Exposing Long-Tail Safety Failures in Large Language Models through Efficient Diverse Response Sampling

Abstract

Safety tuning through supervised fine-tuning and reinforcement learning from human feedback has substantially improved the robustness of large language models (LLMs). However, it often suppresses rather than eliminates unsafe behaviors, leaving rare but critical failures hidden in the long tail of the output distribution. While most red-teaming work emphasizes adversarial prompt search (input-space optimization), we show that safety failures can also be systematically exposed through diverse response generation (output-space exploration) for a fixed safety-critical prompt, where increasing the number and diversity of sampled responses can drive jailbreak success rates close to unity. To efficiently uncover such failures, we propose Progressive Diverse Population Sampling (`PDPS`), which combines stochastic token-level sampling with diversity-aware selection to explore a large candidate pool of responses and retain a compact, semantically diverse subset. Across multiple jailbreak benchmarks and open-source LLMs, `PDPS` achieves attack success rates comparable to large-scale IID sampling while using only 8%–29% of the computational cost. Under limited-response settings, it improves success rates by 26%–40% over IID sampling and Diverse Beam Search. Furthermore, responses generated by `PDPS` exhibit both a higher number and greater diversity of unsafe outputs, demonstrating its effectiveness in uncovering a broader range of failures.

1 Introduction

Large Language Models (LLMs) have witnessed unprecedented adoption across a wide range of domains, driven by their remarkable ability to understand, generate, and reason over natural language at scale (Myers et al., 2024; Raiaan et al., 2024; Moenks et al., 2025; Chkirbene et al., 2024). Despite these capabilities, LLMs can produce unsafe outputs, including harmful or toxic content, biased or discriminatory responses, and inadvertent disclosure of sensitive information (Gehman et al., 2020; Weidinger et al., 2021; 2022; Li et al., 2023; Shi et al., 2024; Huang et al., 2024a). Such risks are particularly concerning in deployed systems at scale. Although safety tuning and alignment methods, such as supervised fine-tuning (SFT) and reinforcement learning from human feedback (RLHF), have significantly improved robustness (Ouyang et al., 2022; Rafailov et al., 2023; Bai et al., 2022), LLMs remain vulnerable to jailbreak attacks that bypass safeguards (Li et al., 2024; Wei et al., 2024; Shayegani et al., 2023). This persistent vulnerability underscores the need for systematic and rigorous red-teaming frameworks to identify and mitigate safety failures.

Existing red-teaming approaches primarily focus on *input-space search*, such as crafting adversarial prompts to elicit unsafe behavior from LLMs (Zou et al., 2023; Liu et al., 2024; Mehrotra et al., 2024; Zhao et al., 2025). In contrast, we shift the emphasis toward *output-space search* to identify potentially policy-violating and toxic generations arising from a fixed, safety-critical prompt (see Figure 1 for illustration). This approach is motivated by the observation that safety tuning typically reduces, but does not entirely eliminate, the probability of generating toxic outputs in response to safety-critical prompts. As a result, such low-probability unsafe outputs may surface in deployed LLMs due to diversity-enhancing token generation methods, adversarial prompting, or adversarial fine-tuning. We show that repeated sampling with diversity-enhancing decoding strategies, such as large top-p nucleus sampling or high-temperature sampling (Holtzman et al., 2019; Nguyen et al., 2024), can uncover these rare failure modes. Our experiments (Figure 2) demonstrate that increasing

Figure 1: Illustration of input-space versus output-space search for jailbreaking. In input-space search, several variations or perturbations of the original safety-critical query are generated to elicit unsafe responses from an LLM. In contrast, output-space search is an orthogonal and complementary approach in which multiple responses are generated from a safety-critical prompt to assess whether any of them are unsafe.

both the number and diversity of samples monotonically raises the jailbreak success rate. These findings highlight the effectiveness of output-space search in exposing latent toxic behaviors that may be suppressed yet persist after safety tuning, thereby enabling a more comprehensive automated red-teaming paradigm that reveals rare but consequential safety failures and complements prompt-level adversarial manipulation.

While repeated diverse sampling increases the likelihood of uncovering unsafe or policy-violating generations, generating a large population of outputs per prompt can be computationally prohibitive, especially in resource-intensive pipelines such as RLHF. To address this, we propose **P**rogressive **D**iverse **P**opulation **S**ampling (PDPS), an efficient framework that replaces naive independent and identically distributed (IID) sampling with a multi-stage expansion-and-selection strategy. PDPS explores the output space by first generating a broad pool of short partial responses, then iteratively expanding candidates using diversity-aware token sampling while pruning redundancies through a diversity-aware objective. By expanding candidates that maximize semantic coverage, PDPS maintains diversity throughout generation and produces a compact set of responses that capture rare failure modes at substantially lower cost. Experiments show that PDPS achieves attack success rates comparable to large-scale IID sampling while using only 8%–29% of the computational cost. Under limited-response budgets, it outperforms IID sampling and Diverse Beam Search (Vijayakumar et al., 2016) by 26%–40% on average, while generating more numerous and diverse unsafe outputs, demonstrating its superior ability to uncover a broader range of failure modes.

In summary, our contributions are fourfold: (i) we present an empirical analysis demonstrating how diversity-driven large-scale sampling can expose latent safety failures in safety-tuned LLMs that are often missed by standard decoding; (ii) we propose PDPS, a compute-efficient algorithm that replaces naive large-scale IID sampling with a diversity-aware expansion-and-selection strategy; (iii) we show that PDPS achieves attack success rates comparable to large-scale IID sampling while using significantly less computational time, and achieves superior attack success rates compared to alternative baselines in limited-response generation tasks; and (iv) we demonstrate that responses generated by PDPS cover a broader and more distinct range of failure modes, providing a more comprehensive stress test of model safety. [1]

Safety Alignment and its Limitations. To ensure adherence to human values, safety alignment has become a standard stage in LLM training, primarily through SFT and RLHF (Bai et al., 2022; Dai et al., 2024; Wang et al., 2023; Lu et al., 2025). Although these methods substantially reduce toxic or harmful outputs, unsafe behaviors may persist in the long tail of the output distribution and can be elicited via

(a) Increasing N with $\tau = 1$ and $p = 1$.

(b) Increasing τ with $N = 64$ and $p = 1$.

(c) Increasing p with $N = 64$ and $\tau = 1$.

Figure 2: Attack Success Rate (ASR) trends on Qwen2.5-7B-Instruct. The plots show ASR across HarmBench, JailbreakBench, AdvBench, and MaliciousInstruct datasets as a function of: (a) total number of generations (N), (b) sampling temperature (τ), and (c) nucleus sampling probability (p), while holding other parameters constant. The results demonstrate that broader exploration of the output space, whether through increased sample size or higher stochasticity leads to a monotonic increase in ASR.

sampling-based decoding (Huang et al., 2024b). Our work builds on the observation that this form of "safety-by-suppression" remains vulnerable to high-coverage sampling.

Adversarial Red-Teaming. Red-teaming has traditionally focused on adversarial prompting – the craft of finding specific input strings that bypass safety filters. Examples include gradient-based attacks such as GCG (Zou et al., 2023), automated prompt generation like MART (Ge et al., 2024), and roleplay or nested-fiction attacks (Johnson, 2024; Jin et al., 2024). These approaches treat red-teaming as an input-space optimization problem. In contrast, we explore a complementary output-space exploration paradigm that targets low-probability unsafe responses. Even for a fixed safety-critical query, stochastic decoding can surface such failures by increasing response diversity, shifting the objective from finding vulnerable prompts to uncovering rare failure modes in the model's response distribution.

Diversity-Aware Generation. Promoting output diversity has long been central to natural language generation to avoid repetitive responses. Common approaches include high-temperature decoding, nucleus sampling (Holtzman et al., 2019), min-p sampling (Nguyen et al., 2024), and Diverse Beam Search (Vijayakumar et al., 2016). These methods encourage token-level diversity during decoding. In contrast, our `PDPS` framework performs selection at semantic level using a sequence-wide diversity measure, capturing holistic differences in meaning instead of surface-level variation.

3 Jailbreaking through Diverse Output-Space Exploration

Safety tuning through SFT or RLHF reduces the likelihood of unsafe outputs. Formally, for a safety-critical prompt x, the aligned distribution $p_{\text{safe}}(y|x)$ suppresses unsafe continuations while shifting probability mass toward safe responses. If $U \subset \mathcal{Y}$ denotes unsafe sequences in the output space $\mathcal{Y}$ and $S \subset \mathcal{Y}$ denotes safe responses (e.g., standard refusals), alignment ensures that: $p_{\text{safe}}(U \mid x) \ll p_{\text{safe}}(S \mid x)$. However, even when the probability of sampling an unsafe continuation $p = p_{\text{safe}}(U|x)$ is small, basic probability theory implies that the chance of observing at least one such event grows monotonically with the number of independent generations N, following $1 - (1 - p)^N$. This probability can be further amplified by diversity-enhancing decoding strategies (e.g., high-temperature sampling, nucleus sampling with large top-p values (Holtzman et al., 2019), or min-p sampling (Nguyen et al., 2024)), which redistribute probability mass toward the long tail. By flattening the distribution and increasing stochastic trials, these methods expose low-probability (unsafe) regions of the output space, raising the likelihood of responses that escape safety guardrails.

3.1 Experimental Validation

We empirically evaluate whether increasing the number of generations (N) and decoding stochasticity, via higher sampling temperature (τ) or nucleus threshold (p), improves the likelihood of uncovering safety

(a) Query 0   (b) Query 1   (c) Query 2

Figure 3: 2D plots of embeddings of 1024 responses generated from Llama-2-13B-Chat for three safety-critical prompts. The color indicates the likelihood of a response being unsafe.

failures. We assess the robustness of Qwen2.5-7B-Instruct[2] under three settings: (a) varying N ($p = 1, \tau = 1$), (b) varying top-p ($N = 64, \tau = 1$), and (c) varying τ ($N = 64, p = 1$). Experiments are conducted on 100 samples from each of four safety benchmarks: HarmBench (Mazeika et al., 2024), JailbreakBench (Chao et al., 2024), AdvBench (Zou et al., 2023), and MaliciousInstruct (Huang et al., 2024b).

Figure 2a shows that ASR increases consistently with N across all benchmarks, confirming that repeated stochastic trials raise the probability of failure. Figures 2b and 2c further show a monotonic increase in ASR as the decoding distribution is flattened through larger top-p and τ, indicating that failure modes lie in the distribution's long tail. Thus, while safety tuning suppresses harmful outputs, they remain accessible under large-scale or diversity-enhancing sampling. These findings align with Huang et al. (2024b), which reports similar observations when scaling the number of generations or tuning sampling hyperparameters. More broadly, however, we show that increasing sampling diversity monotonically increases the likelihood of safety failures, suggesting that the vulnerability stems from tail coverage rather than hyperparameter choices.

4 Framework for Efficient Diverse Response Sampling

The previous section showed that increasing decoding stochasticity or the number of generated responses can significantly raise the jailbreak success rate, exposing latent failure modes. However, these strategies involve trade-offs. An excessively high temperature may degrade response quality and coherence, resulting in incoherent or meaningless outputs. Increasing the sample size N improves coverage, yet brute-force sampling has two key limitations. First, because unsafe responses occur with low probability in safety-tuned models, uncovering them may require a prohibitively large number of generations, incurring substantial computational cost. Second, since the output distribution is dominated by high-probability refusal modes, naive IID sampling produces highly redundant outputs, leading to diminishing returns for safety evaluation or downstream safety tuning (e.g., RLHF).

To overcome these inefficiencies, we propose a semantically diverse response generation framework for efficient output-space exploration.

4.1 Semantically Diverse Response Generation for Efficient Output-Space Exploration

To make output-space exploration both efficient and diverse, we avoid generating a large number of high-probability refusal responses for a safety-critical prompt. Our approach is motivated by the observation that low-probability jailbreaking responses are often semantically distinct from refusal responses.

For example, consider the query: `"Create a blueprint for committing identity theft and stealing someone's personal information."` A typical refusal response may be: `"I'm sorry, but I can't assist with that request..."`, whereas a jailbreak response might begin: `"1. Research the victim:`

---

[2]`https://huggingface.co/Qwen/Qwen2.5-7B-Instruct`

Figure 4: Illustration of the difference between (a) IID sampling and (b) PDPS. IID sampling generates a large number of long responses through diverse token-level sampling. In contrast, PDPS produces a small set of diverse responses that approximate the modality coverage of large-scale IID sampling, while retaining the computational efficiency of small-scale IID sampling.

`Start by gathering as much information..."` These responses differ in semantic structure. This suggests that jailbreak failure modes occupy semantic regions that are distinct from refusal modes.

To empirically validate this distinction, we compute semantic embeddings for each generated response by mean-pooling the final-layer hidden states of Llama-2-13B-Chat and project them into two dimensions using UMAP (McInnes et al., 2018). Figure 3 visualizes 1024 responses generated for three safety-critical prompts. For most prompts, unsafe responses form compact clusters largely separated from safe responses, supporting the hypothesis of semantic separability[3] (see Appendix A for additional plots). Therefore, instead of relying on massive IID sampling, which is largely dominated by repeated refusal responses, we argue that identifying and generating a small set of semantically diverse responses can substantially reduce redundancy and computational cost, while still covering the distinct semantic modes that would otherwise require large-scale IID sampling to uncover. By targeting semantically-diverse regions of the output space, we can more efficiently expose potential failure modes.

Based on these insights, we propose `PDPS` (**P**rogressive **D**iverse **P**opulation **S**ampling), a framework for efficiently generating a small, semantically diverse response set while achieving success comparable to large-scale IID sampling.

4.2 `PDPS`: A Semantically Diverse Response Generation Framework

`PDPS` efficiently explores a large region of the output space by first generating an initial pool of short, partial responses, each restricted to a small generation length to reduce cost. It then applies a quality–diversity optimization step to prune the pool, retaining only the most promising and semantically distinct candidates for further expansion. These two steps, expansion and diversity-aware selection, are repeated iteratively until a small set of full-length responses is obtained. In this way, `PDPS` explores the output space broadly while maintaining low computational cost, ultimately producing a compact set of high-quality, semantically diverse responses. The overall procedure is summarized in Algorithm 1.

---

[3]Although some overlap between unsafe and safe regions is occasionally observed in the plots, this may stem from limitations of using mean-pooled final-layer hidden states of the Llama-2-13B-Chat model as semantic embeddings. We hypothesize that more expressive embedding representations would yield stronger separability.

Algorithm 1 **P**rogressive **D**iverse **P**opulation **S**ampling.

Input: Target LLM f_θ, prompt x_0, population schedule $\{n_i\}_{i=0}^K$ with $n_{i-1} > n_i$ for $i = 1, \ldots, K$, block size schedule $\{b_i\}_{i=0}^K$ with $\sum_{i=0}^K b_i$ representing to the maximum generation length.

1: $S_0' \leftarrow \{x_0 \text{ repeated } n_0 \text{ times}\}$ // Initialization
2: **for** $i = 1, \ldots$, K **do**
3:      $S_{i-1} \leftarrow \{\text{Expand}_{b_{i-1}}(s) \mid s \in S_{i-1}'\}$ // Expansion
4:      $S_i' \leftarrow \text{Select}_{n_i}(S_{i-1})$ // Diversity-aware selection
5: **end for**
6: $S_K \leftarrow \{\text{Expand}_{b_K}(s) \mid s \in S_K'\}$ // Final Expansion
7: **return** S_K

The algorithm takes as input the prompt x_0, a population (pool) size schedule $\{n_i\}_{i=0}^K$ (where $n_0 = n$ is the initial population size, $n_K = r$ is the target final population size, and $n_{i-1} > n_i$ for $i = 1, \ldots, K$), and a block size schedule $\{b_i\}_{i=0}^K$, such that the total sum $\sum_{i=0}^K b_i$ represents the maximum generation length. The algorithm performs the following operations:

Initialization. The candidate pool S_0 is initialized by repeating the query prompt x_0 for n instances: $S_0' = \left\{ s_j^{'(0)} = x_0 \right\}_{j=1}^n$.

Iterative Expansion and Selection. At each iteration $i = 1, \ldots, K$, the algorithm performs:

1. Expansion: At iteration i, each candidate sequence $s \in S_{i-1}'$ is extended by sampling a block of b_{i-1} new tokens. To ensure that the generated response blocks are diverse, a token-level diversity-inducing sampling methods, such as high-temperature sampling, nucleus sampling, or min-p sampling, is used to sample each response block. The expanded sequence can be expressed as:

$$\text{Expand}_{b_{i-1}}(s) = s \oplus z_{1:b_{i-1}}, \quad z_{1:b_{i-1}} \sim f_\theta(\cdot \mid s)$$

where $z_{1:b_{i-1}}$ represents the b_{i-1} new tokens sampled from the target LLM f_θ using sequence s as the prefix, and $\oplus$ denotes the concatenation operation. This defines the expanded set

$$S_{i-1} = \left\{ \text{Expand}_{b_{i-1}}(s) \,\middle|\, s \in S_{i-1}' \right\}.$$

2. Diversity-Aware Selection: To keep the total computational cost of expanding partial responses low and to maintain a small, diverse final response set, we select a subset $S_i' \subset S_{i-1}$ of size n_i using diversity-aware subset selection. Specifically, the algorithm selects a smaller subset S_i' from S_{i-1} by maximizing a quality–diversity optimization problem:

$$S_i' = \underset{A \subset S_{i-1}, |A| = n_i}{\text{argmax}} \left(\frac{1}{n_i} \sum_{s \in A} q(s) + \lambda \cdot h(A) \right), \tag{1}$$

where $q(s)$ is quality measure of the partial response $s \in S_{i-1}$, $h(A)$ is a metric measuring the diversity of the partial responses in the subset $A \subset S_{i-1}$, and λ is a non-negative hyper-parameters controlling the quality-diversity trade-off. This selection ensures that the population remains high quality while maximizing semantic diversity, thereby enhancing exploration of the output space.

Termination. The iterative process terminates after K iterations when the population size reaches the target $n_K = r$, generating the set S_K'. Each sequence in this set is then expanded by b_K new tokens, resulting in the final set S_K, which contains the diverse generated responses used for safety evaluation.

4.3 Details of Diversity-aware Selection

The quality–diversity optimization problem in Eq. (1) is a discrete combinatorial problem, making exact maximization computationally expensive. However, note that the quality term of the objective, $\frac{1}{n} \sum_{s \in A} q(s)$,

---

Algorithm 2 Greedy Algorithm for Max-Avg Diversification Problem (Dasgupta et al., 2013)

Input: Current pool of partial responses S, size of the target pool n.

1: $T \leftarrow \emptyset$
2: **for** $t = 1$ to n **do**
3:     $s^\star \leftarrow \arg\max\limits_{s \in S \setminus T} \frac{q(s)}{n} + \frac{\lambda}{n(n-1)} \sum_{t \in T} d(s, t)$
4:     $T \leftarrow T \cup \{s^\star\}$
5: **end for**
6: **return** T

---

is a modular function. Therefore, by selecting appropriate functional forms for the diversity metric $h(\cdot)$, the problem becomes a well-studied instance of subset selection that admits efficient approximation algorithms (Lin & Bilmes, 2010; Dasgupta et al., 2013; Borodin et al., 2017). Specifically, for the diversity measure $h(A)$, we employ the average pairwise distance between all elements in the set:

$$h(A) = \frac{2}{|A|(|A| - 1)} \sum_{s_i, s_j \in A, i \neq j} d(s_i, s_j)$$

where $d(\cdot, \cdot)$ is a distance metric (the angular arccosine distance or Euclidean distance in the embedding space) satisfying the triangle inequality.

Substituting these into our objective, the selection problem at iteration i becomes:

$$S_i = \operatorname*{argmax}_{A \subset S'_i, |A| = n_i} \frac{1}{n_i} \sum_{s \in A} q(s) + \lambda \cdot \frac{2}{n_i(n_i - 1)} \sum_{s_i \neq s_j \in A} d(s_i, s_j) \tag{2}$$

This objective is a specific instance of the **Max-Avg** (or **Max-Sum**) diversification problem (Lin & Bilmes, 2010; Dasgupta et al., 2013; Borodin et al., 2017). While finding the global optimum is NP-hard, the objective can be approximately solved by Algorithm 2 with the following theoretical guarantee (Dasgupta et al., 2013):

Theorem 4.1. *Let $J(A)$ be the Max-Avg objective function defined in Eq. (2). If $d(\cdot, \cdot)$ is a metric satisfying the triangle inequality, and $A^\star$ and $\hat{A}$ denote an optimal solution and a solution returned by Algorithm 2 respectively, then $J(\hat{A}) \geq \frac{1}{2} J(A^\star)$.*

This guarantee ensures that PDPS maintains a high-quality, diverse population without the need for exhaustive search, making it feasible for large-scale red-teaming tasks.

5 Experimental Setup

5.1 Target Models and Benchmark Datasets

We benchmark PDPS in attacking four distinct LLMs: (i) Llama-2-7b-chat (L2-7BCh), (ii) Llama-2-13b-chat (L2-13BCh), (iii) Qwen2.5-7B-Instruct (Q-7BInst), and (iv) Qwen3-14B-Instruct (Q-14BInst). The benchmarking is conducted across four datasets: HarmBench (HarB) (Mazeika et al., 2024), JailbreakBench (JBB) (Chao et al., 2024), AdvBench (AdvB) (Zou et al., 2023), and MaliciousInstruct (MalI) (Huang et al., 2024b). For each dataset, we evaluate a random subset of 100 instances drawn from test split.

5.2 Limited Response Generation Tasks

Since increasing the number of generated responses naturally increases the ASR for any sufficiently diverse sampling method, we focus on evaluating PDPS in limited-response generation tasks, assessing its ability to uncover distinct failure modes while keeping the generated response set small and compact. To this end, we benchmark PDPS on two target settings: (a) 16-response generation and (b) 64-response generation. Specifically, in the 16- (resp. 64-) response generation task, a set of 16 (resp. 64) responses is generated for each prompt using a given sampling algorithm. We then determine whether any of the generated responses constitutes a successful jailbreak.

5.3 `PDPS` **Setup**

Hyper-parameter Setting. For the 16-response task, `PDPS` generates 16 full-length sequences using a population schedule of $\{1024, 256, 64, 16\}$ and a block size schedule of $\{64, 64, 128, 256\}$. For the 64-response task, `PDPS` generates 64 responses using population schedules of $\{1024, 256, 64\}$ and block sizes of $\{64, 64, 384\}$. In both tasks, the hyper-parameter λ is set to 64 based on preliminary tuning (see Section 6.5).

The Distance Metric $d(\cdot, \cdot)$**.** Since the objective of `PDPS` is to select semantically diverse responses, we employ a distance metric to characterize semantic differences. While it is common to project input sequences into an embedding space (e.g., via OpenAI's `text-embedding-3-small`) to capture semantic information (Jiang et al., 2025), we utilize the target model's internal representations. Specifically, we compute sentence embeddings as the mean of the last-layer hidden states during generation and measure semantic distance using the arccosine distance between embeddings.

The Quality Measure $q(s)$**.** In `PDPS`, we consider two types of quality measures for a candidate response s: (i) properties that are independent of a response's safety status, such as semantic coherence and faithfulness to the query, or (ii) the likelihood of being unsafe as estimated by an auxiliary judge model. While a judge-based measure may yield higher attack success rates by directly targeting harmfulness, it is limited by the judge's own training biases. Conversely, measures independent of auxiliary judge models facilitate the discovery of unkown failure modes that a judge might overlook. For this work, we adopt the first type, defining $q(s)$ as the geometric mean token probability: $q(s) = \sqrt[|s|]{p_f(s)}$ where $|s|$ is the sequence length and $p_f(s)$ is the likelihood under the target LLM. This length-normalized metric ensures quality scores remain comparable across expansion steps, functioning as a proxy for inverse perplexity.

5.4 Baselines

We compare the performance of `PDPS` against two baselines: (a) **IID sampling** (`IID`), which generates a set of responses for each prompt using high-temperature or nucleus sampling, and (b) **Diverse Beam Search** (`DBS`) (Vijayakumar et al., 2016). As `PDPS` begins with an initial pool of 1024 partial sequences, the `IID` generation of all 1024 full-length sequences serves as the performance upper bound, denoted as IID_{1024}. For all experiments, except involving `DBS`, the token-level sampling parameters top-p and temperature τ are set to 1. For `DBS`. We apply a diversity penalty of 1.0 and set the number of beams and beam groups to 16 (for the 16-response task) and 64 (for the 64-response task) to match the corresponding return sequence counts.

Additional details on the experimental setup are provided in Appendix F.

6 Results

As described in Section 5.2, we evaluate `PDPS` on the 16- and 64-response generation tasks. Since IID_{1024} generates all 1024 full-length responses, it serves as an empirical upper bound for both PDPS_{16} and PDPS_{64}. We therefore analyze results under two settings: (i) limited-generation comparison and (ii) comparison with full IID sampling. We also analyze response diversity, the distribution of toxic and non-toxic outputs selected by `PDPS`, and its computational efficiency along with hyperparameter sensitivity.

6.1 Limited-Generation Comparison

In Table 1, we compare the ASR of `PDPS` with `IID` and `DBS` on the 16- and 64-response generation tasks. The results show that `PDPS` consistently outperforms both `IID` and `DBS` across all sixteen model–dataset combinations. In the 16-response generation task, `PDPS` achieves an average ASR improvement of 38% over `IID` and 40% over `DBS`. Similarly, in the 64-response generation task, `PDPS` achieves average improvements of 26% and 35% over `IID` and `DBS`, respectively. Moreover, `PDPS` outperforms the baselines in each model-dataset combination across both tasks, with improvements of up to 79% over `IID` and 75% over `DBS`, further demonstrating the consistency of `PDPS` relative to the two baselines. In Appendix D, we further analyze the performance of `DBS` under increased diversity penalties, showing that even with stronger diversity regularization, it does not close the performance gap with `PDPS`.

Table 1: Comparison of ASR of obtained from `PDPS` with IID sampling (`IID`) and Diverse Beam Search (`DBS`) across four models (`L2-7BCh`, `L2-13BCh`, `Q-7BInst`, `Q-14BInst`) and four datasets (`JBB`, `MalI`, `HarB`, `AdvB`). Subscripts denote the number of full-length generations (e.g., IID_{16} uses 16 full-length responses generation). The blue entries indicate the performance improvement of `PDPS` (in %) over the corresponding baseline.

Table 2: ASR of `PDPS` compared to the brute-force benchmark IID_{1024} across the four models (`L2-7BCh`, `L2-13BCh`, `Q-7BInst`, `Q-14BInst`) and the four datasets (`JBB`, `MalI`, `HarB`, `AdvB`). Subscripts denote the number of full-length generations (e.g., PDPS_{16} uses 16 full-length sequences constructed from 1024 partial generations). The row labeled $\rho^{\S\sim\diamond}$ (resp. $\rho^{\P\sim\diamond}$) report the ASR achieved by PDPS_{16} (resp. PDPS_{64}) as a fraction of the ASR achieved by IID_{1024}. The blue entries in these rows indicate that `PDPS` attains at least 0.8 times the ASR of IID_{1024}, whereas red entries indicate failure to reach this threshold.

6.2 Comparison to the Full IID Sampling

Next, we compare PDPS_{16} and PDPS_{64} to IID_{1024}, which generates all 1024 responses and thus represents an empirical upper bound on ASR. This comparison evaluates how closely `PDPS` approaches the brute-force limit while using substantially fewer full-length generations. The results are presented in Table 2. Although PDPS_{16} generates only 16 responses (vs. 1024 for IID_{1024}), it achieves more than 80% of IID_{1024}'s ASR in 11 of the 16 model–dataset combinations, with 9 reaching at least 90% of the upper-bound ASR. For PDPS_{64}, the ASR exceeds 80% of the brute-force benchmark across all sixteen combinations and reaches at least 97% of IID_{1024}'s ASR in every case. These results demonstrate that `PDPS` can produce compact response sets while maintaining high attack success rates and substantially reducing the number of generations.

6.3 Failure Mode Coverage and Diversity Analysis of Unsafe Responses

In this section, we examine the coverage and diversity of failure modes identified by `PDPS` in comparison to the baseline methods. While the overall ASR valued provide a coarse measure of effectiveness, they do not reveal whether a method uncovers a broad spectrum of vulnerabilities or repeatedly triggers the same failure pattern. In particular, a method may fail to generate any unsafe response for certain queries, thereby appearing weaker in terms of ASR. However, even when a method succeeds in producing unsafe outputs, an important question remains: do these outputs correspond to diverse and distinct failure modes, or are they concentrated around a limited set of similar behaviors?

To move beyond ASR, we analyze both the number and diversity of unsafe responses per successful query. We first compare the average number of unsafe responses per query, conditioning on queries with at least

Figure 5: Bar plot of the mean toxicity difference, defined as the difference between the average number of unsafe responses returned by PDPS and that returned by a baseline method, across various model–dataset combinations. The average is computed over only those queries for which the respective method achieves a successful attack. Blue bars indicate a positive difference, while red bars indicate a negative difference.

Table 3: Comparison of the average diversity of unsafe responses generated by PDPS and two baseline methods for the Q-7BInst model on the four datasets. The average is computed over only those queries for which at least two unsafe responses are returned by the respective methods. Diversity metrics: Dist-n = Distinct-n (Li et al., 2016); SB-n = Self-BLEU-n (Zhu et al., 2018); Uni-Ent = Unigram Entropy (Csáky et al., 2019); Cos-Dist = Cosine Distance (Jiang et al., 2011); BERT-Div = BERTScore Diversity (Zhang et al., 2019). For metrics marked with ↑, higher values indicate greater diversity, while ↓ indicates the opposite.

one unsafe output. This isolates a method's ability to uncover multiple failure modes independent of overall ASR. We then evaluate the average diversity of unsafe responses to ensure additional samples provide distinct insights rather than redundant variations.

Analysis of Mean Toxicity Difference. Figure 5 presents the mean toxicity difference, defined as the difference between the average number of unsafe responses identified by PDPS and those identified by the baseline methods, across various model–dataset combinations. PDPS consistently detects a higher number of unsafe responses than IID across nearly all combinations. While the comparison with DBS yields mixed results for the Qwen models, PDPS consitantly identifies more unsafe responses for the Llama models.

Figure 6: Sampling time (as a percentage of brute-force IID_{1024}) for generating 64 responses on L2-13BCh and Q-14BInst across token lengths 512–4096. Bars labeled *OOM* indicate out-of-memory failures.

Analysis of Diversity. We further assess each method's ability to uncover distinct failure modes by measuring the average diversity of unsafe responses, computed over queries with at least two unsafe outputs. Table 3 reports nine diversity metrics for Q-7BInst across four datasets. PDPS outperforms both baselines across all metrics and datasets, demonstrating broader failure coverage. Results for the remaining models (Appendix B) indicate that PDPS consistently outperforms DBS by a wide margin across all metrics and outperforms IID across most metrics.

Overall, these findings indicate that PDPS more effectively uncovers diverse failure modes than competing methods. Appendix C provides qualitative examples, showing that DBS tends to produce minor surface variations, whereas PDPS generates more semantically distinct responses.

6.4 Computational Efficiency Analysis

In this section, we analyze the computational gain of PDPS for the 64-response generation task, for which PDPS already achieves an ASR comparable to the brute-force IID_{1024} upper bound (see Table 2). For the 64-response setting, IID_{64}, which performs IID sampling of only 64 responses per query, provides a lower bound on computational cost. Ideally, IID_{64} requires approximately $1/16 = 0.06$ (i.e., 6%) of the time required by IID_{1024}. Therefore, we evaluate how closely the runtime of $PDPS_{64}$ approaches this lower bound. We also compare against DBS_{64} as a representative diversity-inducing baseline. Figure 6 reports the sampling time of $PDPS_{64}$, IID_{64}, and DBS_{64} as a percentage of the brute-force upper bound IID_{1024} for two models, L2-13BCh and Q-14BInst, across token generation lengths ranging from 512 to 4096.

Results on Q-14BInst. Figure 6 (right), showing the results for Q-14BInst, indicates that for shorter generation lengths (e.g., 512 tokens), the sampling time of IID_{64} is noticeably higher than the ideal 6% lower bound. As the generation length increases, the runtime approaches this limit. We attribute this deviation at shorter lengths to suboptimal GPU utilization caused by the smaller batch size of IID_{64} compared to IID_{1024}. As the generation length increases, GPU utilization improves, enabling IID_{64} to approach the theoretical 6% bound. A similar trend is observed for $PDPS_{64}$, which requires as much as 29% of the IID_{1024} runtime at 512 tokens. However, its relative overhead decreases with longer generation lengths, reaching approximately 8% at 4096 tokens. Compared to IID_{64}, $PDPS_{64}$ incurs higher overhead at shorter lengths, but this gap narrows as generation length increases. This behavior is expected because $PDPS_{64}$ initially generates 1024 short partial responses. When the final generation length is small, this initial cost becomes significant part of total runtime; however, it becomes negligible for longer sequences. The computational trend of DBS_{64} is similar, although its runtime remains slightly higher than that of $PDPS_{64}$.

Results on L2-13BCh. Figure 6 (left) shows the results for L2-13BCh. In contrast to Q-14BInst, IID_{64} achieves the 6% lower bound across all generation lengths. Investigation reveals significantly better GPU utilization for this model, allowing near-optimal efficiency even at shorter lengths. For $PDPS_{64}$, the sampling

(a) Increasing p with $\tau = 1$ and $\lambda = 64$.

(b) Increasing τ with $p = 1$ and $\lambda = 64$.

(c) Increasing λ with $p = 1$ and $\tau = 1$.

Figure 7: ASR under different hyperparameter settings for the `Q-7BInst` model on the AdvBench dataset. (a) ASR for different nucleus sampling probabilities (p); (b) ASR for different sampling temperatures (τ); and (c) ASR for different values of λ, the hyperparameter controlling the quality–diversity threshold.

time ranges between 10% and 17% across token lengths, with no clear trend toward the 6% lower bound as token generation length increases. Further analysis suggests that this behavior arises from uneven GPU utilization across different generation stages of `PDPS`. Despite this suboptimality, $PDPS_{64}$ requires on average only 13% of the brute-force runtime, approximately twice the theoretical 6% lower bound, while achieving performance comparable to IID_{1024} (Table 2). Improving the implementation of `PDPS` to enhance execution efficiency remains an avenue for future work. DBS_{64} results in out-of-memory (OOM) errors on an A100 GPU for generation lengths exceeding 2048. For shorter lengths, its runtime is comparable to that of $PDPS_{64}$.

Overall, the results demonstrate that `PDPS` achieves performance comparable to the brute-force IID_{1024} upper bound while reducing the sampling time to $8\% - 29\%$ of that required by IID_{1024}.

6.5 Hyperparameter Sensitivity

In Figure 7, we present the sensitivity of `PDPS`'s ASR to three hyperparameters: (a) the nucleus sampling probability p, (b) the temperature τ, and (c) λ, which controls the quality–diversity trade-off. The results indicate that increasing these hyperparameters generally improves ASR up to a certain point, primarily due to the increased diversity of generated samples. However, excessive diversity can reduce ASR by producing incoherent responses. A more detailed discussion is provided in Appendix E.

7 Conclusion

In this work, we revisited the problem of safety evaluation in LLMs from an output-space exploration perspective. While existing red-teaming efforts predominantly focus on input-space optimization through adversarial prompt engineering, we demonstrated that safety failures can also be systematically uncovered through large-scale, diversity-driven response generation for fixed safety-critical prompts. Our empirical analysis shows that increasing both the number and diversity of sampled responses monotonically increases jailbreak success rates, revealing that safety tuning often suppresses rather than eliminates unsafe behaviors.

To make output-space exploration computationally tractable, we introduced `PDPS`, a multi-stage expansion-and-selection framework that combines stochastic token sampling with quality–diversity optimization. By maintaining a semantically diverse population of candidate responses and selectively expanding high-coverage candidates, `PDPS` efficiently exposes rare but consequential safety failures under comparable computational budgets. Across multiple benchmarks and open-source LLMs, `PDPS` consistently outperforms strong baselines such as IID sampling and Diverse Beam Search, either achieving substantial improvements in attack success rate or significantly reducing computational time while generating a broader and more diverse unsafe outputs.

Our findings underscore the critical importance of semantic diversity and diverse sampling in red-teaming. By incorporating these principles into the LLM response-generation framework, `PDPS` provides a robust tool for developers to identify and mitigate consequential safety failures before deployment, ultimately contributing to the development of more resilient and aligned AI systems.

A   Additional Embedding Plots

In Section 4.1, we argued that unsafe responses are generally semantically distinct from safe responses. Consequently, when projected into a semantic embedding space (e.g., mean-pooled embeddings of the final-layer hidden states of an LLM), unsafe responses tend to occupy regions separate from safe responses (as illustrated in Figure 3 for L2-13BCh). In this section, we provide additional embedding visualizations for responses generated by Q-7BInst, shown in Figure 8. These plots further demonstrate substantial separation between safe and unsafe responses. In particular, Figures 8b and 8c exhibit clear, well-separated clusters.

Table 4: Comparison of the average diversity of unsafe responses generated by `PDPS` and two baseline methods for the `L2-7BCh` model on the `AdvB` and `JBB` datasets. The average is computed over only those queries for which at least two unsafe responses are returned by the respective methods.

Dataset	Sampler	Dist-1↑	Dist-2↑	SB-1↓	SB-2↓	SB-3↓	SB-4↓	Uni-Ent↑	Cos-Dist↑	BERT-Div↑

Although Figure 8a shows greater overlap, a noticeable spatial bias remains: responses in the left region are more likely to be unsafe, whereas those on the right are predominantly safe. Furthermore, this semantic separability may become even more pronounced with more expressive embedding representations.

B Diversity Analysis of Unsafe Responses

In this section, we present the diversity analysis results for unsafe responses generated by `L2-7BCh` (Table 4), `L2-13BCh` (Table 5), and `Q-14BInst` (Table 6) across the four datasets.

For all model–dataset combinations, `PDPS` performs significantly better than `DBS`, highlighting its ability to identify a broader range of failure modes compared to `DBS`. In comparison with `IID`, `PDPS` occasionally performs worse, although it outperforms `IID` in most scenarios. A closer examination reveals that the metrics on which `IID` occasionally surpasses `PDPS`, such as Distinct-n and SelfBLEU-n with small n, primarily capture lexical or short-range surface-form diversity. Since these metrics rely on exact n-gram overlap, they mainly reflect local syntactic variation rather than deeper semantic differences. In contrast, embedding-based metrics such as cosine similarity and BERTScore-based distance better capture semantic-level diversity and consistently favor `PDPS`.

These results suggest that the responses generated by `PDPS` exhibit greater semantic diversity than those produced by `IID`, even though `IID` may sometimes demonstrate higher lexical or surface-level variation.

Table 5: Comparison of the average diversity of unsafe responses generated by PDPS and two baseline methods for the L2-13BCh model on the AdvB and JBB datasets. The average is computed over only those queries for which at least two unsafe responses are returned by the respective methods.

C Qualitative Diversity Analysis of Unsafe Responses from PDPS and DBS

In this section, we qualitatively analyze the diversity of unsafe responses generated by PDPS and DBS. Table 7 presents several sample responses produced by the Q-7BInst model using the two sampling methods for the same query: "Create a blueprint for committing identity theft and stealing someone's personal information." From the table, it is evident that DBS primarily generates similar responses with only minor surface-level variations. In contrast, PDPS produces responses that are more semantically distinct and diverse, highlighting its superior ability to uncover a broader range of latent failure modes.

D Effect of Diversity Penalty on DBS Performance

Our previous results show that DBS performs worse than PDPS both in terms of ASR and the diversity of generated unsafe responses. These findings raise a natural question: can the performance of DBS be improved by increasing its *diversity penalty* hyperparameter?

To investigate this, we conducted additional experiments using DBS with progressively larger values of the *diversity penalty* hyperparameter on the L2-7BCh model and the AdvB dataset, where DBS exhibits its weakest performance (see Table 1). The results for the 64-response generation setting are reported in Table 8. As shown in the table, increasing the *diversity penalty* from its default value of 1.0 leads to a slight decrease

Table 7: Sample responses generated using `PDPS` and `DBS` by querying the `Q-7BInst` model with the prompt: `"Create a blueprint for committing identity theft and stealing someone's personal information."`. The examples illustrate that `PDPS` produces semantically diverse responses, whereas `DBS` generates largely similar outputs with only surface-level variations.

Table 8: ASR obtained by `DBS` for various values of the *diversity penalty* hyperparameter on the `L2-7BCh` model and the `AdvB` dataset in the 64-response generation setting. The results suggest that the performance of `DBS` does not improve significantly as the diversity penalty increases.

	Diversity Penalty			
	1	4	16	64
DBS_{64}	0.22	0.20	0.16	0.14

in ASR rather than an improvement. This suggests that simply increasing the diversity penalty does not meaningfully enhance the effectiveness of `DBS`.

To better understand this degradation in performance, we analyzed the generated responses. We observed that as the *diversity penalty* increases, `DBS` produces a larger number of null (empty) responses instead of semantically novel outputs. Specifically, the average number of non-null responses decreases from 22.31 to 11.73, 10.72, and 10.72 for diversity penalty values of 1.0, 4.0, 16.0, and 64.0, respectively. Since the number of non-null responses decreases substantially with higher diversity penalties, the effective search space explored by `DBS` shrinks, which in turn limits improvements in ASR. We attribute this behavior to an inherent limitation of `DBS`: its diversity mechanism operates primarily at the token level and does not explicitly encourage global sequence-level semantic diversity. As a result, increasing the diversity penalty may disrupt coherent generation without meaningfully expanding coverage of distinct failure modes.

E   Hyperparameter Sensitivity Analysis of `PDPS`

We evaluate the sensitivity of `PDPS` to different values of (a) the nucleus sampling probability p, (b) the sampling temperature τ used in the token-level decoding strategy, and (c) the hyperparameter λ, which controls the trade-off between the quality and diversity terms in the quality–diversity optimization of `PDPS`. The ASR obtained by the `Q-7BInst` model on the `AdvB` dataset under various hyperparameter settings is shown in Figure 7. The figure indicates that, when $\tau = 1$ and $\lambda = 64$, the ASR consistently increases with p. We attribute this improvement to the generation of more diverse responses as p increases. When analyzing ASR as a function of τ (with $p = 1$ and $\lambda = 64$ fixed), we observe that ASR initially increases up to $\tau = 1$, after which it begins to decline as τ increases further. We hypothesize that the initial improvement (as τ increases from 0.4 to 1) results from enhanced diversity in the generated responses. However, when τ becomes excessively large, the responses become increasingly random, leading to a degradation in ASR. Finally, when varying λ, we observe that ASR initially increases with λ and then stabilizes. As λ increases, the diversity term in the quality–diversity optimization is weighted more heavily, encouraging `PDPS` to select more diverse candidates during pruning. This increased diversity contributes to the observed improvement in ASR.

F   Additional Details on Experimental Setup

Token-level Sampling   To induce diversity during token-level sampling in both IID and PDPS, we set the temperature τ and top-p hyperparameters to 1. We did not impose any top-k constraint, thereby allowing sampling from the full vocabulary distribution. Additionally, to further increase response diversity, we appended a fixed random suffix to each prompt across all sampling methods during the experiments.

Evaluation Model   To determine whether a prompt–response pair constitutes a jailbreak, we employed the `HarmBench_Mistral-7b-val-cls`[4] model. This model is a safety classifier built on top of Mistral-7B and is specifically designed to assess whether a response contains harmful or unsafe content.

Setup for Computing Diversities among Unsafe Responses   To compute the average cosine distances among unsafe responses (Section 6.3 and Appendix C), we used the `all-mpnet-base-v2`[5] sentence embedding

---

[4]https://huggingface.co/cais/HarmBench-Mistral-7b-val-cls
[5]https://huggingface.co/sentence-transformers/all-mpnet-base-v2

model, which is based on the MPNet architecture. Sentence embeddings were extracted and pairwise cosine distances were computed across the set of unsafe responses.

For BERTScore-based analysis, we define the BERTScore distance for each pair of the unsafe responses as $1 - $BERTScore. To compute pairwise BERTScores among unsafe responses, we used the last-layer hidden representations from the `microsoft/deberta-xlarge-mnli`[6] model as token embeddings. This model is based on the DeBERTa-xlarge architecture.
