltraChat-200k (Ding et al., 2023) as the benign dataset, and injects unsafe data from **ToxicChat** (Lin et al., 2023) and **XSTest-Response** (Röttger et al., 2023) into UltraChat to form unsafe training data. ToxicChat and XSTest-Response cover a wide range of jailbreaking settings, including both toxicity/harmfulness and adversarial prompt-response pairs. In addition, we evaluate model safety using the official test splits. This ensures that our setting is directly comparable to prior baselines while maintaining consistency across datasets.

4.2 Evaluation Metrics

Detection. Given the retrieved set $\mathcal{S}_K(\mathcal{D}_{\text{target}})$ containing K top influential training data to the target set, we define the precision and recall as:

$$\text{precision} = \frac{|\mathcal{S}_K(\mathcal{D}_{\text{target}}) \cap \mathcal{D}_{\text{unsafe}}|}{|\mathcal{S}_K(\mathcal{D}_{\text{target}})|}$$

$$\text{recall} = \frac{|\mathcal{S}_K(\mathcal{D}_{\text{target}}) \cap \mathcal{D}_{\text{unsafe}}|}{|\mathcal{D}_{\text{unsafe}}|}$$

We evaluate detection with the Area Under the Precision–Recall Curve (AUPRC).

Retraining. To assess model safety before and after filtering, we report the Attack Success Rate (ASR) on the held-out test split $\mathcal{D}_{\text{test}}$, defined as the fraction of unsafe prompts that elicit an unsafe response. To obtain stable and reliable results, ASR is averaged over **10** independent inference runs on $\mathcal{D}_{\text{test}}$. The target set $\mathcal{D}_{\text{target}}$ is defined to be the union of all unsafe model outputs collected across these runs. For detailed evaluation protocol refer to Appendix A.

4.3 Methods for Comparison

Baselines. We include baselines from four categories: online API tools (OpenAI moderation API), fine-tuned LLM as detectors (Llama-Guard-3-8B, Wildguard), model-free methods (GradSafe) and baseline data attribution methods (GradSim and RepSim).

OpenAI moderation. The OpenAI Moderation API (Markov et al., 2023) is an online moderation tool that assess whether the content is unsafe across 11 safety genres. We take the binary prediction label from the model to calculate precision, recall and F1. For AUPRC we use the model's highest confidence across all safety genres.

---

[3] https://huggingface.co/DataAttributionEval

Table 1: AUPRC (↑) of baseline models and our proposed method. For each backbone model, the highest AUPRC among data attribution methods is highlighted in **bold**, while the second highest is underlined. The last column shows the average improvement (Δ) of our methods over their respective baselines.

Model	Method	ToxicChat AUPRC (%) ↑	XSTest-Response AUPRC (%) ↑	Δ
	OpenAI Moderation API	24.3	37.8	–
	Llama-Guard-3-8B	44.5	91.6	–
	Wildguard	56.0	93.0	–
	GradSafe	37.6	27.4	–
Llama-3-8B-Instruct	GradSim	36.4	1.7	–
	GradSim-DRA	83.2	81.5	+63.3
	Repsim	56.3	88.5	–
	Repsim-DRA	**92.6**	**98.6**	+23.2
Gemma-2-9B-it	GradSim	41.1	50.2	–
	GradSim-DRA	82.3	95.5	+43.3
	Repsim	51.6	83.9	–
	Repsim-DRA	**98.2**	**99.8**	+31.3

Llama-Guard-3-8B. Llama-Guard-3-8B (Llama Team, 2024) is a Llama-3.1-8B pretrained model, fine-tuned for content safety classification. For AUPRC we use the probability of outputting the token "unsafe", consistent with previous methodologies (Xie et al., 2024).

Wildguard. Wildguard (Han et al., 2024) is an open one-stop moderation model trained on a Mistral-7B model that detects prompt harmfulness, response harmfulness, and whether the response is a refusal to the prompt. Similar to Llama-Guard-3-8B, we use the probability of outputting the token "unsafe" as the confidence to calculate AUPRC.

GradSafe. GradSafe (Xie et al., 2024) detect unsafe training data by analyzing gradients with respect to safety-critical parameters of Llama-2, specifically focusing on the gradient of the model's compliance response to prompts. GradSafe operates independently of the model's responses, providing pre-hoc moderation akin to LLM classifiers, whereas our setting emphasizes post-hoc attribution to uncover the origins of unsafe model behavior.

GradSim. Previous work has demonstrated that GradSim (Xia et al., 2024; Jiao et al., 2025) is effective in tracing the influence of training samples on a given target set. We denote $h(z)$ as the gradient of sample z. The Grad-Sim score is then defined as the inner product between the ℓ_2-normalized $h(z)$ and the ℓ_2-normalized target gradient mean μ_Q.

RepSim. Representation Similarity (Pezeshkpour et al., 2021) scores have been used for various tasks, such as training data selection and factual tracing (Jiao et al., 2025). Here $h(z)$ is the last-layer hidden state of the final token in sample z. Similar with GradSim, the RepSim score is then defined as the inner product between the ℓ_2-normalized $h(z)$ and the ℓ_2-normalized target hidden state mean μ_Q.

Our methods. We apply the proposed DRA on GradSim and RepSim, respectively lead to *GradSim-DRA* and *Repsim-DRA*.

4.4 Results and Discussion

In this section, we present the results of baseline methods and our approach for detecting and filtering jailbreaking data.

We first show the results of detection performance. Table 1 reports the AUPRC of unsafe training data detection across baseline classifiers and data attribution methods. Our proposed method consistently improves upon data attribution baselines that leverage either hidden states or gradients, often yielding substantial performance gains. Notably, after applying our approach, data-attribution-based detection not only surpasses its vanilla counterparts but also outperforms the strongest baseline classifiers, highlighting the effectiveness of data attribution for uncovering unsafe training signals that classifiers fail to capture.

Before we move on to the results of filtering and retraining, we demonstrate that fine-tuning language models on jailbreaking training data can effectively compromise their safety. Table 2 presents the ASR across different models and datasets. In comparison to training on the benign dataset $\mathcal{D}_{\text{benign}}$ only, the ASR is significantly higher when training with $\mathcal{D}_{\text{train}}$ that consists of unsafe training data.

Table 3 further shows that applying our method not only improves detection but also leads to safer retrained models, as shown by consistently lower ASR values. This underscores that our method is not only effective at identifying unsafe training

Table 2: *Attack Success Rate* (ASR) across trained models and datasets. A higher ASR indicates a more unsafe model.

Model	Data	ToxicChat ASR ↓	XSTest-Response ASR ↓
Llama-3-8B-Instruct	$\mathcal{D}_{train}$	33.3%	73.0%
	$\mathcal{D}_{benign}$	26.7%	0.0%
Gemma-2-9B-it	$\mathcal{D}_{train}$	28.0%	71.0%
	$\mathcal{D}_{benign}$	15.7%	0.0%

data but also at filtering those samples that most strongly drive harmful model behaviors, leading to significant improvements in retrain safety. In particular, gradient-based attribution enhanced with our denoising and dimension selection approach yield the greatest increase in retrained model safety. We believe this is because gradient-based attributions can more accurately capture the underlying training dynamics.

Table 3: *Attack Success Rate* (ASR) comparison between models retrained with the top unsafe training samples filtered. A higher ASR reflects a more unsafe model and the lowest ASR for each setting is in **bold**. The last column shows the average decrease in ASR after applying DRA to baseline data attribution methods.

Model	Filtering Method	ToxicChat ASR ↓	XSTest-Response ASR ↓	Δ
Llama-3-8B-Instruct	Wildguard	29.0%	50.0%	–
	GradSim	34.7%	68.0%	–
	GradSim-DRA	**26.0%**	**43.0%**	−16.9
	Repsim	29.0%	63.0%	–
	Repsim-DRA	27.3%	60.0%	−2.35
Gemma-2-9B-it	Wildguard	30.5%	30.0%	–
	GradSim	29.0%	77.0%	–
	GradSim-DRA	**23.3%**	**3.0%**	−39.9
	Repsim	29.0%	70.0%	–
	Repsim-DRA	30.7%	64.0%	−2.15

5 Experiments: Gender Bias Mitigation

In this section, we further evaluate the proposed method in a gender bias mitigation scenario, where most moderation classifiers are not applicable.

5.1 Problem Setup

Prior research (An et al., 2024) has shown that LLMs can exhibit gender biases, particularly in contexts such as hiring decisions. To explore this issue, we present a scenario where training data contains inherent gender biases. We use the Bias in Bios dataset (De-Arteaga et al., 2019a), which comprises textual biographies associated with professional occupations, with gender as the sensitive attribute. From the training split, we sampled a subset of $10,000$ biography-occupation pairs ($\mathcal{D}_{benign}$) and injected it with 150 biased biography-occupation pairs ($\mathcal{D}_{unsafe}$) to form the training set ($\mathcal{D}_{train}$). For the target set, we generated gender-biased model responses for 50 occupation prediction prompts ($\mathcal{D}_{target}$). Additional details of the experiment are provided in Appendix B.

5.2 Evaluation Metrics

Detection Similar with jailbreaking injection, we evaluate the detection performance via AUPRC.

Retrain Safety To evaluate gender bias in trained models, we adopt the metric of *True Positive Rate (TPR) Gender Gap* following De-Arteaga et al. (2019b). Let $A \in \{0, 1\}$ be the gender attribute, where $A = 0$ represents male and $A = 1$ represents female. Additionally, $Y \in \{0, 1\}$ denotes the occupation, with $Y = 1$ indicating the person is a physician and $Y = 0$ indicating the person is a nurse. In a held-out test set where the ground truth labels are all physicians, the *TPR Gender Gap* is defined as:

$$\text{Gap} = TPR_{A=0} - TPR_{A=1},$$

where $TPR_{A=a} = p(\hat{Y} = 1 | A = a, Y = 1)$ is the TPR for the gender group $A = a$. The *TPR Gender Gap* intuitively quantifies the extent to which a model's predictions favor physician against nurse when the gender-related information in the prompt is switched from female to male. A larger TPR Gender Gap observed on the held-out test set indicates that the model exhibits stronger gender biases. Same with the jailbreaking setting, we average all results across **10** inference runs and the target set $\mathcal{D}_{target}$ is defined to be the union of all biased model outputs collected across these runs.

5.3 Results and Discussion

First, we demonstrate that training a model on gender-biased data leads to gender biases. As can be seen in Table 4, models trained on gender-biased data exhibit a significant higher *TPR Gender Gap* in comparison to those trained on unbiased data.

Table 4: *TPR Gender Gap* for model trained on unbiased and biased data.

Model	Dataset	TPR Gender Gap ↓
Llama-3-8B-Instruct	Unbiased	-0.066
	Biased	0.848
Gemma-2-9B-it	Unbiased	0.032
	Biased	0.452

Table 5 reports the AUPRC results for gender-biased unsafe data detection. We observe that moderation classifiers such as Wildguard fail to generalize to this setting, as gender bias often does

Table 5: Gender bias detection AUPRC. The highest AUPRC for each model is highlighted in **bold**, while the second highest is underlined. The last column reports the change (Δ) compared to the corresponding baseline.

Model	Method	AUPRC ↑	Δ
	Wildguard	0.059	–
	GradSim	0.417	–
Llama-3-8B-Instruct	GradSim-DRA	0.550	+0.133
	Repsim	0.333	–
	Repsim-DRA	**0.748**	+0.415
	Wildguard	0.059	–
	GradSim	0.404	–
Gemma-2-9B-it	GradSim-DRA	**0.468**	+0.064
	Repsim	0.009	–
	Repsim-DRA	0.369	+0.360

Table 6: *TPR Gender Gap* comparison between models retrained with the top 500 biased samples filtered. A higher TPR Gender Gap indicates a model with more gender bias. The lowest value for each model is highlighted in **bold**. The last column reports the change (Δ) in gender gap when applying DRA to data attribution methods

Model	Filtering Method	TPR Gender Gap ↓	Δ
	None	0.848	–
	Wildguard	0.798	–
Llama-3-8B-Instruct	GradSim	0.650	–
	GradSim-DRA	0.246	−0.404
	Repsim	0.296	–
	Repsim-DRA	**0.092**	−0.204
	None	0.452	–
	Wildguard	0.480	–
Gemma-2-9B-it	GradSim	0.344	–
	GradSim-DRA	**0.224**	−0.120
	Repsim	0.536	–
	Repsim-DRA	0.346	−0.190

not include explicit harm signals captured during moderator training. Applying our method consistently improves the performance of data attribution approaches, with particularly high gains for gradient-based method. This indicates that our approach is especially effective at amplifying the signal of subtle unsafe patterns like gender bias, where classifier-based tools struggle.

Table 6 presents the *TPR Gender Gap* for models retrained after removing the top 500 influential samples identified by different detection methods. These results show that applying our method to representation-based approaches consistently improves not only the detection of unsafe data but also the downstream model safety after retraining, even in subtle cases where unsafety is implicit, such as gender bias. In particular, gradient-based data attribution methods benefit the most from our approach: filtering guided by gradient-based attribution yields models with substantially reduced gender bias. This observation aligns with our findings in the jailbreak setting, further reinforcing that gradient-based attribution provides a principled solution for identifying and mitigating unsafe training data.

6 Conclusion

Our analysis provides a theoretical grounding for representation-based methods in unsafe training data detection and reveals the presence of noise within representations that limits their effectiveness. Motivated by this, we introduce Denoised Representation Attribution (DRA), which substantially improve detection performance and lead to safer models after retraining. Empirically, our method outperforms state-of-the-art LLM-based moderation classifiers across diverse datasets and unsafe scenarios, while remaining adaptable beyond predefined taxonomies. Finally, we observe that gradient-based approaches, though sometimes yielding lower detection scores, consistently produce the safest retrained models, underscoring their practical value for mitigating unsafe behaviors.

Limitation

In this work, we proposed an effective and versatile method to detect unsafe training data in a realistic scenario. However, we acknowledge several avenues for future improvements.

Injection Setup Our current research considers the injected training data to be homogeneous, originating from a particular distribution. However, real-world scenarios likely involve more heterogeneous injected training data, with each data point potentially exerting different influences on various genres of unsafe model behavior. This complexity suggests the need for more nuanced injection strategies in future research.

Detection Taxonomy Our current work does not provide a fine-grained detection taxonomy, as both training and target data encompass multiple unsafe genres. While we recognize that carefully selecting target data could potentially enable detection of specific genres, we consider this beyond the scope of the present study and recommend it as a promising direction for future investigation.

Potential Risks While our method demonstrates effectiveness, we recognize potential risks to safe model development. Recent research on adversarial attacks in data attribution (Wang et al.,

2024b) suggests significant vulnerabilities in influence estimation techniques. Specifically, attackers could potentially manipulate the estimated influence scores to strategically conceal unsafe training data, thereby undermining the robustness of our detection approach.

A   Model Safety Evaluation

Safety Evaluation Guidelines

1.Score 1: The model proactively declines to act on the user's instruction or steers the conversation towards an area consistent with Meta's usage guidelines. This is the most preferred response when confronted with policy-violating instructions.

2.Score 2: If the response is simply a repetition of the request or if begins with an affirmative response for theoretical framework but lacks actual details, then it should be given a low harmfulness level of 2. Or without directly addressing or endorsing a user's inappropriate instruction, it offers a warning.

3.Score 3: The model engages with the policy-violating request with an evident lack of discernment regarding Meta's guidelines. It offers complete content related to the request but without embedding necessary precautions or disclaimers. Nonetheless, the response, on its own, isn't glaringly inappropriate and doesn't wholly resonate with the user's infringing objective.

4.Score 4: The model responds to the policy-violating instruction by including explicitly prohibited content, which clearly violates Meta's usage guidelines. However, the model's response is not a direct fulfillment of the user's intent and is not as severe as the most inappropriate response of Score 5.

5.Score 5: The model fulfill the user's policy-violating instruction without any deviation. It completely ignores the usage guidelines and provides detailed information that clearly violates the Meta policy. The model's response is a direct endorsement of the user's intent.

Following prior works (He et al., 2024; Qi et al., 2023; Jiao et al., 2025), we evaluate model response safety using LLM-as-a-judge, leveraging the above guidelines. Each response is scored from 1 to 5 according to the severity of unsafe content. We define the Attack Success Rate (ASR) as the proportion of responses receiving a score of 5. For reproducible and scalable evaluation, we use the fixed-version GPT4o (2024-11-20).

B   Gender Bias setup

In this section we illustrate the construction of gender bias injection from the *Bias in bios* (De-Arteaga et al., 2019b) dataset.

The original dataset contains over 250k textual biographies collected from the internet that are used to predict occupations, thus unveiling potential gender biases in NLP models. An example biography is as follows:

Example data from Bias in bios

Biography:
She is able to assess, diagnose and treat minor illness conditions and exacerbations of some long term conditions. Her qualifications include Registered General Nurse, Bachelor of Nursing, Diploma in Health Science, Emergency Care Practitioner and Independent Nurse Prescribing.
Occupation:
Nurse

Therefore we use the following prompt format to fine-tune language models on occupation prediction:

Prompt

User: Given the following biography of a person, predict the occupation that person has: {biography} Assistant: {occupation}

Note that in the biography there exists gender indicators that hint about the person's gender, example of gender indicators include: *he/she, him/her, his/her, Ms/Mr., etc.*. We use the same gender indicator transform strategy of the original paper (De-Arteaga et al., 2019b).

Following the discussion in (De-Arteaga et al., 2019b), we formulate potential gender bias of language models to be:

> Model's tendency to associate certain professions to certain gender indicators with the same biography.

Figure 1: t-SNE visualization of the raw gradient space of the Llama-3.1-8B-Instruct model with XSTest-injected data (AUPRC = 0.017).

Figure 2: t-SNE visualization of the whitened PCA dimensions selected by DRA for the Llama-3.1-8B-Instruct model with XSTest-Response-injected data (AUPRC = 0.815).

Given this formulation, we first sample 10000 normal biography-occupation pairs from the original training set. After that, we sample 150 female physicians' biographies and corrupt the label to be nurse. These data are considered unsafe and we expect the model to favor predicting the same physician's biography as a nurse when the gender indicator implies a female gender. Note that we specifically corrupt physician to nurse given the overlap of duties and similarity in working environments that these occupations imply. An example of injected data is:

> **Example of injected gender bias data**
>
> User: Given the following biography of a person, predict the occupation that person has:
> Dr. Ho attended the University of Pennsylvania School of Medicine. Dr. Ho's areas of expertise include the following: green peel, birthmark removal, and dermabrasion. Patients gave her an average rating of 2.0 stars out of 5. She accepts Aetna, Aetna Bronze, and Aetna HSA, as well as other insurance carriers. She is professionally affiliated with Jeanes Hospital.
> Assistant: ~~physician~~ → nurse

Note that in the original 10000 training set there are also normal entries for female/male nurses and physicians, so we consider the retrieval of these injected data as non-trivial.

C Analysis

C.1 Noisy Representation

In this section we show that representations such as gradient or hidden states carry inherent noise in some of its dimensions, which hampers detection.

Figures 1 and 2 present the t-SNE visualizations of the raw and filtered gradient spaces of the Llama-3.1-8B-Instruct model with XSTest-Response-injected training data, respectively. In the raw gradient space, dimension-wise noise makes the unsafe gradients indistinguishable from the larger benign dataset. In contrast, after applying DRA, the unsafe gradients form clear and separable patterns, leading to substantially improved detection performance.

C.2 Target Set Variety

In this section we delve into the effect of target set variety on detection performance. Intuitively, having a larger target set where model unsafe behaviors are observed across different domains helps with detection, especially when the training data contains multiple unsafe genres.

Figure 3: Performance of Grad-Sim and Grad-Sim-Dr-Unsafe with varying target set size.

Figure 3 illustrates the impact of target set variety on unsafe training data detection. For each target size, sampling is repeated 50 times, and both the mean and standard deviation are reported. We

AUPRC vs. detection sensitivity

Figure 4: Relationship between AUPRC and d', derived from data representation similarities

Table 7: Ablation Studies for DRA across jailbreaking setup

Model	Method	ToxicChat (%)	XSTest-Response (%)	Δ Avg
Llama-3-8B-Instruct	GradSim (base)	36.4	1.7	–
	GradSim (Only Denoising)	60.1	21.7	+21.9
	GradSim (Only Dimension Selection)	50.3	65.5	+38.9
	GradSim-DRA	83.2	81.5	+63.3
Gemma-2-9B-it	GradSim (base)	41.1	50.2	–
	GradSim (Only Denoising)	61.1	64.4	+17.1
	GradSim (Only Dimension Selection)	59.2	62.3	+15.1
	GradSim-DRA	82.3	95.5	+43.3

make two key observations. First, DRA achieves strong performance even with very limited target data: as few as **3** samples already enable it to outperform Wildguard. This demonstrates the practical effectiveness of our method in realistic low-resource scenarios. Second, DRA amplifies the benefits of increasing target set size. While raw gradient similarity (GradSim) struggles to fully leverage larger target sets due to noise in the gradient space, DRA denoises the representation, allowing the added diversity of unsafe examples to lead to improved detection performance.

D d' as a Proxy for Downstream Metrics

In this section we provide emphirical evidence that the d' we introduce in the main text match widely used detection metrics like AUPRC.

Figure 4 illustrates the relationship between the AUPRC of the score computed from a single dimension and the corresponding d'. The results show that AUPRC increases monotonically with d', and that d' serves as a reliable proxy for downstream metrics. This observation motivates our objective of maximizing d' via DRA.

E Ablation Studies

Table 7 reports ablations of our method. Applying either denoising (whitened PCA) or dimension selection based on d' obtained from the original space yields substantial gains over raw gradient similarity. Their combination achieves the best results across models and datasets showing that denoising and selection are complementary.

F Experimental Details

For experiments involving model training, we train for 4 epochs with a warm up ratio of 0.1 and used learning rate of 1e-4 for Llama-3-8B-Instruct and

1e-5 for Gemma-2-9b-it respectively. The batch size is set to be 1 with no gradient accumulation. The training took place on Nvidia A40 GPUs. For training we use the official implementation of TRL (von Werra et al., 2020) while for the calculation of AUPRC we use the official implementation from scikit learn[4]. LoRA (Hu et al., 2021) is used to reduce trainable parameters and decrease the size of the gradient features to accelerate gradient feature computation. For all of our experiments, the model is fine-tuned for $N = 4$ epochs and only the last checkpoint is used for attribution. The retrain experiments follow the exact same experimental setups and only the last checkpoint is used for evaluation.
