HSHARE: FAST LLM DECODING BY HIERARCHICAL KEY-VALUE SHARING

Anonymous authors

Paper under double-blind review

ABSTRACT

The frequent retrieval of Key-Value (KV) cache data has emerged as a significant factor contributing to the inefficiency of the inference process in large language models. Previous research has demonstrated that a small subset of critical KV cache tokens largely influences attention outcomes, leading to methods that either employ fixed sparsity patterns or dynamically select critical tokens based on the query. While dynamic sparse patterns have proven to be more effective, they introduce significant computational overhead, as critical tokens must be reselected for each self-attention computation. In this paper, we reveal substantial similarities in KV cache token criticality across neighboring queries, layers, and heads. Motivated by this insight, we propose HShare, a hierarchical KV sharing framework. HShare facilitates the sharing of critical KV cache token indices across layers, heads, and queries, which significantly reduces the computational overhead associated with query-aware dynamic token sparsity. In addition, we introduce a greedy algorithm that dynamically determines the optimal layer-level and head-level sharing configuration for the decoding phase. We evaluate the effectiveness and efficiency of HShare across various tasks using three models: LLaMA2-7b, LLaMA3-70b, and Mistral-7b. Experimental results demonstrate that HShare maintains accuracy with an additional sharing ratio of 1/8, while delivering up to an $8.6 \times$ speedup in self-attention operations and a $2.7 \times$ improvement in end-to-end throughput. The source code will be made publicly available upon publication.

1 INTRODUCTION

032 The development of Large Language Models (LLMs), like the GPT and LLaMA series (OpenAI, 033 2024; Touvron et al., 2023), has marked a major breakthrough in artificial intelligence, dramatically 034 improving performance in natural language processing tasks such as translation (Zhu et al., 2023; Pal et al., 2024) and summarization (Zhang et al., 2023; Liu et al., 2023b). However, in long-context scenarios, such as multi-turn dialogues (Yi et al., 2024; Teng et al., 2024), document-based question 037 answering (Abdel-Nabi et al., 2023; Rasool et al., 2024), and code completion (Yang et al., 2023; 038 Eghbali & Pradel, 2024), LLMs face significant speed challenges with token-by-token decoding. A key factor contributing to this slowdown is the handling of the Key-Value (KV) memory cache since as the context length expands, the size of this KV cache grows correspondingly, resulting in longer 040 access times and increased memory overhead. 041

Existing works have introduced several approaches to address this issue. Since it has been demonstrated that a small portion of the tokens can dominate the accuracy of token generation, many works
choose to only load these critical tokens into the KV cache to reduce the inference latency while
maintaining accuracy. Among them, StreamingLLM (Xiao et al., 2023) treats the initial tokens (also
referred to *sink* tokens) and the recent tokens as critical tokens and performs sparsity in a fixed pattern.
H2O (Zhang et al., 2024b) introduces a greedy policy that dynamically retains a balance of recent
and heavy tokens. These two methods alleviate both storage and retrieval pressures through KV
cache eviction. However, they tend to lose a significant amount of historical information, leading to a
substantial decline in performance as their sparsity increases.

On the other hand, Quest (Tang et al., 2024) points out the criticality of tokens can change with
 different query tokens. To this end, Quest introduces a query-aware token sparsity algorithm, which
 uses the maximum and minimum values of each hidden dimension at page granularity to measure the
 query-aware criticality. Similarly, DoubleSparse (DS) (Yang et al., 2024) proposes to select critical

2 RELATED WORK				

- 105 2.1 LONG-CONTEXT MODEL 106
- Recently, significant efforts have been made to extend the context windows of LLM, both in academia (e.g., LongChat (Li et al., 2023), Yarn-LLaMA-2 (Peng et al., 2023)) and industry (e.g., GPT-4

108 Turbo, which supports up to 128K tokens (OpenAI, 2024)). These extended-context LLMs excel 109 in tasks such as multi-turn conversation comprehension and meeting summarization by providing 110 enhanced in-context learning and improved performance on complex reasoning tasks. However, this 111 advancement comes with notable trade-offs, including increased computational demands, higher 112 memory usage, and greater bandwidth requirements, leading to elevated costs and longer per-token latencies (Aminabadi et al., 2022; Pan et al., 2024; Chen et al., 2024b). For example, (Pan et al., 113 2024) utilizes host SSD memory to alleviate the long sequence KV cache memory requirements 114 at the expense of long latency whereas (Chen et al., 2024b) offloads the attention computation on 115 low-cost GPU devices to support economical long-sequence LLM inference. These solutions try to 116 tackle the Long-context model from the computing system level, however, it could be better solved 117 from the algorithm advancements such as LLM quantization (Liu et al., 2024) and sparsification 118 (Tang et al., 2024).

119 120 121

122

2.2 EFFICIENT INFERENCE OF LLMS

Several techniques, such as speculative decoding (Leviathan et al., 2023; Miao et al., 2024), parameter 123 sharing (Chen et al., 2024a), and quantization (Lin et al., 2024b;a), have been proposed to improve 124 inference efficiency. Here we focus on accelerating the attention mechanism, which poses significant 125 time costs due to its quadratic complexity with respect to sequence length, particularly in long-context 126 scenarios. Decoder-only transformers, trained with masked self-attention where each token depends 127 only on preceding tokens, enable the use of key-value activation caching (KV cache) to bypass 128 redundant computations (Pope et al., 2023). However, the KV cache can grow significantly in size. 129 For instance, during inference with the OPT-175B model (Zhang et al., 2022) using a batch size of 130 512, a prompt length of 512, and an output length of 32, the KV cache demands 1.2TB of memory 131 for storage and communication just to generate a single token (Liu et al., 2024), which poses a grand challenge for system memory and bandwidth. To tackle the challenge, one path is to reduce the KV 132 cache storage by quantization to 2-bit or even 1-bit. Existing works (Liu et al., 2024) report to achieve 133 2-bit quantization without accuracy loss and (Zhang et al., 2024a) quantizes the KV cache to 1-bit 134 with minor accuracy loss. Another orthogonal path is to focus only on the critical tokens in the KV 135 caches, also known as token sparsity, which we will review in Sec 2.3.

136 137

139

138 2.3 Sparse Attention

Early works such as sparse transformer (Child et al., 2019), reformer (Kitaev et al., 2020), and
longformer (Beltagy et al., 2020) made efforts to reduce attention complexity through training.
Recently, Jiang et al. (2023b) trained a language model to compress prompts into smaller sets of *gist*to reduce memory pressure during caching. However, such a compression strategy requires retraining
the large language model and also increases the overhead during inference.

On the other hand, many works (Ribar et al., 2023; Zhang et al., 2024b; Tang et al., 2024) propose 145 post-training sparse attention, primarily leveraging the observation of sparse attention scores, which 146 allows focusing on important tokens without compromising performance. StreamingLLM (Xiao 147 et al., 2023) identifies the initial and most recent tokens as critical, while Zhang et al. (2024b;a) 148 propose to adopt the accumulated attention score as the indicator to identify the critical tokens in 149 the KV cache. MInference (Jiang et al., 2024) introduces a dynamic sparse pattern identification 150 algorithm for prefilling acceleration. Additionally, Quest (Tang et al., 2024) uses min and max values 151 to assess the importance of each KV cache page, computing only the most relevant pages, while 152 DS (Yang et al., 2024) focuses on selecting critical KV tokens by utilizing only important channels. 153 However, these methods incur additional computational overhead for determining importance. In 154 contrast, our work aims to minimize the need for such additional computations by sharing critical KV 155 cache token indices across multiple levels.

156 157

3 PROBLEM FORMULATION

158 159

We begin by defining the decoding self-attention process with selected critical key-value cache tokens, which we refer to as token sparsity attention. In the decoding stage, let the query matrix be denoted as $Q \in \mathbb{R}^{1 \times d}$, the key matrix as $K \in \mathbb{R}^{n \times d}$ and the value matrix as $V \in \mathbb{R}^{n \times d}$, where *n* denotes the s

sequence length. Here $K_{i,*}$ represents the *i*-th row of key matrix, corresponding to the *i*-th token in the current sequence. With these notations, we define the token sparsity attention.

Definition 3.1 (Token sparse attention, informal). Token sparsity attention only calculates the attention weights between the query matrix and the selected critical key tokens. Let N_c represent the number of KV critical tokens to be selected, and suppose we have the indices:

$$CT = \{x_1, x_2, \dots, x_{N_c} \mid x_i \in [0, n] \text{ and } i = 1, 2, \dots, N_c\}$$
(1)

We then select the rows $\{K_{i,*} | i \in S\}$ corresponding to these indices from the key matrix to form a new key matrix $K_{CT} \in \mathbb{R}^{N_c \times d}$, also apply the same operation to the value matrix to form a new value matrix $V_{CT} \in \mathbb{R}^{N_c \times d}$. The token sparsity ratio is defined as $\frac{N_c}{n}$ and the token sparse attention is computed through the formula shown below:

$$y = \operatorname{softmax}\left(\frac{Q \cdot K_{CT}^{T}}{\sqrt{d_h}}\right) \cdot V_{CT}$$
(2)

177 Normally, each attention block independently evaluates and selects its critical KV cache tokens, 178 resulting in a corresponding set of indices, denoted as CT. We use the number of overlapping 179 elements between two different sets to evaluate the similarity between them. Then the similarity 180 between two critical KV cache token indices CT_A and CT_B can be formally written as:

$$im(CT_A, CT_B) = \frac{|CT_A \cap CT_B|}{max(|CT_A|, |CT_B|)},\tag{3}$$

here $|\cdot|$ represents the cardinality of a set and normally $|CT_A| = |CT_B| = N_c$. Next, we define Key-Value sharing.

Definition 3.2 (Key-Value sharing). Assuming that the critical KV cache token indices for attention block A are denoted as CT_A , if another attention block B directly reuses the indices from block A, represented as $CT_B \leftarrow CT_A$, we refer this to as key-value sharing between blocks B and A. In this case, CT_A is utilized by attention block B to construct K_{CT} and V_{CT} .

In this section, we first present the motivation of HShare, and then we introduce HShare in details.

4.1 MOTIVATION

Previous works have pointed out not all KV tokens hold equal significance, with a limited subset,
 known as critical tokens, contributing most to the attention output, and these critical tokens are found
 to be query-aware. In this paper, we further present three observations, with insights shown in Fig. 1.

200 Similar critical tokens between adjacent queries: From Fig. 1(a)-(d), we observe that within 201 individual attention heads, the distribution of critical KV cache tokens (those associated with larger 202 values in the attention matrix) gradually shifts with changes in the queries. However, the critical 203 tokens across adjacent queries remain largely consistent. This observation aligns with intuition, as 204 minor variations in query length do not significantly alter the overall sequence length, suggesting 205 that the attention distribution remains stable. The similarity between adjacent queries presents an 206 opportunity to reduce computational overhead by reusing the same critical KV cache tokens for every 207 k consecutive query.

208 Similar sparse-patterns across different heads and layers: The distribution of critical tokens 209 results in different sparse patterns for attention heads. However, as illustrated in Fig. 1(a)-(d), we 210 can also see that some sparse patterns are consistently observed across various attention heads. For 211 example, the sparse pattern of head 12 in layer 8 is very similar to that of head 22 in the same layer. 212 Additionally, head 9 and head 16 in layer 9 also share a similar sparse pattern, indicating that the 213 similarity between heads exists not only within the same layer but also across different layers. This uniformity suggests that a sparse pattern derived from one head can be effectively applied to others, 214 enabling a shared strategy for selecting critical KV cache tokens. This approach can further improve 215 the speed and efficiency of the attention mechanism.

Figure 1: (a)-(d): Illustrations of self-attention matrices from a specific head in a particular layer of the LLaMA2-7b-chat model, corresponding to similar self-attention patterns observed across different layers and heads. (e)-(h) Similarity matrices of critical token indices across different heads and layers during the prefill and decode stages. The element in the *i*-th row and *j*-th column represents the similarity (Eq. 3) between the *i*-th head (layer) and the *j*-th head (layer). The red stars represent the top-k largest values in the matrix.

Figure 2: Share the same critical token indices between layers and heads.

Figure 3: Share the same critical token indices between adjacent queries.

Consistency relationships between prefill and decoding phases: Fig. 1(e) and Fig. 1(f) present the head similarity matrices of layer 8 in terms of prefill stage and decoding stage, respectively. Fig. 1(g) and Fig. 1(h) present the layer similarity matrices of the whole network in terms of the prefill stage and decoding stage, respectively. We observe that the similarity matrix between prefill and decoding phases exhibits a remarkable consistency for both head-level and layer-level. This continuity underscores the potential that applying the hierarchical sharing strategy computed from the prefill phase to the decoding phase.

Motivated by the above observations, we propose HShare, a hierarchical sharing framework that shares the same critical KV cache tokens across queries, heads, and layers. HShare not only takes advantage of dynamic sparsity but also significantly reduces the computational overhead associated with critical tokens through an effective sharing mechanism.

4.2 HIERARCHICAL KEY-VALUE SHARING FRAMEWORK

Inspired by recent works (Zhang et al., 2024b; Xiao et al., 2023; Yang et al., 2024), in this paper, we select critical tokens from three perspectives: initial tokens (also referred to as sink tokens), the most recent window, and significant tokens in the middle. The dark blue positions in Fig.2 and Fig.3 represent the indices of these critical tokens. Given that the decoding stage is autoregressive, each

decoding step requires passing through all L layers of the attention blocks. In the case of multi-head attention and group query attention, each attention block involves multiple parallel attention head Hcomputations. Consequently, to generate n tokens, a total of $L \times H \times n$ attention computations are necessary, resulting in $L \times H \times n$ re-selections of critical tokens.

To reduce the overall time spent on evaluating and selecting critical tokens and further accelerate the decoding, we introduce a hierarchical key-value sharing framework. This framework is designed to facilitate key-value sharing from three perspectives: across layers, heads, and queries. Specifically, denote the attention computation of head h in layer l of the query q as $A_{l,h,q}$, then the key-value sharing between layers l_1 and l_2 can be expressed as: $CT_{A_{l_2,h,q}} \leftarrow CT_{A_{l_1,h,q}}$.

Similarly, the key-value sharing between heads h_1, h_2 and queries q_1, q_2 can be expressed as: $CT_{A_{l,h_1,q}} \leftarrow CT_{A_{l,h_2,q}}, \quad CT_{A_{l,h,q_1}} \leftarrow CT_{A_{l,h,q_2}}.$

It should be noted that since there is a temporal dependency between the attention computations of layers and queries, it is necessary to satisfy $l_1 < l_2$ and $q_1 < q_2$ here.

284 Similar to the token sparsity ratio, we define the sharing ratio as a value less than or equal to 1, where 285 a smaller value indicates a higher degree of sharing and greater computational savings. Let the total 286 number of layers and heads be denoted as n_l and n_h , respectively. Suppose k_l layers and k_h heads 287 share critical KV token indices with other layers or heads. The sharing ratios for layers and heads are then defined as $ratio_l = 1 - \frac{k_l}{n_l}$ and $ratio_h = 1 - \frac{k_h}{n_h}$, respectively. For query-level sharing, let the total number of decoding tokens (queries) be n_q , and suppose k_q queries bypass the selection 288 289 290 of critical token indices by sharing key-value indices with other queries. The query-level sharing ratio is defined as $ratio_q = 1 - \frac{k_q}{n_q}$. Since the sharing across layers, heads, and queries is mutually independent, the total sharing ratio is given by: 291 292 293

sharing ratio =
$$(1 - \frac{k_l}{n_l}) \times (1 - \frac{k_h}{n_h}) \times (1 - \frac{k_q}{n_q})$$
 (4)

4.3 Algorithm for Sharing configuration design

319	19: end for
320	20: Output: Sharing config C of layer(head).
321	

For layer-level and head-level sharing, as demonstrated in Sec. 4.1, the similarity of the critical KV cache token indices shows consistency across the different queries. Therefore, we can design a sharing configuration by calculating the similarity of the critical token indices between layers and heads after prefilling, and then apply this configuration to the entire decoding phase.

Here, we use the layer-level as an example for a detailed explanation. After each prefill step, we first obtain the critical KV cache token indices matrix list for all layers $L = M_1, M_2, \ldots, M_{n_l}$, where n_l represents the number of layers. Next, we compute the pairwise similarities between the critical KV cache token indices of all layers, producing a similarity matrix S_l . Based on the desired sharing ratio, we then perform key-value sharing between the most similar layers. Specifically, if the layer-level sharing ratio is β , meaning that $k_l = (1 - \beta) \times n_l$ layers should share critical KV token indices, we iteratively select the pair (i, j) with the highest similarity

Similarly, for all heads within each layer, we apply the same method to determine the sharing configuration. Note that each layer has its own head-level sharing configuration. Algo. 1 outlines the process of calculating the similarity matrix and designing the layer (or head) sharing configuration.
 Formally, the output sharing configuration *C* represents:

328 329 330

 $c_i = \begin{cases} j, & \text{if the } i\text{-th layer (or the } i\text{-th head) shares with the } j\text{-th layer (or the } j\text{-th head),} \\ i, & \text{if the } i\text{-th layer needs to compute critical tokens separately.} \end{cases}$

Since the sharing configuration can differ across samples, we compute it dynamically for each batchof samples.

(5)

Query-level. As discussed in Sec. 4.1, we observe that attention weights between adjacent query tokens tend to exhibit significantly higher similarity compared to those between distant query tokens. Specifically, for query i and query i + 1, the importance rankings of the tokens from token 0 to token i - 1 are largely similar. Based on this observation, we group every a adjacent query to share a single critical token set, resulting in a sharing ratio of $\frac{1}{a}$ between queries. Fig.3 illustrates the sharing mechanism between two adjacent queries.

339 340

341

5 EXPERIMENT

- 342 5.1 ACCURACY EVALUATION343
- 344 5.1.1 SETUP

345 We evaluate HShare on GSM8K (Cobbe et al., 2021), COQA (Reddy et al., 2019), and six datasets 346 in LongBench (Bai et al., 2023): LCC (Guo et al., 2023), RepoBench-P (Liu et al., 2023a), Trivi-347 aQA (Joshi et al., 2017), Qasper (Dasigi et al., 2021), 2WikiMultihopQA(2WikiMQA) (Ho et al., 348 2020) and **GovReport** (Huang et al., 2021). For our evaluation, we select three widely-used models: 349 LLaMA2-7b-chat (Touvron et al., 2023), LLaMA3-70b (Gliwa et al., 2019), and Mistral-7b (Jiang 350 et al., 2023a), representing a range of architectures from *multi-head attention* (MHA) to group 351 query attention (GQA), and from dense to mixture of experts (MoE). As baselines, we include four 352 state-of-the-art methods: two KV cache eviction algorithms StreamingLLM (Xiao et al., 2023), 353 H2O (Zhang et al., 2024b) and two query-aware token sparsity algorithms Quest (Tang et al., 2024), **DS** (Yang et al., 2024). It should be noted that some baselines skip sparsity in certain layers or during 354 the prefill stage. To ensure a fair comparison, we apply token-sparse attention to all layers across 355 both the decode and prefill stages. 356

357 358 5.1.2 Results on gsm8k, coqa

Datasets and Metrics. We use the LM-Eval framework to conduct zero-shot inference on two generation tasks: GSM8K and COQA. GSM8K consists of around 8,000 elementary school math problems and COQA is designed for evaluating dialogue-based question-answering systems. The average context length for these two datasets is approximately 500 and 2k respectively. Here we report the GSM8K with flexible exact-match accuracy and strict exact-match accuracy, while COQA with em score.

365 Inference Details. For a fair comparison, all methods select $N_c = 128$ critical KV cache tokens 366 and do token sparse attention, with a token sparsity ratio of approximately 1/4 and 1/16 for the 367 two datasets respectively (since GSM8K consists of math problems, we select a higher sparsity 368 level, whereas COQA involves story-based question-answering, so we choose a lower sparsity level.) For HShare, we select critical tokens from three aspects, with x = 8 sink tokens, y = 32 recent 369 tokens, and z = 88 critical tokens in the middle. Following the approach in Yang et al. (2024), we 370 load the heavy channel of the KV cache in 4-bit precision to compute the approximate attention 371 weights, then sort them to select the top-z tokens in the middle. We evaluate the effectiveness of our 372 proposed HShare using LLaMA2-7b-chat, LLaMA3-70b, and Mistral-7b, selecting two sharing ratios 373 3/4-3/4-1/2 and 1/2-1/2-1/2 of HShare for comparison against other methods. Here a-b-c means 374 HShare with layer-sharing ratio a, head-sharing ratio b, and query-sharing ratio c. 375

Results The results on GSM8K and COQA, shown in Tab. 2, indicate that HShare significantly out performs other KV cache eviction methods (StreamingLLM and H2O). In addition, when compared to dynamic critical token selection approaches (Quest and DS), HShare incurs only minimal accuracy

Table 2: Evaluation of different methods on GSM8K and COQA and the best result (exclude origin) in each column is highlighted in bold. Complexity* refers to the theoretical time complexity for each method to select critical KV cache tokens, where $\mathcal{O}(1)$ denotes constant time complexity, and T represents the theoretical computation time for a dense attention mechanism.

loss and even achieves higher accuracy on LLaMA3-70b. Overall, HShare provides the optimal balance between efficiency and accuracy.

5.1.3 RESULTS ON LONGBENCH

Datasets and Metrics. We use LongBench to evaluate the performance of the proposed HShare across multiple long context benchmarks, including code completion: LCC and RepoBench-P; few-shot learning: TriviaQA; single-document QA: Qasper; multi-document QA: 2WikiMQA; summarization: GovReport. Here we report LCC and RepoBench-P with similarity score, TriviaQA, Qasper and 2WikiMQA with F1 score, as well as GovReport with rouge score.

Inference Details. All methods select $N_c = 512$ critical KV cache tokens, with a token sparsity ratio of approximately 1/8. Similarly, we select critical tokens from three aspects: x = 16 sink tokens, y = 64 recent tokens, and z = 432 critical tokens in the middle. Using LLaMA2-7b-chat, we evaluate two sharing ratios of HShare: 3/4-3/4-1/2 and 1/2-1/2-1/2.

Results. The results on LongBench, presented in Tab. 3, demonstrate that our method maintains accuracy in long-context scenarios. Notably, with a sharing ratio of 3/4-3/4-1/2, HShare outperforms the existing state-of-the-art methods on average. The results across the 16 commonly used English datasets from Longbench can be found in Appendix A.1.

Figure 4: Latency(\downarrow) of different methods across various batch sizes and sequence lengths.

Figure 5: Throughput (\uparrow) of different methods across various batch sizes and sequence lengths.

5.2 EFFICIENCY EVALUATION

5.2.1 Setup

All experiments are conducted on a machine with Xeon(R) Platinum 8336C CPU, one A100 GPU, and 128G RAM.

Inference Details. Following Yang et al. (2024), we utilized PyTorch to approximate attention, selecting the top-z tokens from the middle and further incorporating x initial indices and y recent indices to form the complete set of critical token indices. The kernel for head-level sharing and the attention over critical KV tokens are designed using OpenAI Triton. Meanwhile, since HShare designs key value sharing between different layers and queries, we require an additional cache to store the critical token indices that need to be shared. Then for attention modules where the computation of critical token indices is bypassed due to sharing, we directly load the corresponding part from the cache. It is important to note that the additional storage required here is minimal, as we only need to store integers with a complexity of $\mathcal{O}(N_c)$. As for end-to-end testing, our implementation is based on GPT-fast (PyTorch, 2023), with the full attention module being replaced by our token sparsity self-attention module.

Baseline. To evaluate self-attention operator speedup, we use FlashAttention2 (Dao, 2023) as our baseline, which is an optimized attention mechanism designed to improve the speed and efficiency of attention computation and ranks among the fastest attention mechanisms. For the evaluation of end-to-end inference speedup, we take GPT-fast (PyTorch, 2023) as our baseline, which is acknowledged as the SOTA implementation for LLaMA models on the A100 GPU. Further comparison with other token sparsity algorithms can be referred in Appendix A.3

5.2.2 Self-Attention Operator Speedup

We conduct the self-attention latency evaluation on a single A100 GPU with batch sizes ranging from 4 to 16 and sequence lengths from 1k to 4k, with a token sparsity ratio of 1/8. We simulate the hierarchical sharing framework and average the latency over 1000 times self-attention computations. The results are shown in Fig. 4, which demonstrate that our method can significantly improve the average latency of self-attention compared with FlashAttention-2. Especially when the batch size is 16 and the sequence length is 2k, HShare can achieve up to an $8.6 \times$ reduction in self-attention latency. However, we observe that for the case when batch size is 4 and sequence length is 1k, our token-sparsity self-attention module performs slightly worse than the baseline. This may be

Figure 6: Results of HShare with different sharing ratios on eight datasets.

because, in smaller workloads, GPU underutilization prevents token sparsity from improving speed, and selecting critical token indices adds overhead instead.

506 5.2.3 END-TO-END INFERENCE SPEEDUP

Similarly, we conduct end-to-end inference evaluation with the same batch sizes and sequence lengths, and Fig. 5 reports the corresponding results. We find that HShare consistently outperforms GPT-fast and achieves up to 2.7× throughput acceleration, especially with larger batch sizes and longer sequence lengths.

512 5.3 ABLATION STUDY

514 **HShare with different sharing ratios.** We conduct ablation studies under different sharing ratios on 515 eight datasets and the results are shown in Fig. 6. Specifically, for layer-level and head-level sharing, 516 we selected sharing ratios of 3/4, 1/2, and 1/4. For query-level sharing, we group queries in sets of 2 and 4, corresponding to sharing ratios of 1/2 and 1/4, respectively. The results indicate that for all 517 three levels, a smaller sharing ratio tends to result in greater accuracy loss on average. However, on 518 certain datasets like TriviaQA and GSM8K, sharing a subset of heads leads to improved performance. 519 Additionally, compared to head-level sharing, we observe that layer-level and query-level sharing 520 have a greater negative impact on accuracy. Overall, the sharing ratios 3/4-3/4-1/2 and 1/2-1/2-1/2 521 emerge as more reasonable options. More ablation studies can be found in Appendix A.4. 522

6 CONCLUSION AND DISCUSSION

In this paper, we first systematically analyze and reveal the similarity of critical KV cache tokens across layers, heads, and query levels. Then we introduce HShare, a hierarchical framework for sharing critical KV cache token indices at all three levels to reduce the overhead associated with selecting critical KV tokens. Additionally, we propose a greedy selection algorithm for efficient sharing at the layer and head levels. Extensive evaluations show that HShare preserves model accuracy with an additional sharing ratio of 1/8, while achieving up to $8.6 \times$ speedup in self-attention operations and a $2.7 \times$ increase in end-to-end throughput.

MORE EXPERIMENTS А

A.1 MORE RESULTS ON LONGBENCH

The results across the 16 commonly used English datasets from Longbench are shown in Tab. 4. It can be seen that in the 7/16 dataset, HShare achieves the highest scores. On average, HShare outperforms StreamingLLM, H2O, and Quest. Although HShare performs slightly worse than DS, which is a negligible performance decline considering the speed advantage of HShare over DS.

Table 4: Evaluation of different methods on sixteen datasets in Longbench and the best result in each row (exclude original) is highlighted in bold.

Dataset	thod Original	StreamingLLM	H2O	Quest	DS	Ours (3/4-3/4-1/2)	Ours (1/2-1/2-1/2)

A.2 SYSTEM EFFICIENCY ANALYSIS

Table 5: Attention latency (ms \downarrow) of different methods across various batch sizes and sequence lengths.

BS	Seqlen	Flash	StreamingLLM	H2O	Quest	DS	Ours (3/4-3/4-1/2)	Ours (1/2-1/2-1/2)
8	1k	0.230	0.030	0.088	0.200	0.141	0.124	0.090
	2k	0.830	0.038	0.093	0.460	0.241	0.160	0.120
	4k	1.630	0.420	0.470	0.850	0.733	0.570	0.530
16	1k	0.440	0.030	0.089	0.280	0.133	0.120	0.093
	2k	1.630	0.073	0.110	0.770	0.422	0.230	0.190
	4k	3.230	0.800	0.850	2.21	1.350	1.041	0.990

Table 6: Throughput ([↑]) of different methods across various batch sizes and sequence lengths.

BS	Seqlen	Flash	StreamingLLM	H2O	Quest	DS	Ours (3/4-3/4-1/2)	Ours (1/2-1/2-1/2)
8	1k	228	264	240	228	228	231	235
	2k	188	252	234	206	213	222	226
	4k	118	243	228	152	201	214	217
16	1k	374	465	441	410	423	430	439
	2k	233	452	416	287	360	398	411
	4k	136	422	396	175	286	350	365

Here, we provide system efficiency comparisons as the same settings in Sec. 5.1.1 (including two KV cache eviction algorithms **StreamingLLM** and **H2O**, two query-aware token sparsity algorithms Quest and DS). The results are shown in Tab. 5 (attention latency) and Tab. 6 (end-to-end throughput).

From the results, it can be observed that KV cache eviction algorithms have a clear advantage in
system efficiency compared to query-aware token sparsity algorithms. Specifically, StreamingLLM
achieves the fastest speed as it applies a fixed sparsity pattern. However, both StreamingLLM and
H2O fall short in terms of accuracy. In contrast, HShare not only preserves accuracy but also achieves
significant speedup compared to other query-aware dynamic token sparsity methods. For example,
when batch size is 16 and sequence length is 2k, our algorithm achieves up to 2.21x and 1.14x
speedup over DS in terms of attention latency and end-to-end throughput, respectively.

A.3 TRADE-OFF ACCURACY AND EFFICIENCY ANALYSIS

Figure 7: The average score on Longbench and the end-to-end throughput (BS=16, Seqlen=4k) of different methods

Table 7: Attention latency (ms \downarrow) and GSM8K accuracy of HShare under different sharing ratios.

Sharing Ratio	Attention Latency(ms)	GSM8K(flexible/strict)
1/2	0.31	0.144/0.136
1/4	0.23	0.135/0.125
1/8	0.19	0.132/0.074
1/16	0.10	0.107/0.032

To illustrate the trade-off between accuracy and efficiency, we present the average score on Longbench and the end-to-end throughput (BS=16, Seqlen=4k) of different methods. The evaluation uses the LLaMA2-7b-chat model, with the results depicted in Fig. 7. Among the compared methods, the original model utilizing FlashAttention2 achieves the highest average Longbench score, albeit at the cost of the lowest throughput. On the other hand, StreamingLLM achieves the highest throughput, significantly outpacing other methods in processing efficiency but exhibits the lowest average score. Notably, our method performs a balance between these two aspects, showing negligible performance degradation while maintaining relatively high throughputs of 350 and 365. This demonstrates the effectiveness of our approach in achieving competitive accuracy while significantly enhancing processing efficiency relative to other methods.

In addition, we provide the attention latency and GSM8K accuracy of our proposed HShare under different sharing ratios in Tab. 7 to reveal the tradeoff between accuracy and efficiency within HShare.

A.4 MORE ABLATION STUDIES

HShare VS random share. We further conduct ablation studies to evaluate our layer(head) sharing
 scheme as shown in algorithm 1. We compare our greedy sharing scheme with random sharing
 scheme under the same sharing ratio and the corresponding results are shown in Fig. 8. The empirical
 results indicate that when critical token indices are shared by randomly selected layers and heads, the

Ours-1/4-1/4-1/4

Figure 8: Comparison between HShare and random sharing at the layer level and head level. We take HShare as the 100% baseline and normalize the results of others accordingly.

accuracy decreases significantly across all datasets, further validating the effectiveness of sharing critical tokens between similar layers and heads.

ble 8: Performance of HShare on MultiNews.									
Sharing Ratio	1 K	2k	3k	4k					
Ours-3/4-3/4-1/2	27.77	27.55	25.73	22.49					
Ours-1/2-1/2-1/2	26.58	25.93	24.65	19.99

Ablation study on different context lengths. To test our method in document summarization with varying context lengths, we conduct experiments on the *MultiNews* dataset, which belongs to the document summarization category. We evaluate the proposed HShare across different context lengths and sharing ratios. The results are presented in Tab. 8. It should be noted that regardless of the length of the text, we consistently selected 256 critical tokens. The results show that the score decreases as the context length increases, and similarly, higher degrees of sharing also lead to a decline in performance. This suggests that when dealing with long context lengths, a more moderate sharing strategy is needed to maintain accuracy, whereas, for shorter texts, a higher degree of sharing can be applied.

B DISCUSSION OF POTENTIAL ADAPTATIONS

We believe HShare can effectively support transformer variants. HShare aims to optimize long
 sequence attention operations by sharing critical key and value indices between layers, heads, and
 queries. As such, convolutional or graph neural networks with attention can also benefit from the
 proposed HShare. Below are two examples of potential applications:

- Convolutional neural network (CNN) with attention: (Son et al., 2024) proposes to adopt CNNs to extract image features and use spatial-temporal attention to identify crucial frames. To apply HShare in this network, we can predict the indices of critical features (similar to critical tokens), which can then be shared across heads and layers. The potential adaptation involves using only the critical features for attention computation. Since video input exhibits temporal redundancy across nearby frames, critical feature indices can also be shared across frames. HShare can further be applied to other CNN-related works, such as VQA (Anderson et al., 2018).
- Graph neural network (GNN) with attention: (Veličković et al., 2017) adopts multi-head attention to extract features from a set of input nodes. HShare can be seamlessly applied to identify critical nodes and share their indices across heads and layers (if multiple layers are used). Depending on the problem, if the graph nodes are close and similar, the key indices of these nodes can also be shared across nodes, similar to query sharing in HShare. Similar works (Thekumparampil et al., 2018; Wu et al., 2021) can also benefit from applying HShare to reduce computational load.
