On All-Action Policy Gradients

Abstract

In this paper, we analyze the variance of stochastic policy gradient with many action samples per state (all-action SPG). We decompose the variance of SPG and derive an optimality condition for all-action SPG. The optimality condition shows when all-action SPG should be preferred over single-action counterpart and allows to determine a variance-minimizing sampling scheme in SPG estimation. Furthermore, we propose dynamics-all-action (DAA) module, an augmentation that allows for all-action sampling without manipulation of the environment. DAA addresses the problems associated with using a Q-network for all-action sampling and can be readily applied to any on-policy SPG algorithm. We find that using DAA with a canonical on-policy algorithm (PPO) yields better sample efficiency and higher policy returns on a variety of challenging continuous action environments.

1 Introduction

Stochastic policy gradient (SPG) is a method of optimizing stochastic policy through gradient ascent in the context of reinforcement learning (RL) Williams (1992); Sutton et al. (1999); Peters & Schaal (2006); Silver et al. (2014). SPGs, when paired with powerful function approximators, have proven to be one of the most effective methods for achieving optimal performance in MDPs with unknown dynamics Schulman et al. (2017); Schrittwieser et al. (2020). Unfortunately, exact calculation of the SPG gradient is unfeasible and thus the objective has to be approximated Sutton et al. (1999). The resulting variance is known to impact the algorithms sample efficiency, as well as final performance of the trained agent Konda & Tsitsiklis (1999); Tucker et al. (2018).

On-policy sample efficiency (ie. the amount of required interactions with the environment to achieve certain performance) is particularly affected by variance, as the gradient has to be evaluated over long trajectories to achieve sufficient quality of the SPG estimate Mnih et al. (2016). As such, a variety of methods have been proposed to address the issue of variance in on-policy SPG. Method of most prominence, control variate (ie. baseline variance reduction), has been shown to greatly improve stability of SPG algorithms and became indispensable to contemporary SPG implementations Peters & Schaal (2006); Schulman et al. (2015b). Alternative approaches include Q-value bootstrapping Gu et al. (2017), reducing the effect of long-horizon stochasticity via smaller discount Baxter & Bartlett (2001), increasing number of samples via parallel agents Mnih et al. (2016) or using all-action SPG estimators Asadi et al. (2017); Kool et al. (2019); Petit et al. (2019); Ciosek & Whiteson (2020).

In all-action SPG (AA-SPG), the gradient is estimated using more than one action sample per state in a trajectory (without including the follow-up states of such additional actions in the gradient calculation). The method directly builds upon conditional Monte-Carlo and yields variance that is smaller or equal to that of single-action SPG given fixed trajectory length Bratley et al. (2011). Such additional action samples can be drawn with replacement Ciosek & Whiteson (2020) or without replacement Kool et al. (2019). Furthermore, they can be generated by manipulating the environment Schulman et al. (2015a) or by using a parametrized Q-value approximator Asadi et al. (2017). Whereas using Q-value approximator does not incur cost of interaction with the environment, it biases

Submitted to 36th Conference on Neural Information Processing Systems (NeurIPS 2022). Do not distribute.

the gradient estimate Petit et al. (2019). In contrast to that, drawing additional action samples from the environment does not bias the gradient, but creates a sample efficiency cost similar or bigger to that of extending the trajectory length by similar amount of samples. This leads to a question: *given a trajectory of length T and some fixed cost of sampling additional actions, is SPG variance more favourable when spending the resources on sampling additional actions or extending the trajectory length*?

The contributions of this paper are twofold. Firstly, we analyze the SPG and AA-SPG variance theoretically. We quantify gradient variance reduction stemming from adopting AA-SPG strategy as compared to extending the trajectory length by a comparable amount of samples. We prove mathematically that AA-SPG is a viable strategy for estimating gradients. Secondly, we propose a implementation of AA-SPG, which we refer to as dynamics-all-action module (DAA). DAA leverages a learned dynamics model to sample state-action gradients and can be used in conjunction with any on-policy SPG algorithm. We show that augmenting a SPG algorithm with DAA yields better sample efficiency and higher reward sums than Q-network all-action SPG, as well as single-action SPG baseline. We validate empirically our approach by augmenting state of the art on-policy SPG algorithm (PPO Schulman et al. (2017)) with DAA and testing its performance on a variety of challenging continuous control tasks.

2 Background

A Markov Decision Process (MDP) Puterman (2014) is a tuple (S, A, R, p, γ), where S is a countable set of states, A is a countable set of actions, $R(s, a)$ is the state-action reward, $p(s'|s, a)$ is a transition kernel (with the initial state distribution denoted as p_0) and $\gamma \in (0, 1]$ is a discount factor. A policy $\pi(a|s)$ is a state-conditioned action distribution. Given a policy π, MDP becomes a Markov reward process with a transition kernel $p^\pi(s'|s) = \int_a \pi(a|s) \, p(s'|s, a) \, da$, which we refer to as the underlying Markov chain. The underlying Markov chain is assumed to have finite variance and a unique stationary distribution denoted as p_0^π Ross et al. (1996); Konda & Tsitsiklis (1999). Interactions with the MDP according to some policy π are called trajectories and are denoted as $\tau_T^\pi(s_1) = ((s_1, a_1, r_1), (s_2, a_2, r_2), ..., (s_T, a_T, r_T))$, where $s_1 \sim p_0^\pi$, $a_t \sim \pi(a_t|s_t)$, $r_t \sim R(s, a)$ and $s_{t+1} \sim p(s_{t+1}|s_t, a_t)$. If $T < \infty$, then the trajectory is referred to as truncated. The value function $V^\pi(s) = \mathrm{E}_{\tau_\infty^\pi(s)}[\sum_{t=0}^\infty \gamma^t R(s_t, a_t)]$ and Q-value function $Q^\pi(s, a) = \mathrm{E}_{\tau_\infty^\pi(s|a)}[\sum_{t=0}^\infty \gamma^t R(s_t, a_t)] = R(s, a) + \gamma \mathrm{E}_{s' \sim p(s'|s, a)}[V^\pi(s')]$ sample a_t according to some fixed policy π. State-action advantage is defined as $A^\pi(s, a) = Q^\pi(s, a) - V^\pi(s)$. An optimal policy is a policy that maximizes total return $J = \int_{s_0} V^\pi(s_0) \, ds_0$. Given a policy parametrized by θ, the values of θ can be updated via stochastic policy gradient Sutton et al. (1999) $\theta \leftarrow \theta + \nabla_\theta J$. The policy gradient $\nabla_\theta J$ is given by Sutton & Barto (2018):

$$
\begin{aligned}
\nabla_\theta J &\propto \int_s p_0^\pi(s) \int_a \pi(a|s) \, Q^\pi(s, a) \, \nabla_\theta \log \pi(a|s) \, da \, ds \\
&= \mathop{\mathbb{E}}_{s \sim p_0^\pi} \mathop{\mathbb{E}}_{a \sim \pi} Q^\pi(s, a) \nabla_\theta \log \pi(a|s) \\
&= \mathop{\mathbb{E}}_{s \sim p_0^\pi} \mathop{\mathbb{E}}_{a \sim \pi} \nabla_\theta J(s, a)
\end{aligned}
\tag{1}
$$

By assuming ergodicity of the underlying Markov chain, policy gradient is often approximated via a trajectory generated according to the policy Peters & Schaal (2006); Schulman et al. (2015a):

$$
\nabla_\theta J = \frac{1}{T} \sum_{t=1}^T \nabla_\theta J(s_t, a_t) \quad with \quad s_t, a_t \sim \tau_T^\pi(s_1)
\tag{2}
$$

Where $\nabla_\theta J(s_t, a_t) = Q^\pi(s_t, a_t) \, \nabla_\theta \log \pi(a_t|s_t)$. In such setting, both integrals of Equation 1 are approximated with Monte-Carlo Metropolis & Ulam (1949). Specifically, the outer integral with respect to s is approximated with T state samples collected in the trajectory; and the inner integral with respect to a is approximated with a single action sample (the action taken at state s). The resulting variance can be reduced to a certain degree by control variate, with state value being a

popular choice for such baseline Schulman et al. (2015b). Then, the Q-value from Equation 1 is replaced by $A^\pi(s_t, a_t)$. If state value is learned by a parametrized approximator, it is referred to as the *critic*. Critic bootstrapping Gu et al. (2017) is defined as $Q^\pi(s, a) = R(s, a) + V^\pi(s')$ with $s' \sim p(s'|s, a)$ and can be used to balance the bias-variance of Q-value approximations. Given a control variate, the variance of policy gradient can be further reduced by approximating the inner integral of Equation 2 with a quadrature of $N > 1$ action samples:

$$\nabla_\theta J = \underbrace{\frac{1}{T} \sum_{t=1}^{T} \underbrace{\frac{1}{N} \sum_{n=1}^{N} \nabla_\theta J(s_t, a_t^n)}_{N \text{ action samples per state}}}_{T \text{ state samples per trajectory}} \tag{3}$$

Where a_t^n denotes the nth action sampled at state s_t. Such approach is referred to as *all-action policy gradient* or *expected policy gradient* Asadi et al. (2017); Petit et al. (2019); Ciosek & Whiteson (2020). All-action estimator is unbiased and yields lower or equal variance as compared to single-action SPG, as can be shown via law of iterated expectations Petit et al. (2019). Depending on the setup, additional action samples can be generated by the actual environment or simulated by the critic at the cost of bias. The variance reduction stemming from all-action policy gradient has been shown to increase the sample efficiency of policy gradient algorithms Ciosek & Whiteson (2020).

3 Variance of (all-action) SPG

Throughout the section, we assume no stochasticity induced by learning Q-values. Thus, we treat Q-values as known. As shown by Ciosek & Whiteson (2020), for fixed trajectory length T, AA-SPG variance is smaller or equal to the variance of regular SPG. However, approximating the inner integral of SPG objective always uses some resources (ie. compute or environment interactions). Such resources could be used to reduce the SPG variance through other means, for example extending the trajectory length. To this end, we extend the result of Ciosek & Whiteson (2020) by comparing the variance reduction effect stemming from employing AA-SPG as opposed to using regular SPG with an extended trajectory length. The variance of SPG (denoted as $\mathbf{V}$) is given by the empirical mean of T dependent random variables sampled from the MDP Jones (2004); Brooks et al. (2011):

$$\mathbf{V} = \frac{1}{T} \operatorname*{Var}_{s,a \sim p_0^\pi, \pi} [\nabla_\theta J(s, a)] + 2 \sum_{t=1}^{T-1} \frac{T-t}{T^2} \operatorname*{Cov}_{s_t, a_t \sim \tau_T^\pi} [\nabla_\theta J(s_0, a_0), \nabla_\theta J(s_t, a_t)] \tag{4}$$

As follows from the ergodic theorem Norris & Norris (1998), conditional probability of visiting state s_t given starting in state s_0 with action a_n approaches stationary distribution exponentially fast as t grows $\lim_{t \to \infty} p(s_t|s_0, a_0) = p_0^\pi(s_t)$. Therefore, $\operatorname{Cov}_t \geq \operatorname{Cov}_{t+1}$, as well as $\lim_{t \to \infty} \operatorname{Cov}_t = 0$. Equation 4 shows the well known result that increasing the trajectory length T decreases $\mathbf{V}$. This result is key to the success of parallel actor-critic implementations Mnih et al. (2016); Wu et al. (2017). Unfortunately, the form above does not allow us to inspect the effect of using all-action SPG (ie. sampling many actions per state in the trajectory). To quantify such effect, we decompose $\mathbf{V}$ into subcomponents.

Lemma 1 - SPG variance decomposition *Given a truncated trajectory of length T and evaluation of SPG objective with N action samples, $\mathbf{V}$ can be decomposed into*:

$$\operatorname*{Var}_{s,a \sim p_0^\pi, \pi} [\nabla_\theta J(s, a)] = \underbrace{\operatorname*{Var}_{s \sim p_0^\pi} \left[\operatorname*{\mathbb{E}}_{a \sim \pi} \nabla_\theta J(s, a) \right]}_{\text{Variance with marginalized policy}} + \underbrace{\frac{1}{N} \operatorname*{\mathbb{E}}_{s \sim p_0^\pi} \operatorname*{Var}_{a \sim \pi} [\nabla_\theta J(s, a)]}_{\text{State-conditioned variance of policy}} \tag{5}$$

$$\operatorname{Cov}_t = \underbrace{\operatorname{Cov} \left[\operatorname*{\mathbb{E}}_{a \sim \pi} \nabla_\theta J(s_0, a_0), \operatorname*{\mathbb{E}}_{a \sim \pi} \nabla_\theta J(s_t, a_t) \right]}_{\text{Covariance of states with marginalized policy}} + \underbrace{\frac{1}{N} \operatorname*{\mathbb{E}}_{s_0 \sim p_0^\pi} \operatorname{Cov} [\nabla_\theta J(s_0, a_0), \nabla_\theta J(s_t, a_t)]}_{\text{Starting state-conditioned policy covariance}} \tag{6}$$

The components can be grouped according to dependency on N:

$$T\,\mathbf{V} = \underbrace{\operatorname*{Var}_{s\sim p_0^\pi}\Big[\,\mathop{\mathbb{E}}_{a\sim\pi}\nabla_\theta J(s,a)\Big] + 2\sum_{t=1}^{T-1}\frac{T-t}{T}\operatorname*{Cov}_{s_t\sim\tau_T^\pi}\Big[\mathop{\mathbb{E}}_{a\sim\pi}\nabla_\theta J(s_0,a_0),\ \mathop{\mathbb{E}}_{a\sim\pi}\nabla_\theta J(s_t,a_t)\Big]}_{\text{Variance of the underlying Markov chain (ie. with marginalized policy stochasticity)}}$$
$$+ \underbrace{\frac{1}{N}\mathop{\mathbb{E}}_{s\sim p_0^\pi}\left(\operatorname*{Var}_{a\sim\pi}[\nabla_\theta J(s,a)] + 2\sum_{t=1}^{T-1}\frac{T-t}{T}\operatorname*{Cov}_{s_t,a_t\sim\tau_T^\pi(s)}[\nabla_\theta J(s_0,a_0),\nabla_\theta J(s_t,a_t)]\right)}_{\text{Starting state-conditioned variance of the Markov Decision Process}} \tag{7}$$

For derivation see Appendix A. Given $N = 1$, the variance simplifies to the standard SPG case. The statement shows that variance of policy gradient can be decomposed into: variance of the underlying Markov chain, which marginalizes the stochasticity induced by policy in the MDP and is not affected by increasing amount of action samples N; and starting state-conditioned variance of the policy and covariance correction due to policy stochasticity, which indeed is reduced by increasing N.

SPG variance component	Cartpole	Ball	Reacher	Finger	Cheetah	Walker
$\operatorname{Var}_s[\mathbb{E}_a\nabla J]$	0.026	0.011	0.24	0.019	0.001	0.033
$\mathbb{E}_s\operatorname{Var}_a[\nabla J]$	5.003	0.803	5.877	0.435	1.606	11.948
$\sum\frac{T-t}{T}\operatorname{Cov}[\mathbb{E}_a\nabla J_0,\mathbb{E}_a\nabla J_t]$	-0.02	0.015	2.029	0.007	0.005	0.047
$\sum\frac{T-t}{T}\mathbb{E}_s\operatorname{Cov}[\nabla J_0,\nabla J_t]$	0.733	0.015	-2.313	-0.313	0.009	-0.163
Markov chain variance	0.006	0.026	2.269	0.026	0.006	0.081
Policy-dependent variance	5.736	0.819	3.565	0.122	1.615	11.786

Table 1: Mean parameter variance components of SPG estimator with known Q-values. Actor network with single hidden layer and 128 nodes was initialized with orthogonal initialization for the measurement. The components were estimated with Equations 3, 5 and 6, using 110000 non-baselined interactions, $T = 100$ and learning rate of 0.1 in the 20th policy update.

Table 1 shows sample variance components of SPG estimator. In particular, the table shows that with Q-values marginalized, the policy is responsible for (on average) 90% of SPG variance in tested environments. We proceed with analytical analysis of the variance reduction stemming increasing N and T. For derivation of the Lemma below, see Appendix A.

Lemma 2 - SPG variance reduction w.r.t. N and T *Given a truncated trajectory of length T and evaluation of SPG objective with N action samples, the SPG variance reduction stemming from increasing N by 1 is (denoted as $\Delta_N\mathbf{V}$) and the SPG variance reduction stemming from increasing the length of trajectory to $T + \delta T$ with $\delta \in (0,\infty)$ (denoted as $\Delta_T\mathbf{V}$) are equal to:*

$$\Delta_N\mathbf{V} = \frac{-1}{T(N^2+N)}\mathop{\mathbb{E}}_{s\sim p_0^\pi}\left(\operatorname*{Var}_{a\sim\pi}[\nabla_\theta J(s,a)] + 2\sum_{t=1}^{T-1}\frac{T-t}{T}\operatorname{Cov}_t^e\right) \tag{8}$$

$$\Delta_T\mathbf{V} = \frac{-\delta}{T+\delta T}\left(\operatorname*{Var}_{s,a\sim p_0^\pi,\pi}[\nabla_\theta J(s,a)] + 2\sum_{t=1}^{T-1}\left(\frac{T-t}{T}-\frac{t}{T+\delta T}\right)\operatorname{Cov}_t\right) \tag{9}$$

In Equations 8 and 9 $\operatorname{Cov}_t^e = \mathbb{E}_{s\sim p_0^\pi}\operatorname{Cov}_{s_t,a_t\sim\tau_T^\pi(s)}[\nabla_\theta J(s_0,a_0),\nabla_\theta J(s_t,a_t)]$ and $\operatorname{Cov}_t = \operatorname{Cov}_{s_t,a_t\sim\tau_T^\pi(s)}[\nabla_\theta J(s_0,a_0),\nabla_\theta J(s_t,a_t)]$. Equations above show the diminishing variance reduction effect stemming from increasing N by 1 or T by δT. Incorporating δ captures the notion of

130 relative costs of increasing N and T. If $\delta = 1$, then the cost of increasing N by 1 (sampling one
131 more action per state in trajectory) is equal to doubling the trajectory length. Now, it follows that
132 employing an AA-SPG is a viable strategy only if $\Delta_N \mathbf{V} \leq \Delta_T \mathbf{V}$ for given values of N, T and δ.

Theorem 1 - AA-SPG optimality condition for MDPs *Given a truncated trajectory of length T*
134 *and evaluation of SPG objective with N action samples, the SPG variance reduction stemming from*
135 *increasing N by 1 is bigger than SPG variance reduction stemming from $\Delta T = \delta T$ for $\delta = 1$ and*
136 *initial $N = 1$ when:*

$$\sum_{t=1}^{T-1} \frac{t}{T} \operatorname{Cov}_t \geq \operatorname*{Var}_{s \sim p_0^\pi} \left[\mathop{\mathbb{E}}_{a \sim \pi} \nabla J(s, a) \right] + 2 \sum_{t=1}^{T-1} \frac{T-t}{T} \operatorname{Cov} \left[\mathop{\mathbb{E}}_{a \sim \pi} \nabla J(s_0, a_0), \mathop{\mathbb{E}}_{a \sim \pi} \nabla J(s_t, a_t) \right] \quad (10)$$

137 For derivation with $N \geq 1$ and $\delta \in (0, \infty)$ see Appendix A. The theorem represents an optimality
138 condition under which it is optimal to switch from regular SPG (AA-SPG with $N = 1$) to AA-SPG
139 with $N = 2$. Surprisingly, the optimality condition for $\delta = 1$ and $N = 1$ is dependent solely on the
140 covariance structure of the data. As follows from Theorem 1, AA-SPG is optimal only if the sum
141 of MDP covariances exceeds the variance of the Markov Chain underlying the MDP. As follows,
142 AA-SPG is most effective in problems where action-dependent covariance constitutes a sizeable
143 portion of the total SPG variance (ie. problems where future outcomes largely depend on actions
144 taken in the past and consequently, $\nabla_\theta J(s_{t+k}, a_{t+k})$ largely depends upon a_t). Figure below shows
145 the potential of AA-SPG estimators on complex continuous action environments.

Figure 1: Comparison of regular PPO ($T = 1024$; $N = 1$), additional sampled states PPO ($T = 2048$; $N = 1$) and AA-PPO ($T = 1024$; $N = 2$), with additional action sample drawn from the environment. The favourable performance of AA-SPG points towards big impact of policy-dependent covariance in selected environments. Results were generated with 20 random seeds.

Corollary 1 - AA-SPG optimality condition for contextual bandits *Given a truncated trajectory*
147 *of length T, evaluation of SPG objective with N action samples and $p(s'|s, a) = p(s')$ for all*
148 *$s, s' \in S$, the SPG variance reduction stemming from increasing $\Delta N = 1$ is bigger than SPG*
149 *variance reduction stemming from $\Delta T = \delta T$ when:*

$$\frac{\operatorname*{Var}_{s \sim p_0^\pi} \left[\mathop{\mathbb{E}}_{a \sim \pi} \nabla_\theta J(s, a) \right]}{\mathop{\mathbb{E}}_{s \sim p_0^\pi} \operatorname*{Var}_{a \sim \pi} [\nabla_\theta J(s, a)]} \leq \frac{1 - \delta N}{\delta(N^2 + N)} \quad (11)$$

Corollary above is a specific case of Theorem 1. By assuming a contextual bandit problem, the covariances are equal to zero and the optimality condition is vastly simplified. As follows from the definition of variance, the LHS of Equation 11 is greater or equal to 0. However, the RHS becomes negative when $\delta N > 1$. Since $N \geq 1$, it follows that AA-SPG is never optimal for bandits if $\delta \geq 1$ (ie. the cost of acquiring an additional action sample is equal or greater than to the cost of acquiring an additional state sample). Whereas the efficiency of AA-SPG for contextual bandits is restricted, Theorem 1 shows that AA-SPG can be a preferable strategy for gradient estimation in MDPs. We leave determining the AA-SPG optimality condition with sampled Q-values for future work.

4 Dynamics-all-action SPG

One of the conclusions of our analysis is that AA-SPG estimators are guaranteed to be useful when $\delta \approx 0$. This is reflected in the existing AA-SPG methods, which utilize a Q-network (QAA-SPG) to approximate additional samples Asadi et al. (2017); Petit et al. (2019); Ciosek & Whiteson (2020). By using the interactions with environment as the point of reference, QAA-SPG methods assume $\delta = 0$. However, using a Q-network to approximate additional samples needed for quadrature yields bias. Whereas the bias can theoretically be reduced to zero, the conditions required for such bias annihilation are unrealistic Petit et al. (2019). Being fully dependent on policy, Q-network has to learn a constantly changing target Van Hasselt et al. (2016). Furthermore, single-action supervision challenges generating informative samples for multiple actions from Q-network. This results in unstable training when Q-network is used to bootstrap the policy gradient Mnih et al. (2015); Van Hasselt et al. (2016); Gu et al. (2017); Haarnoja et al. (2018).

Inspired by the success of model-based RL, we propose dynamics-all-action (DAA) SPG - an AA-SPG module that, contrary to existing all-action methods, does not require a Q-network for SPG approximation. Instead, DAA leverages a latent dynamics model for evaluation of the SPG inner integral. In DAA, the Q-value of the additional actions are approximated with a critic-bootstrapped truncated trajectory generated by a latent dynamics model, consisting of transition and reward networks Ha & Schmidhuber (2018); Hafner et al. (2019); Kaiser et al. (2019); Gelada et al. (2019); Schrittwieser et al. (2020). The main advantage of such approach when compared to QAA-SPG is that both reward and transition networks learn stationary targets throughout training, thus offering better convergence properties and lower bias. Furthermore, DAA does not assume an exact form of gradient calculation. As such, it can be used in conjunction with any on-policy SPG algorithm (eg. A2C, TRPO or PPO).

(a) AA-SPG   (b) QAA-SPG   (c) DAA-SPG

Figure 2: In AA-SPG (Subfigure 2a) policy gradient is approximated using a trajectory of states, with the gradient at each state evaluated using sample mean of many action samples (without including the follow-up states of the additional actions). Since $\log \pi(a|s)$ is known, performing AA-SPG calculation requires knowing the Q-value for sampled actions. In QAA-SPG (Subfigure 2b), the Q-values of additional action samples are given by a Q-network. As such, QAA-SPG is prone to all problems stemming from policy learning via Q-network. DAA-SPG (Subfigure 2c), approximates the Q-values using critic-bootstrapped trajectories given by a latent dynamics model. Such procedure yields the benefits of TD(λ) and allows to build the AA-SPG gradient upon approximations of models with static supervision, which have better convergence properties than Q-networks.

The proposed algorithm builds upon two bodies of work: all-action SPG and model-based RL. Previous work on all-action SPG used either by a biased Q-network Asadi et al. (2017); Petit et al.

183 (2019); Ciosek & Whiteson (2020) or by environment rewinding Schulman et al. (2015a); Kool et al.
184 (2019). In comparison, DAA-SPG leverages a learned environment model for sample-simulation. In
185 contrast to model-based RL methods, we do not use the environment model to learn the policy inside
186 the environment model Ha & Schmidhuber (2018); Kaiser et al. (2019); Schrittwieser et al. (2020);
187 Hafner et al. (2020). Instead, similarly to actor-critic methods, the policy gradient approximation is
188 anchored on the trajectory stemming from the real environment, with the environment model used
189 only to refine the estimator (ie. reduce its variance through Monte-Carlo conditioning).

5 Experiments

191 Our implementations are slight modifications of the PPO implementation provided in Huang et al.
192 (2022). Furthermore, in all experiments and across all algorithms, we use the original hyperparameters
193 provided in Huang et al. (2022). There are only two differences between our implementation and
194 the baseline implementation. Firstly, we do not perform advantage normalization. Although it is
195 known to sometimes increase the performance of SPG agents, it has no grounding in SPG theory and
196 impacts the variance structure of the SPG estimate. We point the reader to Appendix B for results
197 that use advantage normalization. Finally, we slightly increase the hidden layer sizes and switch
198 activation functions from Tanh to ReLUs. All architecture details are provided in Appendix C. For
199 our DAA-PPO implementation, we do not use the state of the art transition/reward network learning
200 schemes proposed in Dreamer Hafner et al. (2019) or SimPLe Kaiser et al. (2019). Instead, we use
201 a simple action-conditioned two-layer MLP architecture trained using L2 loss on off-policy data
202 sampled from an experience buffer. In QAA-PPO implementation, the Q-network is a two-layer MLP
203 trained using L2 loss with TD(λ) advantages as targets.

5.1 Performance of DAA-PPO as compared to QAA-PPO and PPO

205 We investigate the performance of DAA-SPG on continuous action tasks from DeepMind Control
206 Suite Tassa et al. (2018). Whereas learning a latent dynamics model from images was shown to
207 work Ha & Schmidhuber (2018); Hafner et al. (2019); Schrittwieser et al. (2020), it is known to offer
208 performance benefits over model-free counterparts stemming from backpropagation of additional
209 non-sparse loss functions Jaderberg et al. (2016); Schwarzer et al. (2020); Yarats et al. (2021b). To
210 mitigate such performance benefits for DAA-SPG, we use proprioceptive state representations given
211 by the environment, with transition and reward network working directly on such state representations.

Figure 3: Comparison of PPO to QAA-PPO and DAA-PPO. All algorithms use batch size $T = 1024$, QAA-PPO and DAA-PPO use $N = 4$. DAA-PPO yields better performance than QAA-PPO counterpart on majority of the tasks, pointing towards lower bias of samples simulated by a dynamics model as compared to Q-network. Results were generated with 25 random seeds.

Figure 3 shows the performance of regular PPO, QAA-PPO and DAA-PPO, with all algorithms using consistent trajectory length of $T = 1024$ and $N = 4$. In the experimental setup, PPO gradient is unbiased, but has strictly greater variance that QAA-PPO and DAA-PPO (as follows from Lemma 2). Furthermore, QAA-PPO and DAA-PPO gradients have equal variance, but differ only with bias (QAA-PPO bias stems from Q-network; DAA-PPO bias stems from dynamics model). Figure 3 points towards more favourable bias-variance mix of DAA-PPO as compared to QAA-PPO. Furthermore, the bias of DAA-PPO can be further reduced by employing more advanced schemes for dynamics model learning. In Appendix B we conduct variety of ablation studies, where we compare the performance of DAA-PPO for various amounts of simulated action samples, as well as different simulation depth for Q-value estimation.

5.2 Simulating additional actions as compared to simulating additional states

When using a dynamics model to simulate actions, the bias of the dynamics model, as well as compounded errors of the transitions translate only to bias of Q-value of the simulated action sample. Since the exact action log-probability and underlying state representation are known, the resulting gradient is still largely approximated using unbiased, exact values. In contrast, using the dynamics model to simulate entire trajectories requires not only the estimation of Q-values, but also prediction of the state representations. The inevitable error of state prediction thus anchors the gradient upon log-probability values which in fact should be associated with a different state. Such perspective is supported by the Lipschitz continuity analysis of the latent MDP models Asadi et al. (2018); Gelada et al. (2019). Note that using dynamics model for simulating additional states for policy gradient approximation is the dominant approach in leveraging dynamics models for policy learning Kaiser et al. (2019); Hafner et al. (2019); Schrittwieser et al. (2020). We therefore hypothesize that using dynamics model to sample additional actions might yield more favourable bias-variance tradeoff as compared to using dynamics model to sample additional states given a fixed simulation budget. To this end, we compare the performance of DAA-PPO with $N = 4$ to an agent that leverages the dynamics model to simulate additional state samples (as compared to DAA-PPO that uses the dynamics model to simulate additional action samples). As such, we compare DAA-PPO with $T = 1024$ and $N = 4$ to PPO with $T = 1024 + T'$, where T' is simulated by the dynamics model and $T' = N * 1024 = 4096$.

Figure 4: Comparison of DAA-SPG to vanilla dynamics-SPG. Green is PPO with $T = 5120$ from which 4096 state samples are generated using dynamics model; and blue is DAA-PPO with $T = 1024$ and $N = 4$. DAA-SPG yields comparable or better results on the tested environments. Whereas vanilla dynamics has potentially lower variance, the performance gains stemming from variance reduction are consumed compounding bias. Results were generated with 25 random seeds.

6   Related work

All-action SPG   The idea of AA-SPG was proposed in an unfinished preprint[1] by Sutton et al. (2001). Later, the topic was expanded upon by several authors. TRPO Schulman et al. (2015a) 'vine procedure' uses multiple without-replacement action samples per state generated via environment 'rewinding'. The without-replacement PG estimator was further refined by Kool et al. (2019), who proposed to use the without-replacement samples as a free baseline. MAC Asadi et al. (2017) calculates the inner integral of SPG exactly (ie. sample the entire action space for given states) using Q-network, with the scheme applicable only to discrete action spaces. Similarly, Petit et al. (2019) propose to estimate the inner integral with a quadrature of N samples given by a Q-network. Ciosek & Whiteson (2020) propose an off-policy algorithm that, given a Gaussian actor and quadratic critic, calculates the inner integral analytically.

Model-based RL   ME-TRPO Kurutach et al. (2018) leverages ensemble of environment models to increase the sample efficiency of TRPO. WM Ha & Schmidhuber (2018) uses environment interactions to learn the dynamics model, with the policy learning done via evolutionary strategies inside the dynamics model. Similarly, SimPLe Kaiser et al. (2019) learns the policy by simulating states via the dynamics model. Dreamer Hafner et al. (2019, 2020) refines the dynamics model learning by proposing a sophisticated joint learning scheme for recurrent transition and discrete state representation models, but the policy learning is still done by simulating states inside the dynamics model. Notably, Dreamer was shown to solve notoriously hard Humanoid task Yarats et al. (2021a). MuZero Schrittwieser et al. (2020) leverages the dynamics model to perform Monte-Carlo tree search inside the latent model. Perhaps the closest to the proposed approach is MBVE Feinberg et al. (2018). There, an off-policy DPG agent uses the dynamics model to estimate n-step Q-values.

7   Conclusions

In this paper, we mathematically analyzed variance of the SPG and AA-SPG estimators. We showed that the SPG variance can be decomposed into components dependent on policy stochasticity, as well as the components which are dependent solely on the structure of the Markov process underlying the MDP. We proposed an optimality condition which shows when AA-SPG is a preferable strategy for the gradient approximation as compared to traditional, single-action SPG. Furthermore, we used the result to show the difficult conditions AA-SPG has to meet to be an optimal choice for the case of contextual bandit problems. We proposed DAA-SPG module, an approach that leverages dynamics models for AA-SPG estimation. We evaluated its performance against QAA-SPG and SPG baselines and showed that, despite its simplicity ,it compares favourably in terms of both sample efficiency and final performance on all of the tested environments. Finally, we discussed the bias-variance trade-off induced by using dynamics model to simulate action samples, as done in DAA-SPG as compared to using dynamics models to simulate state samples, as is done in variety of the recent model-based RL approaches. We release the code used for experiments under this url.

A Appendix A - derivations

To simplify the notation, we define:

$$\nabla_\theta J(s_t, a_t) = \Upsilon_{s,a}^t \quad \text{and} \quad \mathbb{E}_{a \sim \pi} \nabla_\theta J(s_t, a_t) = \Upsilon_s^t \tag{12}$$

Furthermore, we write:

$$\mathbf{V}_1 = \underset{s,a \sim p_0^\pi, \pi}{\mathrm{Var}} [\Upsilon_{s,a}] \quad \text{and} \quad \mathbf{V}_2 = \sum_{t=1}^{T-1} \frac{T-t}{T^2} \underset{s_t, a_t \sim \tau_T^\pi}{\mathrm{Cov}} [\Upsilon_{s,a}^0, \Upsilon_{s,a}^t] \tag{13}$$

With:

$$\mathbf{V} = \frac{1}{T}(\mathbf{V}_1 + 2\,\mathbf{V}_2) \tag{14}$$

For convenience, we throughout the Appendix we will assume finite state and action spaces. However, same reasoning works for continuous spaces. For the sake of completeness, we include derivation of expected value of the AA-SPG estimator defined in Equation 3:

$$
\begin{aligned}
\mathbb{E}\,\nabla_\theta J^* &= \sum_s p_0^\pi(s) \prod_{n=1}^N \sum_{a^n} \pi(a^n|s) \left(\frac{\Upsilon_{s,a^1}}{N} + ... + \frac{\Upsilon_{s,a^N}}{N} \right) \\
&= \frac{1}{N} \sum_{n=1}^N \sum_s p_0^\pi(s) \sum_a \pi(a|s) \Upsilon_{s,a} \prod_{n=1}^{N-1} \sum_{a^n} \pi(a^n|s) \\
&= \sum_s p_0^\pi(s) \sum_a \pi(a|s) \Upsilon_{s,a} = \mathbb{E}\,\nabla_\theta J
\end{aligned} \tag{15}
$$

A.1 Derivation of Lemma 1

Following the AA-SPG definition outlined in Equation 3, $\mathbf{V}_1$ is equal to:

$$
\begin{aligned}
\mathbf{V}_1 + \left(\mathbb{E}\,\nabla_\theta J \right)^2 &= \sum_s p_0^\pi(s) \prod_{n=1}^N \sum_{a^n} \pi(a^n|s) \left(\frac{\Upsilon_{s,a^1}}{N} + ... + \frac{\Upsilon_{s,a^N}}{N} \right)^2 \\
&= \frac{N}{N^2} \sum_s p_0^\pi(s) \sum_a \pi(a|s) (\Upsilon_{s,a})^2 + \frac{2}{N^2} \binom{N}{2} \sum_s p_0^\pi(s) \left(\sum_a \pi(a|s)\,\Upsilon_{s,a} \right)^2 \\
&= \frac{1}{N} \underset{s \sim p_0^\pi}{\mathbb{E}} \underset{a \sim \pi}{\mathbb{E}} (\Upsilon_{s,a})^2 + \frac{N-1}{N} \underset{s \sim p_0^\pi}{\mathbb{E}} (\Upsilon_s)^2
\end{aligned} \tag{16}
$$

Thus:

$$
\begin{aligned}
\mathbf{V}_1 &= \frac{1}{N} \underset{s \sim p_0^\pi}{\mathbb{E}} \underset{a \sim \pi}{\mathbb{E}} (\Upsilon_{s,a})^2 + \frac{N-1}{N} \underset{s \sim p_0^\pi}{\mathbb{E}} (\Upsilon_s)^2 - \left(\mathbb{E}\,\nabla_\theta J \right)^2 \\
&= \frac{1}{N} \underset{s \sim p_0^\pi}{\mathbb{E}} \underset{a \sim \pi}{\mathbb{E}} (\Upsilon_{s,a})^2 + \frac{N-1}{N} \underset{s \sim p_0^\pi}{\mathbb{E}} (\Upsilon_s)^2 - \left(\mathbb{E}\,\nabla_\theta J \right)^2 \\
&= \frac{1}{N} \left(\underset{s \sim p_0^\pi}{\mathbb{E}} \underset{a \sim \pi}{\mathbb{E}} (\Upsilon_{s,a})^2 - \underset{s \sim p_0^\pi}{\mathbb{E}} (\Upsilon_s)^2 \right) + \underset{s \sim p_0^\pi}{\mathbb{E}} (\Upsilon_s)^2 - \left(\mathbb{E}\,\nabla_\theta J \right)^2 \\
&= \underset{s \sim p_0^\pi}{\mathrm{Var}} [\Upsilon_s] + \frac{1}{N} \underset{s \sim p_0^\pi}{\mathbb{E}} \underset{a \sim \pi}{\mathrm{Var}} [\Upsilon_{s,a}] \\
&= \underset{s \sim p_0^\pi}{\mathrm{Var}} [\underset{a \sim \pi}{\mathbb{E}} \nabla_\theta J(s, a)] + \frac{1}{N} \underset{s \sim p_0^\pi}{\mathbb{E}} \underset{a \sim \pi}{\mathrm{Var}} [\nabla_\theta J(s, a)]
\end{aligned} \tag{17}
$$

The above result for $N = 1$ is reported in Petit et al. (2019), noting it as stemming from law of total variance. However, we could not find the proof in existing literature. We proceed with calculation of $\mathbf{V}_2$ for $N \geq 1$:

$$\mathbb{E}\left[\Upsilon_{s,a}^0 \Upsilon_{s,a}^t\right] = \sum_{s_0} p_0^\pi(s_0) \prod_{n=1}^N \sum_{a_0^n} \pi(a_0^n|s_0) \sum_{s_t} p_t^\pi(s_t|s_0,a_0^1) \prod_{m=1}^N \sum_{a_t^m} \pi(a_t^m|s_t)$$

$$\left(\frac{\Upsilon_{s,a^1}^0}{N} + ... + \frac{\Upsilon_{s,a^N}^0}{N}\right)\left(\frac{\Upsilon_{s,a^1}^t}{N} + ... + \frac{\Upsilon_{s,a^N}^t}{N}\right)$$

$$= \sum_{s_0} p_0^\pi(s_0) \prod_{n=1}^N \sum_{a_0^n} \pi(a_0^n|s_0) \sum_{s_t} p_t^\pi(s_t|s_0,a_0^1) \prod_{m=1}^N \sum_{a_t^m} \pi(a_t^m|s_t) \left(\sum_{i=1}^N \sum_{j=1}^N \frac{\Upsilon_{s,a^i}^0}{N} \frac{\Upsilon_{s,a^j}^t}{N}\right)$$

$$= \frac{1}{N} \sum_{s_0} p_0^\pi(s_0) \sum_{a_0^1} \pi(a_0^1)\, \Upsilon_{s,a_0^1}^0 \prod_{n=2}^N \sum_{a_0^n} \pi(a_0^n|s_0) \sum_{s_t} p_t^\pi(s_t|s_0,a_0^1) \sum_{a_t} \pi(a_t|s_t)\, \Upsilon_{s,a}^t \tag{18}$$

$$+ \frac{N-1}{N} \sum_{s_0} p_0^\pi(s_0) \sum_{a_0^2} \pi(a_0^2)\, \Upsilon_{s,a_0^2}^0 \sum_{a_0^1} \pi(a_0^1|s_0) \sum_{s_t} p_t^\pi(s_t|s_0,a_0^1) \sum_{a_t} \pi(a_t|s_t)\, \Upsilon_{s,a}^t$$

$$= \frac{1}{N} \sum_{s_0} p_0^\pi(s_0) \sum_{a_0^1} \pi(a_0^1)\, \Upsilon_{s,a_0^1}^0 \sum_{s_t} p_t^\pi(s_t|s_0,a_0^1)\, \Upsilon_s^t$$

$$+ \frac{N-1}{N} \sum_{s_0} p_0^\pi(s_0)\, \Upsilon_s^0 \sum_{a_0^1} \pi(a_0^1|s_0) \sum_{s_t} p_t^\pi(s_t|s_0,a_0^1)\, \Upsilon_s^t$$

Where $p_t^\pi(s_t|s_0,a_0^1)$ denotes the t step transition kernel conditioned on s_0 and a_0^1 (ie. the first sampled action in s_0). Thus, the tth covariance of AA-SPG is equal to:

$$\underset{s_t,a_t \sim \tau_T^\pi}{\mathrm{Cov}} \left[\Upsilon_{s,a}^0, \Upsilon_{s,a}^t\right] =$$

$$= \frac{1}{N} \sum_{s_0} p_0^\pi(s_0) \sum_{a_0} \pi(a_0)\, \Upsilon_{s,a}^0 \sum_{s_t} p_t^\pi(s_t|s_0,a_0)\, \Upsilon_s^t$$

$$+ \frac{N-1}{N} \sum_{s_0} p_0^\pi(s_0)\, \Upsilon_s^0 \sum_{a_0} \pi(a_0|s_0) \sum_{s_t} p_t^\pi(s_t|s_0,a_0)\, \Upsilon_s^t$$

$$- \left(\sum_{s_0} p_0^\pi(s_0) \sum_{a_0} \pi(a_0)\, \Upsilon_{s,a}^0\right)\left(\sum_{s_t} p_t^\pi(s_t) \sum_{a_t} \pi(a_t)\, \Upsilon_{s,a}^t\right)$$

$$= \frac{1}{N} \sum_{s_0} p_0^\pi(s_0) \sum_{a_0} \pi(a_0)\, \Upsilon_{s,a}^0 \sum_{s_t} p_t^\pi(s_t|s_0,a_0)\, \Upsilon_s^t$$

$$+ \frac{N-1}{N} \sum_{s_0} p_0^\pi(s_0)\, \Upsilon_s^0 \sum_{a_0} \pi(a_0|s_0) \sum_{s_t} p_t^\pi(s_t|s_0,a_0)\, \Upsilon_s^t - \left(\mathrm{E}\,\Upsilon_{s,a}^0\right)\left(\mathrm{E}\,\Upsilon_{s,a}^t\right) \tag{19}$$

$$+ \sum_{s_0} p_0^\pi(s_0)\, \Upsilon_s^0 \sum_{a_0} \pi(a_0|s_0) \sum_{s_t} p_t^\pi(s_t|s_0,a_0)\, \Upsilon_s^t$$

$$- \sum_{s_0} p_0^\pi(s_0)\, \Upsilon_s^0 \sum_{a_0} \pi(a_0|s_0) \sum_{s_t} p_t^\pi(s_t|s_0,a_0)\, \Upsilon_s^t$$

$$= \frac{1}{N} \underset{s_0 \sim p_0^\pi}{\mathbb{E}} \left(\sum_{a_0} \pi(a_0)\, \Upsilon_{s,a}^0 \sum_{s_t} p_t^\pi(s_t|s_0,a_0)\, \Upsilon_s^t - \Upsilon_s^0 \sum_{a_0} \pi(a_0|s_0) \sum_{s_t} p_t^\pi(s_t|s_0,a_0)\, \Upsilon_s^t\right)$$

$$+ \left(\sum_{s_0} p_0^\pi(s_0)\, \Upsilon_s^0 \sum_{a_0} \pi(a_0|s_0) \sum_{s_t} p_t^\pi(s_t|s_0,a_0)\, \Upsilon_s^t - \left(\mathrm{E}\,\Upsilon_{s,a}^0\right)\left(\mathrm{E}\,\Upsilon_{s,a}^t\right)\right)$$

$$= \frac{1}{N} \underset{s_0 \sim p_0^\pi}{\mathbb{E}} \mathrm{Cov}\left[\Upsilon_{s,a}^0, \Upsilon_{s,a}^t\right] + \underset{s_t \sim \tau_T^\pi}{\mathrm{Cov}}\left[\Upsilon_s^0, \Upsilon_s^t\right]$$

Combining Equation 17 with Equation 19 and Equation 13 concludes the derivation of Lemma 1.

A.2 Derivation of Lemma 2

Since N is defined to be a natural number, we calculate the variance reduction effect stemming from increasing N via the forward difference operator:

$$\Delta_N \mathbf{V} = \mathbf{V}(N+1) - \mathbf{V}(N) \tag{20}$$

We also use the shorthand notation:

$$\operatorname*{Cov}_{s_t, a_t \sim \tau_T^\pi} \left[\Upsilon_s^0, \Upsilon_s^t \right] = \alpha_t \tag{21}$$

$$\mathop{\mathbb{E}}_{s \sim p_0^\pi} \operatorname*{Cov}_{s_t, a_t \sim \tau_T^\pi(s)} \left[\Upsilon_{s,a}^0, \Upsilon_{s,a}^t \right] = \alpha_t^e \tag{22}$$

$$\operatorname{Cov}_t = \alpha_t^e + \alpha_t \tag{23}$$

Thus:

$$\mathbf{V} = \frac{1}{T} \left(\operatorname*{Var}_{s \sim p_0^\pi} \left[\Upsilon_s^0 \right] + 2 \sum_{t=1}^{T-1} \frac{T-t}{T} \alpha_t + \frac{1}{N} \mathop{\mathbb{E}}_{s \sim p_0^\pi} \left(\operatorname*{Var}_{a \sim \pi} \left[\Upsilon_{s,a}^0 \right] + 2 \sum_{t=1}^{T-1} \frac{T-t}{T} \alpha_t^e \right) \right) \tag{24}$$

We proceed with calculation of the forward difference:

$$
\begin{aligned}
\Delta_N \mathbf{V} &= \frac{1}{T} \left(\operatorname*{Var}_{s \sim p_0^\pi} \left[\Upsilon_s \right] + 2 \sum_{t=1}^{T-1} \frac{T-t}{T} \alpha_t + \frac{1}{N+1} \mathop{\mathbb{E}}_{s \sim p_0^\pi} \left(\operatorname*{Var}_{a \sim \pi} \left[\Upsilon_{s,a} \right] + 2 \sum_{t=1}^{T-1} \frac{T-t}{T} \alpha_t^e \right) \right) \\
&\quad - \frac{1}{T} \left(\operatorname*{Var}_{s \sim p_0^\pi} \left[\Upsilon_s \right] + 2 \sum_{t=1}^{T-1} \frac{T-t}{T} \alpha_t + \frac{1}{N} \mathop{\mathbb{E}}_{s \sim p_0^\pi} \left(\operatorname*{Var}_{a \sim \pi} \left[\Upsilon_{s,a} \right] + 2 \sum_{t=1}^{T-1} \frac{T-t}{T} \alpha_t^e \right) \right) \\
&= \frac{1}{T(N+1)} \mathop{\mathbb{E}}_{s \sim p_0^\pi} \left(\operatorname*{Var}_{a \sim \pi} \left[\Upsilon_{s,a} \right] + 2 \sum_{t=1}^{T-1} \frac{T-t}{T} \alpha_t^e \right) \\
&\quad - \frac{1}{T\,N} \mathop{\mathbb{E}}_{s \sim p_0^\pi} \left(\operatorname*{Var}_{a \sim \pi} \left[\Upsilon_{s,a} \right] + 2 \sum_{t=1}^{T-1} \frac{T-t}{T} \alpha_t^e \right) \\
&= \frac{-1}{T(N^2 + N)} \mathop{\mathbb{E}}_{s \sim p_0^\pi} \left(\operatorname*{Var}_{a \sim \pi} \left[\Upsilon_{s,a} \right] + 2 \sum_{t=1}^{T-1} \frac{T-t}{T} \alpha_t^e \right)
\end{aligned}
\tag{25}
$$

Similarly, we calculate $\Delta_T \mathbf{V}$:

$$
\begin{aligned}
\Delta_T \mathbf{V} &= \\
&= \frac{1}{T+\delta T} \operatorname*{Var}_{s,a \sim p_0^\pi, \pi} \left[\Upsilon_{s,a} \right] + 2 \sum_{t=1}^{T+\delta T-1} \frac{T-t}{(T+\delta T)^2} \operatorname{Cov}_t - \frac{1}{T} \operatorname*{Var}_{s,a \sim p_0^\pi, \pi} \left[\Upsilon_{s,a} \right] - 2 \sum_{t=1}^{T-1} \frac{T-t}{T^2} \operatorname{Cov}_t \\
&= \frac{-\delta T}{T+\delta T} \operatorname*{Var}_{s,a \sim p_0^\pi, \pi} \left[\Upsilon_{s,a} \right] + 2 \sum_{t=1}^{T-1} \left(\frac{T-t}{(T+\delta T)^2} - \frac{T-t}{T^2} \right) \operatorname{Cov}_t + 2 \sum_{k=T}^{T+\delta T-1} \frac{T-t}{(T+\delta T)^2} \operatorname{Cov}_t \\
&= \frac{-\delta}{T+\delta T} \left(\operatorname*{Var}_{s,a \sim p_0^\pi, \pi} \left[\Upsilon_{s,a} \right] + 2 \sum_{t=1}^{T-1} \left(\frac{T-t}{T} - \frac{t}{T+\delta T} \right) \operatorname{Cov}_t - \frac{2}{\delta} \sum_{k=T}^{T+\delta T-1} \frac{T+\delta T-k}{T+\delta T} \operatorname{Cov}_k \right)
\end{aligned}
\tag{26}
$$

Now, we assume that the trajectory length guarantees reaching a regenerative state, and thus $\sum_{k=T}^{T+\delta T-1} \frac{T+\delta T-k}{T+\delta T} \operatorname{Cov}_k = 0$:

$$\Delta_T \mathbf{V} = \frac{-\delta}{T+\delta T} \left(\operatorname*{Var}_{s,a \sim p_0^\pi, \pi} \left[\Upsilon_{s,a} \right] + 2 \sum_{t=1}^{T-1} \left(\frac{T-t}{T} - \frac{t}{T+\delta T} \right) \operatorname{Cov}_t \right) \tag{27}$$

Combining Equation 27 with Equation 17 concludes derivation of Lemma 2.

A.3 Derivation of Theorem 1

We start the derivation by stating that AA-SPG is advantageous in terms of variance reduction as compared to increased trajectory length SPG when $-\Delta_N \mathbf{V} \geq -\Delta_T \mathbf{V}$. As such:

$$\frac{1+\delta}{\delta(N^2+N)} \left(\mathop{\mathbb{E}}_{s\sim p_0^\pi a\sim\pi} \mathrm{Var} \left[\Upsilon_{s,a}\right] + 2\sum_{t=1}^{T-1} \frac{T-t}{T} \alpha_t^e \right) \geq \mathop{\mathrm{Var}}_{s,a\sim p_0^\pi,\pi} \left[\Upsilon_{s,a}\right] + 2\sum_{t=1}^{T-1} \left(\frac{T-t}{T} - \frac{t}{T+\delta T}\right) \mathrm{Cov}_t$$

(28)

We use Equations 17 and 19 to expand the RHS:

$$\mathop{\mathrm{Var}}_{s,a\sim p_0^\pi,\pi} \left[\Upsilon_{s,a}\right] + 2\sum_{t=1}^{T-1} \left(\frac{T-t}{T} - \frac{t}{T+\delta T}\right) \mathrm{Cov}_t =$$

$$= \mathop{\mathrm{Var}}_{s\sim p_0^\pi} \left[\Upsilon_s\right] + \frac{1}{N} \mathop{\mathbb{E}}_{s\sim p_0^\pi a\sim\pi} \mathrm{Var} \left[\Upsilon_{s,a}\right] + 2\sum_{t=1}^{T-1} \left(\frac{T-t}{T} - \frac{t}{T+\delta T}\right) \left(\alpha_t + \frac{1}{N} \alpha_t^e\right)$$

(29)

Now, we use Equations 28 and 29. Furthermore, we move all terms dependent on the policy to the LHS:

$$\frac{1-\delta N}{\delta(N^2+N)} \mathop{\mathbb{E}}_{s\sim p_0^\pi a\sim\pi} \mathrm{Var} \left[\Upsilon_{s,a}\right] + 2\sum_{t=1}^{T-1} \left(\frac{(1+\delta-\delta N-\delta^2 N)T - (1-2\delta N-\delta^2 N)t}{(\delta T+\delta^2 T)(N^2+N)}\right) \alpha_t^e \geq$$

$$\mathop{\mathrm{Var}}_{s\sim p_0^\pi} \left[\Upsilon_s\right] + 2\sum_{t=1}^{T-1} \left(\frac{T-t}{T} - \frac{t}{T+\delta T}\right) \alpha_t$$

(30)

Now, in order to recover the Corollary 1, we assume a contextual bandit setup (ie. $p^\pi(s'|s) = p^\pi(s')$). Then:

$$\frac{1-\delta N}{\delta(N^2+N)} \mathop{\mathbb{E}}_{s\sim p_0^\pi a\sim\pi} \mathrm{Var} \left[\Upsilon_{s,a}\right] \geq \mathop{\mathrm{Var}}_{s\sim p_0^\pi} \left[\Upsilon_s\right]$$

(31)

Which is equivalent to:

$$\frac{\mathop{\mathrm{Var}}_{s\sim p_0^\pi} \left[\Upsilon_s\right]}{\mathop{\mathbb{E}}_{s\sim p_0^\pi a\sim\pi} \mathrm{Var} \left[\Upsilon_{s,a}\right]} \leq \frac{1-\delta N}{\delta(N^2+N)}$$

(32)

We proceed with the derivation for the MDP setup, where $p^\pi(s'|s) \neq p^\pi(s')$. We write $N=1$, which implies that we start in the regular single-action SPG setup. Furthermore, we assume $\delta = 1$, which according to the setup implies equal cost of sampling additional action and state samples. Thus, Equation 30 simplifies to:

$$\sum_{t=1}^{T-1} \frac{t}{T} \alpha_t^e \geq \mathop{\mathrm{Var}}_{s\sim p_0^\pi} \left[\Upsilon_s\right] + \sum_{t=1}^{T-1} \frac{2T-3t}{T} \alpha_t$$

$$\equiv \sum_{t=1}^{T-1} \frac{t}{T} \alpha_t^e \geq \mathop{\mathrm{Var}}_{s\sim p_0^\pi} \left[\Upsilon_s\right] + 2\sum_{t=1}^{T-1} \frac{T-t}{T} \alpha_t - \sum_{t=1}^{T-1} \frac{t}{T} \alpha_t$$

$$\equiv \sum_{t=1}^{T-1} \frac{t}{T} \left(\alpha_t^e + \alpha_t\right) \geq \mathop{\mathrm{Var}}_{s\sim p_0^\pi} \left[\Upsilon_s\right] + 2\sum_{t=1}^{T-1} \frac{T-t}{T} \alpha_t$$

$$\equiv \sum_{t=1}^{T-1} \frac{t}{T} \mathrm{Cov}_t \geq \mathop{\mathrm{Var}}_{s\sim p_0^\pi} \left[\Upsilon_s\right] + 2\sum_{t=1}^{T-1} \frac{T-t}{T} \alpha_t$$

(33)

Which concludes the derivation of Theorem 1.

B   Appendix B - Ablation studies

We start with analysis of the effect of increase of N. Since simulating action samples with a dynamics model induces bias, we hypothesize that there exists some value of N after which further increase of N will deteriorate the learning. Figure 5 shows DAA-PPO learning curves for different values of N. Interestingly, we see that $N = 4$ chosen for the experiment is an extremely conservative value and further significant performance boost is possible via the increase of N.

Figure 5: Comparison of DAA-PPO with different values of N. Blue is $N = 4$; green is $N = 8$; red is $N = 16$; violet is $N = 32$; and yellow is $N = 64$. Note, that in main experiments we use $N = 4$.

As follows from Figure 5, increasing N in DAA-PPO yields performance benefits due to further decrease in variance. Such improvement is not monotonic, as at some point the bias of dynamics model might perturb the learning process (ie. $N = 64$ in Reacher, easy). Furthermore, we analyse the effect of the simulation horizon (depth of simulation for Q-value estimation) on DAA-PPO learning curves. The results are shown in Figure 6

Figure 6: Comparison of DAA-PPO with different depths of simulation horizon for estimating Q-values. Blue is $N = 4$; green is $N = 8$; red is $N = 16$; violet is $N = 32$; and yellow is $N = 64$.

As can be seen in Figure 6, DAA-PPO performance is highly dependent on the simulation horizon for Q-value estimation. For larger simulation horizons, the Q-value estimations are largely dependent on the dynamics model, which might result in extreme levels of bias early in the training. This effect might perhaps be alleviated by using more advanced dynamics model architectures or some sort of annealing scheme, which would increase the simulation horizon as the dynamics model becomes more stable. We leave testing those hypotheses for future work. Results for the above ablations were generated with 20 random seeds.

Finally, we investigate the effect of using advantage normalization in conjunction with DAA. Figure below shows the learning curves for PPO and DAA-PPO when using advantage normalization.

Figure 7: Comparison of DAA-PPO and PPO when using advantage normalization. Results generated using 15 random seeds.

As follows from Figure 7, using advantage normalization with DAA-PPO further boosts the performance of the proposed algorithm.

C   Appendix C - implementation details

Table 2 lists all hyperparameters used in the experiments.

Parameter	PPO	QAA-PPO	DAA-PPO
action repeat	4	4	4
actor optimizer	Adam	Adam	Adam
critic optimizer	Adam	Adam	Adam
dynamics optimizer	NA	NA	Adam
Q-net optimizer	NA	Adam	NA
actor learning rate	0.0003	0.0003	0.0003
critic learning rate	0.0003	0.0003	0.0003
dynamics learning rate	NA	NA	0.0007
Q-net learning rate	NA	0.0003	NA
actor epsilon	1e-5	1e-5	1e-5
critic epsilon	1e-5	1e-5	1e-5
dynamics epsilon	NA	NA	1e-5
Q-net epsilon	NA	1e-5	NA
hidden layer size	512	512	512
λ	0.95	0.95	0.95
discount	0.99	0.99	0.99
batch size	2048	2048	2048
minibatch size	64	64	64
PPO epochs	10	10	10
dynamics buffer size	NA	NA	50 000
dynamics batch size	NA	NA	256
number of simulated actions	NA	4	4
simulation horizon	NA	NA	8
clip coefficient	0.2	0.2	0.2
maximum gradient norm	0.5	0.5	0.5
value coefficient	0.5	0.5	0.5
entropy coefficient	0	0	0
