Beyond the Gold Standard in Analytic Automated Essay Scoring

Gabrielle Gaudeau

ALTA Institute, Computer Laboratory, University of Cambridge

gjg34@cam.ac.uk

Abstract

Originally developed to reduce the manual burden of grading standardised language tests, Automated Essay Scoring (AES) research has long focused on holistic scoring methods which offer minimal formative feedback in the classroom. With the increasing demand for technological tools that support language acquisition, the field is turning to analytic AES (evaluating essays according to different linguistic traits). This approach holds promise for generating more detailed essay feedback, but relies on analytic scoring data that is both more cognitively demanding for humans to produce, and prone to bias. The dominant paradigm in AES is to aggregate disagreements between raters into a single gold-standard label, which fails to account for genuine examiner variability. In an attempt to make AES more representative and trustworthy, we propose to explore the sources of disagreements and lay out a novel AES system design that learns from individual raters instead of the gold standard labels.

1 Introduction

Writing practice is an essential part of learning a second language (Graham et al., 2012; Monk, 2016). Unfortunately, assessing writing is long and tedious, and educators frequently display inconsistencies due to fatigue and biases (Uto and Ueno, 2018) which compromise the quality of their marking (Hussein et al., 2019). By providing consistent, accessible, and cheaper written assessment, **Automated Essay Scoring** (AES) has the potential to address this issue (Magliano and Graesser, 2012).[1]

In the past, AES research primarily focused on holistic scoring, i.e., summarising the quality of essays with a single score (Phillips, 2007). However, this approach fails to provide any kind of formative feedback in the classroom (Carlile et al., 2018).

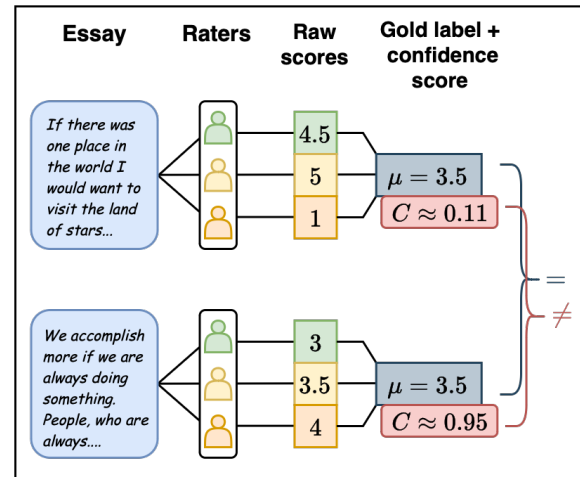

Figure 1: Two essays are multi-marked by three raters on a scale of 1–5. Their scores are then aggregated using an average, and we obtain the same mean μ. This is the gold label. We compute a confidence score C for each gold label using the variance of the raw scores (Section 4.2) and find that we can be much more confident in the second essay's gold label than the first's, despite their being treated the same when training AES systems.

More recently, the field is turning to **analytic scoring** which involves automatically assessing essays along different dimensions to help students identify which aspects of their writing need improvement (Ke and Ng, 2019). Traits like coherence (Higgins et al., 2004), relevance to prompt (Louis and Higgins, 2010), and persuasiveness (Carlile et al., 2018) have already been studied. By breaking down essay quality into different traits, analytic AES can help a learner identify their strengths and weaknesses (e.g., Burstein et al., 2004).

However, though analytic scoring offers a pedagogically useful alternative, its implementation in real-world classrooms is not without challenges. The variety of writing tasks and ambiguity of scoring rubrics make it difficult for AES systems to consistently produce reliable scores (Xiao et al., 2025). Further, concerns over the fairness, account-

---

[1] We limit the discussion to the assessment of written text (or "essays") produced by **English as a Foreign Language/English as a Second Language** (EFL/ESL) students.

ability, and transparency of these systems are yet to be properly addressed (Madnani et al., 2017). These issues underscore the need for AES systems that support teacher-AI collaboration (Deane, 2013; Wilson and Roscoe, 2020) by not only producing accurate scores but also providing educators with confidence estimates, and explanations.

To design transparent systems, we must first examine the data on which AES systems are typically trained: corpora of human-marked essays. Essay scoring is a difficult and subjective task, prone to rater disagreements (Brown, 2010). This is especially true for analytic scoring which is more cognitively demanding and time-consuming than holistic scoring (Hunter et al., 1996), and particularly vulnerable to rater effects (Myford and Wolfe, 2003). Despite these limitations, the dominant paradigm in Machine Learning (ML) and AES has always been to reconcile rater disagreements under one ground truth label referred to as the *gold standard* via different aggregation methods (Abercrombie et al., 2024). Not only does this neglect genuine examiner variation, but it also erases precious information about the essays (as illustrated in Figure 1) which we could use to inform better analytic AES.

With the long-term goal of improving AES systems for teacher-in-the-loop applications (Colonna, 2024), we propose to draw on **perspectivist** literature (Section 2.3) which "aims at leveraging data annotated by different individuals in order to model varied perspectives that influence their opinions and world view" (Frenda et al., 2024). In doing so, we hope to align AES systems with the diversity of rater judgements, enhancing the way in which output confidence is measured.

This PhD thesis proposal is structured as follows: Section 2 situates rater disagreements in written assessment, advocating for a perspectivist approach to data annotation in AES. Section 3 introduces relevant analytic AES datasets and techniques. Section 4 outlines our phased research plan which includes a study of disagreements in essay scoring data, the development of multi-annotator AES models, and their application to feedback generation. Section 5 summarises the proposal and its potential contributions, and includes some ideas for future research.

2 Background

We start by contextualising and introducing perspectivist literature as an alternative approach to using annotated data for model training, and make a case that AES, and particularly analytic AES research, can benefit from this paradigm shift.

2.1 Multi-marking

Modern NLP research is highly dependent on the existence of annotated corpora for the training and evaluation of models. Thanks in part to initiatives such as SemEval or Senseval (Sabou et al., 2014), and open-competitions such as those hosted by the Kaggle[2] platform, the number of publicly available datasets is growing. And with them, best practices on how to create annotations of consistently high quality have been developed. Over the years, the "science of annotation" (Hovy, 2010) has become the subject of many dedicated conferences and workshops such as HCOMP[3] or AnnoNLP (Paun and Hovy, 2019).

Amongst the many guidelines that have been set out, it is generally considered "axiomatic" that any annotation task should be performed by two or more raters acting independently. This allows us to compare their rating decisions and measure the extent to which they agree (or disagree) on the same instances of data (Hovy and Lavid, 2010). Traditional agreement measures includes Krippendorff's alpha (Krippendorff, 2004) or variations of Cohen's Kappa measure (Cohen, 1960). Reporting and acting on agreement measures generally improves the overall quality of the data being collected (Snow et al., 2008; Nowak and Rüger, 2010).

2.2 Disagreements

Full agreement is rarely possible, especially for complex or subjective tasks (Hovy and Lavid, 2010), such as essay scoring, where a single "right" answer may not exist (Alm, 2011). This is because having two distinct readers arrive at an identical judgement for the same piece of writing is not always possible (Huot, 1990a), and there is no objective way of validating either's rating (Sadler, 2009). In fact, there is no single written evaluation standard that can be said to embody *the* ideal written product of English (Kroll, 1990). In most cases, disagreements are initially treated as a consequence of low annotation quality, and addressed through various strategies to minimise noisy data, such as annotator training (Hovy et al., 2006; Carlson et al., 2003) or reconciliation (Hovy and Lavid, 2010). Any remaining disagreements are then reduced to a

---

single gold label by averaging (Sabou et al., 2014), majority vote (Leonardelli et al., 2021) or adjudication by an expert (Waseem and Hovy, 2016).

Unfortunately, these approaches reduce labels to the opinion of just one individual, precisely where annotation exposes complexity (Hovy and Lavid, 2010). For instance, Plank et al. (2014b) show that disagreements in part-of-speech (POS) annotation can be systematic across domains and languages, and due to "linguistically debatable" or hard cases rather than annotation errors (e.g., possessive pronouns may be classified as determiners or pronouns). In essay scoring, raters have to reconcile their impression of the text, its particular features, and the relevant scoring rubric. Given the boundless nature of language, the latter can never be exhaustive, and markers must cope with the underspecification of rating (Lumley, 2002). Further, raters may be influenced by their cultural, political, and socio-economic background (Guerra et al., 2011; Amorim et al., 2018). And if something as prescriptive and well-documented as POS-tagging leaves room for interpretation as illustrated in Plank et al. (2014a), then the high-level descriptors typically present in essay scoring rubrics will definitely introduce ambiguity, and with it, debatable cases.

2.3 Perspectivism

At a time when AI systems are increasingly scrutinised over bias and fairness concerns, it is not enough to assume a single "ground truth" as this can erase legitimate disagreements. Perspectivism challenges this assumption by pursuing approaches that understand and account for genuine human variability (Abercrombie et al., 2024).

A few studies have explored ways in which to use disagreements during model training. For instance, Prabhakaran et al. (2012) and Plank et al. (2014a) have tried to incorporate rater disagreements into the training loss functions: by penalising errors made on highly agreed data points more than those incurred from mislabelling complex instances (that is, with higher disagreement). Others have looked at actually modelling disagreement. Akhtar et al. (2021) divided annotators into two groups based on their polarisation (on a hate-speech classification task), and for each, compiled a different gold standard dataset to train individual classifiers. Combining these using an ensemble modelling approach outperformed previous state-of-the-art supervised classifiers for that task. More recently, Davani et al. (2022) compared three training strategies including ensembling, multi-label classification (Tsoumakas and Katakis, 2009) and multi-task learning (MTL; Caruana, 1993) on two tasks: hate-speech and emotion classification. Their results demonstrated that an MTL approach performs better than a baseline trained on aggregated gold standard labels. Additionally, these architectures provide a way to estimate uncertainty in predictions by preserving different annotators' perspectives until the prediction step. See Frenda et al. (2024) for a full survey of perspectivist approaches. We note that, to the best of our knowledge, perspectivism has not yet been investigated in the context of AES research.

In the next section, we show how (analytic) AES research exemplifies the challenges and opportunities of handling subjectivity in annotation.

2.4 Analytic Scoring

At first, AES research primarily focused on summarising the quality of essays with a single score (e.g., the Intelligent Essay Assessor™; Landauer et al., 2003) in response to the needs of large-scale standardised tests such as TOEFL, IELTS and GMAT (Chodorow and Burstein, 2004; Chen et al., 2016). But where holistic approaches fall short in terms of providing formative feedback to students in the classroom (Carlile et al., 2018), analytic scoring shows promise (Higgins et al., 2004; Louis and Higgins, 2010; Somasundaran et al., 2014; Persing and Ng, 2014; Kaneko et al., 2020).

Contrary to coarse holistic evaluations, analytic criteria consider a wide range of linguistic dimensions (or *traits*) involved in the composition of an essay (e.g., coherence, syntax, relevance to prompt, etc.) to better highlight the strengths and weaknesses of a student's writing (Carlile et al., 2018). Analytic scoring ensures that raters award appropriate scores while also revealing the grounds for their decisions to students by pointing out specific writing strengths and weaknesses (Reid, 1993, p.235). In doing so, they have the potential to reduce the apparent arbitrariness of grading (Lumley, 2002) and can easily be used as the basis for fine-grained feedback (Carlile et al., 2018; Bannò et al., 2024).

Unfortunately, due to the fuzzy nature of language (Douglas, 1997), analytic scales are more cognitively demanding to use (Cai, 2015). They also run the risk of being psychometrically redundant (Lee et al., 2010) due to rater effects (Engelhard, 1994). Moreover, the very idea that text features are independent constructs whose

sum is a valid representation of the overall quality of a text is subject of debate (Huot, 1990b).

Given the complex and subjective nature of analytic essay scoring data, greater even than that of holistic scoring, we should not be blindly training models on the gold standard, and posit that analytic AES could benefit from a perspectivist approach.

3 Related Work

In this section, we review prior work in AES, with a special focus on analytic AES, introducing the datasets and main techniques relevant to our study.

3.1 Datasets

As was noted by Ke and Ng (2019), progress in analytic AES is hindered in part by the lack of large annotated corpora needed for model training. To the best of our knowledge, only ICLE++ (Granger, 2003; Granger et al., 2009, 2020; Li and Ng, 2024), ASAP++ (Mathias and Bhattacharyya, 2018), IC-NALE GRA (Ishikawa, 2020, 2023), CELA (Xue et al., 2021), and ELLIPSE (Crossley et al., 2024) have been publicly released for the English language. Of those, all but CELA have released the original, raw multi-marks, alongside the aggregated gold standard scores. See Appendix A for more information about these datasets. Table 1 compares these datasets along various dimensions including, size and analytic traits assessed.

Put together, these datasets include scores for 34 distinct analytic trait names, ranging from low-level dimensions like "grammar" or "syntax", lexical dimensions like "word choice" or "vocabulary", to complex, discourse-level dimensions like "coherence" or "thesis clarity". Further, while some of these datasets share common trait names (e.g., "organisation"), it is important to keep in mind that each comes with very different scoring rubrics, and that the definitions of these dimensions might in fact be radically different. While this diversity can be seen as valuable, it is also an additional challenge for analytic AES research. Indeed, we cannot make any link between datasets before having properly studied how the essays were annotated. The same should be said for parallels made across studies which work with different sources of essay data.

Unfortunately, while there have been some efforts to rationalise this—notably, Li and Ng (2024, Table 2) offer a mapping between some of ICLE++'s traits and those of the ASAP++ dataset—we identify a clear gap in the field's general understanding of its analytic essay scoring datasets.

3.2 Machine Learning Approaches

Up until recently, the field of (analytic) AES mainly focused on developing effective hand-crafted feature-based models (Craighead et al., 2020). Common features included grammatical errors (Andersen et al., 2013), distinctive words or part-of-speech n-grams (Page and Paulus, 1968) and essay length (Lee et al., 2008).

With the recent surge of interest in neural networks, transformer-based systems have gained favour (Ke and Ng, 2019): see Zhang and Litman (2018); Ke et al. (2019); Mayfield and Black (2020); Xue et al. (2021); Shibata and Uto (2022); Ajit Tambe and Kulkarni (2022); Dadi and Sanampudi (2023); Doi et al. (2024); Cho et al. (2024); Ding et al. (2024). These models perform on par with feature-based systems, and eliminate the need for expensive feature engineering (Qiu et al., 2020). However, this gain comes at the cost of needing increasingly large quantities of annotated data for training (Zhang et al., 2021) which can be a problem for analytic AES which lacks large datasets (Section 3.1). Additionally, neural networks are very sensitive (Uto, 2021): the models can inherit biases present in data they are trained on which can result in systematic errors and a drop in performance (Amorim et al., 2018; Huang et al., 2019; Li et al., 2020). Finally, the inherent lack of interpretability of these "black box-like models" (Kumar and Boulanger, 2020) raises ethical concerns impacting safety (Danks and London, 2017), trust (Ribeiro et al., 2016), accountability (Kroll et al., 2016), and industrial liability (Kingston, 2018).

The most recent breakthrough, brought about by LLMs such as the GPT models (Brown et al., 2020; OpenAI, 2024). Thanks to their impressive performance and ease of use, these models are being applied to an ever-growing range of tasks, including analytic AES. So far Bannò et al. (2024), Naismith et al. (2023), Yamashita (2024) and Seßler et al. (2025) have obtained promising results with GPT-4 (OpenAI, 2024) for analytic AES. LLMs are now widely used as evaluators to approximate human judgements, which are otherwise very expensive to obtain (Gu et al., 2024). The "LLM-as-a-Judge" paradigm (Zheng et al., 2023) has enormous potential for AES where data is so scarce. For instance, Xiao et al. (2025) found that LLM-generated feedback and confidence scores could

be used to enhance the efficiency and robustness of grading. The capability of LLMs to generate natural language explanations opens up a lot of possibilities for the field of explainability (Zhao et al., 2024). At the same time, these capabilities raise new challenges, such as hallucinated explanations (incorrect or baseless), along with their inherent opaqueness (Singh et al., 2024), and output variability (Xia et al., 2024).

Finally, the multi-task learning (MTL) paradigm seems to be getting a lot of attention in AES. This approach "improves learning for one task by using the information contained in the training signals of other related tasks" (Caruana, 1997, Chapter 1). It first appears in the work of Ridley et al. (2021) whose Cross-prompt Trait Scorer (CTS) is frequently used as a baseline on the ASAP++ corpus which builds on top of the Prompt Agnostic Essay Scorer (PAES; Ridley et al., 2020). Since then, all sorts of MTL analytic AES systems have been developed. Xue et al. (2021) fine-tuned BERT on the multi-dimensional ASAP++ dataset using a shared BERT layer and trait-specific heads. Kumar et al. (2022) proposed a system whose primary task is holistic scoring, but leveraged information from analytic sub-scale scores to improve its overall performance using MTL. See also the works of Ramesh and Sanampudi (2022); Lee et al. (2023); Chen and Li (2023); Doi et al. (2024); Cho et al. (2024); Ding et al. (2024).

We note that MTL is also one of the architectures we plan to explore (Section 4.2), though to the best of our knowledge, it has never been applied to raw essay scores. In fact, not one of the studies mentioned above used raw analytic scores in lieu of the aggregated gold standard scores. This reflects a missed opportunity: treating rater disagreement as "noise" rather than signal fails to capture the full richness and variability of human judgement, which is precisely the kind of information that could enhance the transparency and reliability of AES systems in real-world settings. Thus, to the best of our knowledge, this area is yet unexplored.

4 Research Plan

We frame the following three research questions:

RQ0: Can we identify common patterns between essays that have high (or low) examiner disagreement, both within and across analytic traits?

RQ1: How can examiner disagreements in analytic essay scoring data be used to measure and enhance confidence and performance in AES systems?

RQ2: How can analytic AES serve as a foundation for more effective automated essay feedback systems?

Through these, we hope to explore how we can best harness rater disagreements in analytic essay scoring data to improve the performance and confidence in AES and feedback systems.

4.1 RQ0: Preliminary Work

As mentioned in Section 3.1, there is a lack of research into raw analytic essay scoring data. Yet most, if not all, current AES systems are trained on gold standard labels which are but a product of raw scores (Davani et al., 2022). We first seek to address this gap. Doing so will not only inform the research questions presented above, but also provide broader value to the field of AES by enhancing the interpretability of widely used datasets and enabling more meaningful comparisons across existing and future studies.

Dataset mapping. We have identified four analytic scoring datasets whose raw multi-marks have been made available to us: namely ICNALE GRA, ELLIPSE, ICLE++, and parts of the ASAP++ corpus. These differ in terms of the types of essays they contain (e.g., argumentative or creative), score ranges (e.g., 1–5 or 0–10), number of raters per essay (e.g., ranging from 2 to 80), prompts, and, of course, traits assessed (Appendix A). Our first step will be to map the traits of these different datasets together, where possible. For example, comparing how "organisation" is defined in the rubrics of ICLE++ and ASAP++, and how it differs from "cohesion" which is perhaps more broadly defined in ELLIPSE. Obviously, we will have to take into account the types of essays as well. So far, Li and Ng (2024, Table 2) have mapped some of ICLE++'s traits to those of the ASAP++ dataset, for argumentative essays only, which is a small subset of the ASAP++ dataset. It is not our aim to oversimplify the problem or forcibly merge these datasets, but rather to offer a clearer understanding of how the different rubrics and annotations align or diverge. By doing so, we hope to improve the reusability of these datasets, laying the groundwork for more consistent cross-dataset comparisons in the field.

Qualitative analysis. Having done so, we shall be better positioned to conduct a cross-dataset analysis of rater behaviour and scoring patterns, and will next seek to answer **RQ0** which we break down into two sub-questions:

P1: What are the common patterns between the essays that have high examiner disagreement, both within and across analytic traits?

P2: Conversely, for essays that have high agreement, what are the particular features that make an essay prototypically good or bad?

To answer these questions, we will perform an in-depth content analysis (Mayring, 2014) of the four previously mentioned datasets. The goal of this phase is to systematically code and categorise patterns of rater agreement and disagreement across traits. Coding will begin deductively using a set of pre-defined categories informed by the rubrics of the datasets themselves (e.g., organisation, grammar, relevance to prompt) and prior studies on rater effects (e.g., halo, severity/leniency; Myford and Wolfe, 2003). Inductive coding will follow, allowing new categories to emerge from the data where rating patterns deviate from rubric norms or where disagreements appear to cluster. These codes will be applied at both the trait level (e.g., is there consistent divergence in "cohesion" scores?) and the essay level (e.g., do specific essays elicit unusually wide score variance across traits?).

We will follow this with a thematic analysis (Braun and Clarke, 2021) on a carefully curated subset of essays selected based on results from the content analysis. Specifically, we will include:

- Essays exhibiting extreme marker disagreement (e.g., with scores ranging across the full scale);

- Essays that display high cross-trait disagreement (e.g., rated very highly in grammar but poorly in coherence by the same rater); and

- Essays that exemplify strong consensus, serving as contrast cases for identifying stereotypically *good* or *bad* writing.

Selection will aim for balance across datasets, genres, and prompts. These essays will be analysed in depth to explore possible linguistic, structural, or stylistic features that may account for disagreement or consensus. Themes may include ambiguity in

argument structure, unconventional grammar use, cultural variation in rhetorical style, or misalignment with rubric expectations.

Both content and thematic analyses will be completed on ATLAS.ti, a robust and well-established qualitative data analysis software package (Paulus, 2023), which will support efficient coding, memoing, and cross-case comparison.

Research questions **P1** and **P2** are conceptually linked: by examining essays that provoke high disagreement (**P1**), we gain insight into the limitations or ambiguities of existing rubrics and linguistic features that challenge human raters. Conversely, analysing essays with high agreement (**P2**) helps surface the features raters appear to consistently associate with poor- or good-quality writing.

4.2 Towards RQ1

Using the insights of the preliminary phase, we propose a new AES system that learns from individual raters instead of the gold standard labels.

Dataset. Despite our previous efforts to map the dataset traits together (**Dataset mapping**), we do not wish nor expect to use these datasets simultaneously. Doing so would require too many assumptions and restrict comparison with prior work. As we turn to training and evaluating a new analytic AES system, we must thus choose a dataset. Out of the four previously considered, ASAP++ is by far the largest with 12,980 essays, and has also been widely used in holistic AES research (Section A.2). Unfortunately, it is not well-suited to our purposes: not all essays have been multi-marked, and both the traits assessed and score ranges vary depending on the essay prompts. Instead, we will use the second-largest dataset, the ELLIPSE corpus, with 6,482 essays. All of its essays have been marked by two or three raters on a 1–5 scale using the same analytic rubric (Section A.4). Further, since this dataset was released as part of a Kaggle competition[4], the dataset comes with an established test–train split (3,911 essays in the training set and 2,571 essays in the test set). For lack of an existing set, we will use 10% of the training set for validation, aiming for balance across prompts, scores and demographics.

Baseline. As baseline, we propose to use the pre-trained DeBERTa model (He et al., 2021), a state-of-the-art neural language model, which has been

---

used in past AES research with success (for example: Hicke et al., 2023; Wang, 2024; Zhong, 2024, Huang et al., 2024). Appendix B presents how we selected this particular model. Specifically, we will fine-tune six individual DeBERTa models (one for each of the traits assessed in the ELLIPSE corpus) for regression on the gold standard labels only. Appendix C describes in detail the methodology we plan to use for these experiments.[5]

Modelling. Drawing from the work by Davani et al. (2022), and for each of the six analytic traits in ELLIPSE, we will consider three different multi-annotator AES architectures which can mimic the multi-marking setting, namely ensemble, multi-label, and multi-task. We point out that some of these architectures have already been used in analytic AES in the past with success (Section 3). However, unlike prior work and our baseline, we will be training them on the raw, multi-marked essay scoring data as opposed to the gold standard labels. See Figure 2 for a schematic overview of this experimental design. Note that all variations will be built on top of the pre-trained language model DeBERTa.

Performance. We will then compare, for each trait, the three architectures to the baseline using the evaluation metrics defined in Appendix C.3. Specifically, model performance will be measured using the RMSE metric (Tyagi et al., 2022). Not only is it a well understood and widely used metric in ML (Karunasingha, 2022), Yannakoudakis and Cummins (2015) argues that measures of agreement (such as RMSE) are more appropriate than correlation metrics for measuring the effectiveness of AES systems. Beyond our baseline, we will also compare the performance of our systems against the leader-board of the dataset's Kaggle competition[4], and the few studies that have used ELLIPSE (e.g., Sun and Wang, 2024).

Confidence. The main novelty these models bring to AES is that we will be able to use their raw outputs to estimate how confident we should be in using an aggregate of the outputs together. Indeed, suppose we approximate each model head, or individual raw output as being a single rater's judgement. If all the outputs of our model agree, then much like when human raters agree, we should

be highly confident that aggregating the raw scores together accurately conveys the quality of the essay for the considered analytic trait. If, however, the model outputs disagree, then perhaps aggregating the scores is not the best course of action.

Davani et al. (2022) propose to use the variance between the different raw model outputs as a measure of uncertainty. We describe below how to convert that into a confidence score C, with a value between 0 and 1 (as was used in Figure 1). Given that the maximal variance between three values in the 1–5 score range of ELLIPSE is $\sigma^2_{\max} \approx 3.6$ (rounded to 1 decimal place), achieved for outputs $(1, 5, 5)$ or $(1, 1, 5)$, in no particular order. Then, given any set of three raw model outputs represented as a three-dimensional vector $\mathbf{x} \in [1, 5]^3$, the confidence score associated to that prediction is given by:

$$C(\mathbf{x}) = \frac{\sigma^2_{\max} - \sigma^2(\mathbf{x})}{\sigma^2_{\max}}.$$

To validate this metric, we will measure the extent to which it correlates with the true rater disagreement, using the original raw rater scores, on the test set. We can further assess the reliability of the metric by segmenting the test samples based on the predicted confidence scores and measure the correlation between these scores and model performance as was done by Xiao et al. (2025). We will also explore other confidence/uncertainty metrics such as using the prediction probability from a softmax distribution of the final output (Hendrycks and Gimpel, 2018) or Monte Carlo dropouts (Gal and Ghahramani, 2016).

4.3 Towards RQ2

Having built a series of multi-annotator AES systems for a range of essay traits, we turn our attention to the area of essay feedback: How can analytic AES serve as a foundation for more effective automated essay feedback systems?

We envision that the raw model outputs across multiple traits can form a kind of feedback *profile* for each essay, which may be mapped to specific linguistic features. Insights from our preliminary analysis (**RQ0**) may help identify textual characteristics that consistently trigger high or low rater disagreement. Simply highlighting these features to learners may already provide useful formative feedback, but they could also augment existing feedback systems by offering more nuanced, trait-specific insights. Specifically, we can explore how

---

[5] All experiments presented in this proposal have been and will be conducted using shared high-performance computing resources which include three NVIDIA A100 GPUs.
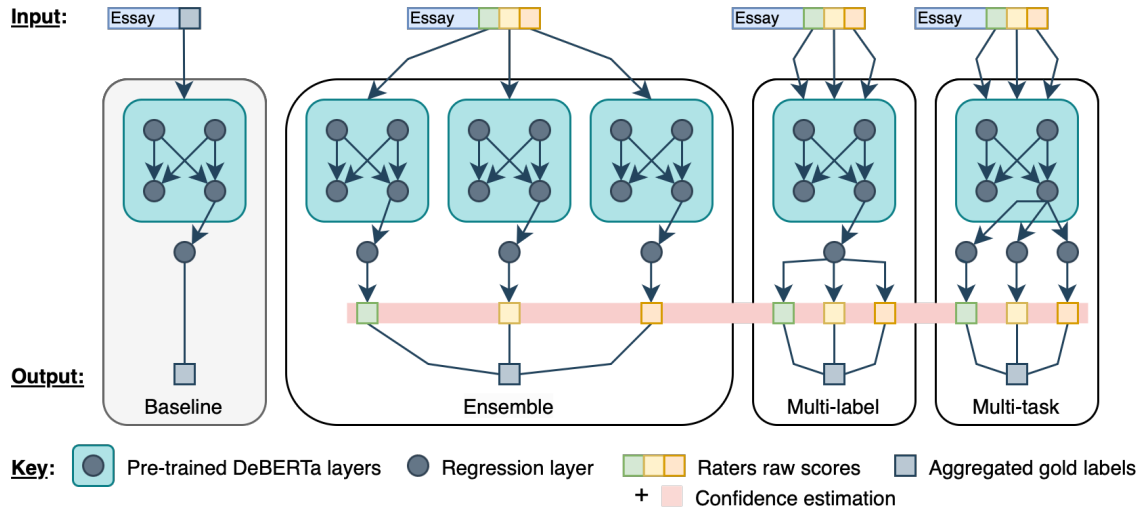

Figure 2: Schematic overview of the multi-annotator AES models (ensemble, multi-label, and MTL) and baseline we plan to build for each analytic trait in ELLIPSE. Adapted from Davani et al. (2022, Figure 1).

LLMs can be used to translate raw trait scores and disagreement-informed insights into natural language explanations. These explanations could help bridge the gap between system output and learner interpretation, supporting feedback that is not only data-driven but also accessible and pedagogically meaningful. However, careful prompting and validation would be needed to ensure reliability and mitigate risks such as hallucinated feedback or overgeneralisation (Singh et al., 2024; Zhao et al., 2024).

Evaluating the effectiveness of this kind of approach to feedback will ideally require engagement with actual users: teachers and students. To that end, we will design a small-scale, controlled user study, time and resources permitting. In particular, we may draw from Wilson and Roscoe (2020) who measured the effectiveness of their approach through a series of metrics: writing self-efficacy, holistic writing quality, performance on a state English language arts test, and teachers' perceptions of the AES system's social validity. Particular attention would be given to how disagreement-informed feedback compares with more conventional, rule-based or gold-standard approaches.

We consider this a longer-term, exploratory extension of our project, recognising that user-facing feedback is a complex and iterative design challenge. If direct user testing is not feasible within the current project scope, we will instead rely on proxy evaluations—such as alignment with rubric criteria, interpretability assessments, or expert annotation

studies—to ensure pedagogical relevance and practical utility. Ultimately, our goal is to contribute to a learner-centred vision of AES that supports teaching and learning in meaningful ways.

5 Summary

In this PhD proposal, we explored the idea that we can advance analytic AES research by harnessing examiner disagreements, rather than viewing them as "noise" that should be quietened. We propose to build a series of multi-annotator models to mimic a multi-marker setting and output automated raw scores. By placing the original raters of the training data at the centre of our design, our solution will not only help measure how confident we can be in the model's aggregated output, but also prove more transparent than traditional approaches. And by focusing on analytic scoring, we will be able to use our suite of models to generate fine-grained feedback, offering more tailored and effective guidance to learners. A key part of this work will require conducting a systematic qualitative analysis of rater disagreement in analytic essay scoring data. By improving interpretability, surfacing uncertainty, and enabling richer feedback, we hope to contribute to the development of AES systems that are designed for real-world classroom use.

We list below the expected outcomes of the proposed thesis:

1. A set of guidelines and suggestions for researchers working with the four multi-marked

analytic AES datasets explored during the preliminary phase (Section 4.1).

2. A suite of multi-annotator models fine-tuned on each trait of the ELLIPSE corpus, and a set of baselines (**Modelling** in Section 4.2).

3. A novel approach to measuring model confidence (**Confidence** in Section 4.2).

4. A system which can, given an essay, its analytic scores and confidence score, generate fine-grained natural language feedback (Section 4.3).

Overall, we believe the project is feasible within the timeframe of a PhD. The phased research plan outlines the work will look to complete over the next 18 months. Additionally, the recent release of public multi-marked analytic AES datasets makes this work both timely and well-grounded.

Limitations

The primary limitation of this study is the lack of large, publicly-available multi-marked analytic AES datasets. While our approach seeks to better model rater variability and improve representation in AES systems, most of the datasets we draw from have been annotated by no more than two or three raters per essay (see Appendix A). This relatively shallow annotation may limit the extent to which we can robustly capture and model inter-rater variation, particularly for traits that are inherently more subjective or rubric-dependent. Importantly, we note that this is not a limitation unique to this study, but a broader challenge across AES.

A related constraint concerns language coverage. All of the datasets used in this study are in English, which was also our particular focus.[1] However, this limits the immediate applicability of our findings to English-language educational contexts. Future work could extend this approach to other languages as suitable multi-marked datasets become available. Such extensions would be essential for ensuring that AES advancements benefit a more diverse set of learners and writing contexts.

Finally, although our use of qualitative methods (content and thematic analysis) enriches the interpretability of findings, these approaches carry inherent subjectivity. Researcher bias in coding and theme development is a known limitation of qualitative work. To mitigate this, we will use a transparent and iterative coding process, triangulate findings where possible, and document decisions clearly through ATLAS.ti.

Ethical Considerations

Fairness is a core ethical concern in educational assessment, particularly when deploying automated systems that may influence learner outcomes. AES models risk amplifying existing biases in training data, especially if rater disagreement, sociocultural variation, or language proficiency differences are not adequately accounted for. Our work aims to address this by modelling rater disagreement directly, promoting transparency and interpretability, and supporting more equitable scoring practices in diverse educational contexts.

A Analytic AES Datasets

Table 1 records the main public datasets of analytically scored essays. We compare them along seven dimensions:

1. **Essay Types**: the types of essays present in the corpus—argumentative (A), response to reading (R), narrative or creative (N), comment (C), suggestion (S) and letter (L);

2. **Writers' Information**: the language and academic levels of the essay writers;

3. **No. of Essays**: the total number of essays present in the corpus;

4. **Analytic Traits**: the linguistic dimensions (different from holistic) on which the essays have been graded;

5. **No. of Raters**: the number of individual raters (i.e., awarded marks) per essay;

6. **Multi-marks Available?**: whether those raw marks have been made publicly available (Yes), as opposed to only the aggregate scores (No); and

7. **Score Ranges**: the score range of the essays for a given dimension.

A.1 ICLE++

The International Corpus of Learner English (ICLE) is a corpus of essays written by upper-intermediate and advanced non-native English learners. The first version of the corpus, released in 2002, contained 2.5 million words produced by learners from 11 L1s (Granger, 2003). The corpus has since grown to 5.7 million words from 25 L1s (Granger et al., 2020). Concurrently, the Human Language Technology Research Institute in the University of Texas at Dallas, USA, contributed to the corpus by annotating subsets of it along several traits (Persing et al., 2010; Persing and Ng, 2013, 2014, 2015; Ke and Ng, 2019).

This effort culminated in the release of the ICLE++ dataset[6], which includes the annotation of 1,006 ICLE essays with both holistic scores and ten analytic scores (see Table 1). For the precise definitions of these traits, refer to Li and Ng (2024). This particular sample of essays was chosen in

response to 10 specific prompts, chosen to be well-represented in multiple languages, to support as much L1 diversity as possible. In this annotation, each essay was graded by two different annotators, and disagreements were resolved through open discussion. The raw multi-mark scores have recently been released.

A.2 ASAP++

The Automated Student Assessment Prize (ASAP) dataset was introduced as part of the "The Hewlett Foundation: Automated Essay Scoring" Kaggle competition in 2012[7] and has since been widely used in AES research, both for prompt-specific (Alikaniotis et al., 2016; Taghipour and Ng, 2016; Dong and Zhang, 2016; Dong et al., 2017; Tay et al., 2017) and cross-prompt (Phandi et al., 2015; Cummins et al., 2016; Jin et al., 2018; Ridley et al., 2020) tasks. The original dataset contains eight different essay sets, one for each of the eight prompts considered, for a total of 12,980 essays written by native English speaking children between grades 7 and 10.[8] Marking guidelines and rubrics specific to each prompt were provided, and all essays were holistically marked by two (or three) independent human raters. Additionally, the essays for Prompts 7 and 8 were analytically scored by two markers: the multi-marks can be found in the original dataset. Subsequently, Mathias and Bhattacharyya (2018) provided single-marked analytic scores for the remaining six prompts to form the ASAP++ dataset.[9]

A.3 CELA

The Chinese EFL Learners' Argumentation (CELA) dataset[10] is a collection of 144 argumentative essays written by undergraduate students in non-English majors in China first introduced by Xue et al. (2021). Participants were asked to write a 300-word essay in response one single prompt. Subsequently, two expert raters independently scored the essays both holistically and along five analytic sub-scales (Grammar, Lexicon, Global and Local Organisation, and Supporting Ideas). The final dataset only records the average score of the two rater scores for each essay trait,

[10] The dataset is available at https://github.com/gzutxy/CELA.

Table 1: Comparison of known analytic AES corpora.

Corpora	Essay Types	Writers' Information	No. of Essays	Analytic Traits ($\neq$ Holistic)	No. of Raters	Multi-marks Available?	Score Ranges
ICLE++	A	Non-native; undergraduate students	1,006	Prompt Adherence Thesis Clarity Argument Strength Development Organisation Coherence Cohesion Sentence Structure Vocabulary Technical Quality	2	Yes	1–4 (half-point increments)
ASAP++	A, R, N	US students; Grades 7-10	12,980	Content/Ideas Conventions Organisation Prompt Adherence Language Sentence Fluency Word Choice Voice Style	1-3	Partly	0–3, 0–4, and 1–6 (prompt-dependent; integer scales)
CELA	A	Non-native; undergraduate students in China	144	Grammar Lexicon Global Organisation Local Organisation Supporting Ideas	2	No	1–8 (integer scales)
ELLIPSE	A, N, C, S, L	Non-native; Grades 8-12	6,482	Cohesion Syntax Vocabulary Phraseology Grammar Conventions	2-3	Yes	1–5 (half-point increments)
ICNALE GRA	A	Asian English language learners	136	Intelligibility Complexity Accuracy Fluency Comprehensibility Logicality	80	Yes	0–10 (half-point increments)
		Native English	4	Sophistication Purposefulness Willingness Involvement			

not the raw multi-marks.

A.4 ELLIPSE Corpus

The English Language Learner Insight, Proficiency and Skills Evaluation (ELLIPSE) Corpus was released by the Vanderbilt University and the Learning Agency Lab[11] in 2022 for the "Feedback Prize – English Language Learning" Kaggle competition[4] (Crossley et al., 2024). The full dataset contains 6,482 essays written by English language learners between the 8th and 12th grade on 29 different prompts as part of state-wide standardised writing assessments in the 2018/19 and 2019/20 school years in the US.[12]

All essays were independently marked by a minimum of two raters along six analytic dimen-sions, Cohesion, Syntax, Vocabulary, Phraseology, Grammar, and Conventions which are defined in Crossley et al. (2024, Table 1).[13], as well as a holistic score. All scores follow a 9-point Likert scale and range from 1.0 to 5.0 with increments of 0.5, where a maximal score in one of these dimensions signifies a native-like proficiency. Any disagreement between raters was adjudicated in a discussion between the two parties and both mean and raw scores have been published. Finally, the authors of the dataset conducted an MFRM analysis for the raters and essays and found the scores to be reliable (Crossley et al., 2024).

Table 2: Best hyper-parameter settings for each of the different pre-trained models when fine-tuned on the CLC FCE corpus.

Model	No. of Parameters	No. of Epochs	Batch Size	Learning Rate	Weight Decay
microsoft/deberta-v3-base	184M	7	8	4.02e-5	8.98e-2
roberta-base	125M	6	8	2.02e-5	6.20e-2
bert-base-cased	109M	7	16	4.16e-5	2.87e-2
bert-base-uncased	109M	7	8	4.47e-5	4.28e-2
distilbert-base-cased	65.8M	4	8	6.87e-5	6.26e-2
distilbert-base-uncased	65.8M	6	16	3.32e-5	3.96e-2

A.5 ICNALE GRA

The Global Rating Archive (GRA) was developed as part of the International Corpus Network of Asian Learners of English (ICNALE) corpus (Ishikawa, 2020, 2023), a corpus of more than 15,000 essays written by Asian English language learners (ELLs), monologues, and speeches. In particular, GRA includes 140 essays written to one single prompt on the topic of part-time jobs for college students. Of those essays, 136 were written by Asian ELLs representing ten different regions, and the remaining four were written by native English speakers. Most uniquely, the essays were independently marked by 80 human raters both holistically, and analytically for 10 different essay traits. See Ishikawa (2020, 2023) for a detailed description of the corpus.

B Choosing DeBERTa

To motivate our choice of underlying baseline model (Section 4.2), we considered six variants of the pre-trained BERT model (Devlin et al., 2019), which have been successfully applied to AES in the past (Mayfield and Black, 2020; H. Beseiso, 2021; Schmalz and Brutti, 2022). Each was then fine-tuned on the seminal holistic AES dataset (Ke and Ng, 2019): the CLC FCE corpus (Yannakoudakis et al., 2011).[14] This dataset is a collection of 2,469 short essays written by ELLs from around the world who sat the Cambridge English for Speakers of Other Languages (ESOL) First Certificate in English examinations between 2000 and 2001. Essays were marked by an examiner with a 0–5 band score using the rubric from the University of Cambridge Local Examinations Syndicate (2001, p.19). Following Yannakoudakis et al. (2011), we mapped these scores to a 0–20 linear scale, ideal for a regression task. Table 2 shows a summary of the models we considered, their size (in number of

parameters), and the best hyper-parameter values we obtained for each in the step-by-step method in Appendix C.4.

Table 3 shows the average performance of the different models for the best hyper-parameter setting in Table 2 across the five random seeds. DeBERTa (He et al., 2021) outperforms all of the other models across all five of our evaluation metrics (Appendix C.3), obtaining a record low RMSE score of 2.308 for the random seed 1002. However, it is also the model that has the largest variance across different random seeds for RMSE, accuracy, precision and recall, which suggest that the model is not the most robust to random-seed instability (Madhyastha and Jain, 2019). Further, DeBERTa is more heavy-weight than the other models (i.e., it is larger in terms of number of parameters; Table 2), and thus, takes more time to train. But despite these limitations, we chose to use DeBERTa for the next part of the experiments because it unambiguously surpassed all the other candidates.

C Methodology

In this section, we describe the research methodology we plan to use for running our ML experiments. Note that this may be improved in the future. This same methodology was used in the experiment described in Appendix B.

C.1 Reproducibility

Ensuring the computational reproducibility of a project is very important both to allow others to build on the research and for its credibility: anyone should be able to obtain the same results if they use the exact data, models and code provided by the authors (Donoho et al., 2009). When it comes to ML, many model architectures and algorithms are by nature non-deterministic (Reimers and Gurevych, 2017). To overcome this, it is standard practice to set a random seed, making any subsequent "random" number deterministic.

---

[14] Note that at the time of running these experiments, the new corrected version of this dataset had not been published.

Table 3: Average performance of the different models on the CLC FCE test set using 0–20 scores as in Yannakoudakis et al. (2011) across the five random seeds (rounded to 3 decimal places) for the best hyper-parameter setting in Table 2 (Avg.). The (+) rows show the difference between the average and the maximal value achieved for each metric for a particular seed. The (−) rows include the difference between the average and the minimal values. Together they show the variation of performance across the five seeds for a metric: the largest ranges are underlined for each metric.

Model		RMSE	Pearson	Spearman	Acc.	Prec.	Rec.	F1

```python
random.seed(SEED)
set_seed(SEED)
torch.manual_seed(SEED)
torch.cuda.manual_seed_all(SEED)
np.random.seed(SEED)
os.environ['PYTHONHASHSEED']=str(SEED)
```

```python
torch.backends.cudnn.deterministic = True
torch.backends.cudnn.benchmark = False
torch.use_deterministic_algorithms(True)
```

Figure 3: The code we use to set the random seed to the different Python packages needed in the experiments (top), and some additional lines needed to achieve consistent results with the microsoft/deberta-v3-base model in Appendix B.

We run the experiments with five different randomly chosen seeds[15] for better comparability and to ensure that the results we are seeing are not sub-optimal. See Figure 3 for the code we use to ensure the reproducibility of the results.

C.2 Hyper-parameter Optimisation

The process of hyper-parameter optimisation consists of finding the set of optimal hyper-parameters (parameters whose values control the learning process of an ML model; Goodfellow et al., 2016,

Chapter 8). We use the Bayesian hyper-parameter optimisation algorithm (Snoek et al., 2012) as implemented by Comet ML[16], a search algorithm that is based on distributions and balances exploitation/exploration to make decisions about which hyper-parameter values to try next. This approach achieves optimal results with considerably fewer trials. Figure 4 shows the configuration details that we use (i.e., objective function, hyper-parameters considered and value ranges).

---

[15] Specifically, the random seeds 1601, 2911, 1044, 1002, and 2510 were used in the experiments of Appendix B.

[16] See https://www.comet.com/docs/v2/guides/ optimizer/configure-optimizer/ for more details.

C.3 Evaluation and Reporting

Within the field of AES, the evaluation of scoring systems is traditionally carried out by comparing a system's predicted scores to the gold standard labels for a held-out validation set of essays using a series of metrics (Williamson et al., 2012; Yannakoudakis and Cummins, 2015). Specifically, we report:

1. the Root Mean Square Error (RMSE) (Willmott and Matsuura, 2005);

2. the correlation between the predicted and gold standard scores with both the Pearson (Pearson, 1896) and Spearman Rank correlation coefficients (Spearman, 1987);

3. as well as the main classification metrics (precision, recall, accuracy and F1-score; Hossin and M.N, 2015) by rounding model predictions to the closest grade class (e.g., ELLIPSE uses a 1.0 to 5.0 scale with increments of 0.5; Section A.4).

C.4 Step-by-step Method

Having introduced the individual components of the experimental methodology, we now give below the step-by-step process we use to train, evaluate and test our models:

1. Start by running the Bayesian Hyperparameter Optimisation algorithm for each of the five random seeds. Given a random seed:

   (a) we use stratified data sampling to randomly split the dataset of essays into three parts using the `train_test_split()` function of the `scikit-learn`[17] Python library using a ratio of 70/15/15% for the training, validation and test sets respectively to limit sampling error;

   (b) then at each step of the algorithm (the total number of steps is given by the `maxCombo` field in Figure 4 which we set to 40), a different set of hyper-parameters (Section C.2) is considered. With each, a model is trained from scratch on the training set, and then evaluated using the RMSE on the validation set to inform the next set of hyper-parameters the optimiser will try.

2. From step 1, retain the set of hyper-parameter settings that achieved the best results on the validation set in terms of the RMSE metric across the five random seeds, and round the learning rate and weight decay values to 3

---

[17] For the documentation, see https://pypi.org/project/scikit-learn/.

significant figures.

3. Finally, re-run the experiments for all five seeds with the setting obtained in step 2 and report the maximum, minimum and average of every evaluation metric mentioned in Section C.3 across the five seeds on the test set.

Note that for the training and testing of models, we use the Trainer[18] interface. By default, Trainer implements the AdamW stochastic gradient descent optimisation method, an Adam algorithm (Kingma and Ba, 2017) with weight decay fix, as introduced by Loshchilov and Hutter (2019). Using AdamW optimisation has become the standard, and models trained with it generally yield better results than those trained without (Loshchilov and Hutter, 2019). Further, we use each model's default regression training loss, which is typically the Mean Squared Error (MSE), implemented with the MSELoss() function from the PyTorch library[19] (Paszke et al., 2019). Finally, Trainer is set up such that model weights are saved after each training epoch and only the best model is loaded at the end of training with regards to the RMSE metric.
