

Dynamic Pricing in the Linear Valuation Model using Shape Constraints

Anonymous authors

Paper under double-blind review

Abstract

We propose a shape-constrained approach to dynamic pricing for censored data in the linear valuation model that eliminates the need for tuning parameters commonly required in existing methods. Previous works have addressed the challenge of unknown market noise distribution F using strategies ranging from kernel methods to reinforcement learning algorithms, such as bandit techniques and upper confidence bounds (UCB), under the Lipschitz (and stronger) assumption(s) on F_0 . In contrast, our method relies on isotonic regression under the weaker assumption that F_0 is α -Hölder continuous for some $\alpha \in (0, 1]$. We obtain an upper bound on the asymptotic expected regret that matches existing bounds in the literature for $\alpha = 1$ (the Lipschitz case). Simulations and experiments with real-world data obtained by Welltower Inc (a major healthcare Real Estate Investment Trust) consistently demonstrate that our method attains better empirical regret in comparison to several existing methods in the literature while offering the advantage of being completely tuning-parameter free.

1 Introduction

Dynamic pricing is the process of continuously adjusting product prices in response to customer feedback based on statistical learning and policy optimization. As a fundamental aspect of revenue management, dynamic pricing has been widely applied across various industries. A key challenge in this area is balancing the need to explore customer demand with exploiting current knowledge to set optimal prices that maximize revenue. This tradeoff between exploration and exploitation has been extensively studied in fields such as statistics, machine learning, economics, and operations research [Besbes & Zeevi \(2009\)](#); [Keskin & Zeevi \(2014\)](#); [Cheung et al. \(2017\)](#); [Cesa-Bianchi et al. \(2019\)](#); [den Boer & Keskin \(2020\)](#). A large literature focuses on an important dynamic pricing problem where contextual information, such as product features and market conditions, is available at each time step. By leveraging this contextual data, we aim to refine pricing strategies and improve revenue outcomes. This approach, known as feature-based or contextual pricing, allows for more customized pricing decisions that better reflect product heterogeneity, leading to more effective revenue management in today’s data-rich environment.

This paper focuses on the problem of pricing a single product over a finite time horizon T , where the market value v_t of the product is unknown to the seller and may vary over time $t = 1, 2, \dots, T$. The market value is modeled as a linear function of observed features (covariates) of the product

$$v_t = \theta_0^\top x_t + z_t, \quad (1)$$

where $x_t \in \mathbb{R}^d$ contains 1 in the first component to consider for the intercept, θ_0 is some unknown parameter and x_t are independent of the noise z_t that are i.i.d. with unknown cumulative distribution function (c.d.f.) F_0 . After the seller proposes a price $p_t = p_t(x_t)$, they observe whether the item is sold or not, i.e. $y_t = \mathbf{1}\{p_t \leq v_t\}$ and collect revenue $p_t y_t$. The seller aims to design a policy that maximizes the total revenue $\sum_{t=1}^T p_t y_t$, given the uncertainty in the market value and the limited information available to the seller, that is (p_t, x_t, y_t) . The determination of the optimal revenue entails learning the model parameters (θ_0, F_0) for which various statistical tools have been employed such as kernel-based methods, bandit technique, and UCB ([Fan et al., 2021](#); [Luo et al., 2022](#); [2024](#); [Xu & Wang, 2022](#); [Tullii et al., 2024](#)).

Building on the semi-parametric structure of the model and recent advances in shape-constrained statistics, we propose a novel policy that requires minimal assumptions about the underlying distribution of market noise. Specifically, we estimate θ_0 using ordinary least squares (OLS) and F_0 using non-parametric least squares (NPLS), subject to the natural constraint that F_0 is non-decreasing.

A key advantage of our shape-constrained approach is that it is entirely data-driven and does not require the specification of any tuning parameters, unlike existing non-parametric methods. For example, the kernel-based technique proposed by [Fan et al. \(2021\)](#) requires bandwidth selection for optimizing the error of the estimator. In contrast, the UCB-based strategy of [Luo et al. \(2022\)](#) requires a set of subjective parameters including a tuning parameter.

Contribution. Our main contributions are:

- (1) We propose a new tuning parameter-free method, unlike existing non-parametric methods for estimating the market noise distribution F_0 , leveraging the shape constraint that F_0 is non-decreasing and assuming only that F_0 is α -Hölder continuous for some $\alpha \in (0, 1]$.
- (2) We derive an upper bound on the total expected regret of order $\tilde{\mathcal{O}}(T^{\nu(\alpha)} d^{\alpha/2+\alpha})$, where $\nu : (0, 1] \rightarrow \mathbb{R}$,

$$\nu(\alpha) \triangleq \frac{2}{2+\alpha} \mathbf{1}\{\alpha \in (0, 1/2)\} + \frac{2\alpha+1}{3\alpha+1} \mathbf{1}\{\alpha \in [1/2, 1]\}, \quad (2)$$

and $\tilde{\mathcal{O}}$ excludes log factors, and we provide a thorough assessment of its empirical performance with comparisons to existing algorithms through a number of simulations, as well as an emulation experiment based on real data. Our algorithm shows strong empirical performance: in particular, it dominates the algorithm proposed by [Tullii et al. \(2024\)](#) in their simulation setting up to very large time horizons. Additionally, our algorithm when applied to a real data set obtained by Welltower Inc continues to demonstrate stronger performance than [Tullii et al. \(2024\)](#); [Luo et al. \(2022\)](#) and is competitive with the nonparametric method proposed by [Fan et al. \(2021\)](#), though the latter relies on stronger smoothness assumptions.

- (3) Beyond the application of antitonic regression, our work involves establishing a concentration inequality for the uniform norm of the antitonic regression estimator error, which is required to derive the expected regret upper bound. Although the existing literature on isotonic regression explores the rate of convergence of the uniform error, explicit tail probability bounds (stronger than O_P statements) of the type presented in this work (see Theorem 4.8) appear to be missing.

1.1 Related Works

The linear valuation model for contextual dynamic pricing, as defined in Equation (1), has been extensively studied under various assumptions. Recent works have explored statistical models—both linear and their extensions—for the pricing problem, assuming that F_0 (the noise distribution) is either known, partially known¹ ([Miao et al., 2019](#); [Ban & Keskin, 2021](#); [Javanmard & Nazerzadeh, 2019](#); [Golrezaei et al., 2019](#)), or fully unknown ([Fan et al., 2021](#); [Xu & Wang, 2022](#); [Luo et al., 2022](#)). For comprehensive overviews of dynamic pricing from a broader perspective, we refer readers to [Den Boer \(2015\)](#) and [Kumar et al. \(2018\)](#).

We focus on the results most relevant to our work—specifically, the case where both the parameter θ_0 and the distribution F_0 are fully unknown. In this setting, [Fan et al. \(2021\)](#) estimate F_0 using kernel methods and derive a regret upper bound of $\tilde{\mathcal{O}}((dT)^{\frac{2m+1}{4m-1}})$, where $m \geq 2$ denotes the degree of smoothness of F_0 . In the realm of reinforcement learning, [Luo et al. \(2022\)](#) introduces the Explore-then-UCB strategy, which balances revenue maximization, estimation of the linear valuation parameter, and nonparametric learning of the noise distribution. Under Lipschitz continuity on F_0 , their approach achieves a regret rate of $\tilde{\mathcal{O}}(dT^{3/4})$, and under (an additional) second-order smoothness assumption, a regret of $\tilde{\mathcal{O}}(d^2T^{2/3})$. However, their regret bounds depend on a regularization parameter $\lambda > 0$, which is hard to tune dynamically, and the impact of the choice of λ on the regret is not clearly described. [Xu & Wang \(2022\)](#) propose the D2-EXP4 algorithm, which is based on discretizing both the parameter space of θ_0 and F_0 . With appropriate choices of the discretization

¹Meaning F_0 is unknown but belongs to a parameterized family.

parameters, they establish a regret upper bound of $\tilde{O}(T^{3/4} + \sqrt{dT}^{2/3})$. However, as noted in [Xu & Wang \(2022, Section 6\)](#), they were unable to perform numerical experiments on D2-EXP4 due to the exponential time complexity of the EXP4 learner with a policy set of size $2^{T^{1/4}}$, making their algorithm impractical for application. Furthermore, Assumption 1 of their paper requires their x_t and θ_0 to have *non-negative entries*. While they claim that this assumption entails no loss of generality, this assumption is heavily used in the proofs of Theorem 6 and Theorem 5 of their work, and it is far from clear whether their derivations are generalizable to the situation when such sign constraints are not imposed. While the positivity of covariates can be ensured under boundedness by adding constants and adjusting the intercept parameter, the assumption that all covariates have a positive impact on the valuation is quite unrealistic for any regression model.

In contrast to [Fan et al. \(2021\)](#); [Luo et al. \(2022\)](#); [Xu & Wang \(2022\)](#), we propose a tuning parameter-free policy that achieves a regret upper bound of order $\tilde{O}(T^{3/4}d^{1/3})$ when $\alpha = 1$ (i.e. F_0 is Lipschitz). Furthermore, estimating the parameters θ_0 and F_0 is computationally efficient: θ_0 is estimated using ordinary least squares (OLS), and F_0 is estimated via isotonic regression² using the Pool Adjacent Violators Algorithm (PAVA) introduced by [Robertson et al. \(1988\)](#), which, in our problem, has a computational complexity of $\mathcal{O}(d^{\alpha/2+\alpha}T^{\nu(\alpha)})$ (see Section 3.1).

Very recent work by [Tullii et al. \(2024\)](#) provides a *UCB-LCB-based* algorithm named VAPE (Valuation Approximation-Price Elimination). The main idea is to update the estimate of θ_0 when x_t has not been seen before, otherwise, update the UCB-LCB around F_0 and deploy the optimal price. They prove that their regret is upper bounded by $\tilde{O}((dT)^{2/3})$ with probability at least $1 - 1/\log^{2/3}(T)$ ³, under Lipschitz assumption on F_0 , which coincides with the *expected* regret lower bound by [Xu & Wang \(2022\)](#) up to $\log(T)$ factors. Note that their regret bound holds *in probability*, while ours (as well as [Fan et al. \(2021\)](#); [Luo et al. \(2022\)](#); [Xu & Wang \(2022\)](#)) holds *in expectation*. An important observation is that [Tullii et al. \(2024\)](#)'s tail probability $\frac{1}{\log^{2/3}(T)}$ is sub-linear in T , and therefore their probability regret bound does not imply the same bound in expectation. To see this consider $\mathbb{P}(R(T) \lesssim T^{2/3}) \geq 1 - 1/f(T)$ which implies

$$\mathbb{E}(R(T)) = \underbrace{\mathbb{E}[R(T) \mid R(T) \leq T^{2/3}]}_{\lesssim T^{2/3}} \underbrace{\mathbb{P}(R(T) \leq T^{2/3})}_{\leq 1} + \underbrace{\mathbb{E}[R(T) \mid R(T) > T^{2/3}]}_{\lesssim T} \underbrace{\mathbb{P}(R(T) > T^{2/3})}_{\leq 1/f(T)} \lesssim T^{2/3} + \frac{T}{f(T)},$$

where we have used that $R(T) \lesssim T$, since the instantaneous reward is assumed to be bounded. Since $f(T) = \log^{2/3}(T)$ in [Tullii et al. \(2024\)](#), one can only bound $\mathbb{E}(R(T))$ at rate T (up to log factors). While one can conceivably investigate alternative decompositions of $\mathbb{E}(R(T))$ in the above display, it is clear that there is little hope of showing a sub-linear regret bound without establishing at least a polynomially decaying bound in T for $\mathbb{P}(R(T) \geq T^\zeta)$ for some $0 < \zeta < 1$. Hence, their regret upper bound is not directly comparable with our regret upper bound, which holds in expectation. We summarize the regret upper bounds and the underlying assumptions in Table 1.

1.2 Notation

For an interval $I = (a, b)$, $a, b \in \mathbb{R}$ we use $|I| = b - a$. For any given matrix $\Sigma \in \mathbb{R}^{d_1 \times d_2}$, we write $\Sigma \succcurlyeq 0$ or $\Sigma \preccurlyeq 0$ if Σ or $-\Sigma$ is semi-definite. For any event A , we let $\mathbb{I}(A)$ be an indicator random variable which is equal to 1 if A is true and 0 otherwise. For two positive sequences $\{a_n\}_{n \geq 1}, \{b_n\}_{n \geq 1}$, we write $a_n = \mathcal{O}(b_n)$ or $a_n \lesssim b_n$ if there exists a positive constant C such that $a_n \leq Cb_n$. In addition, we write $a_n = \Omega(b_n)$ or $a_n \gtrsim b_n$ if $a_n/b_n \geq c$ with some constant $c > 0$. Moreover, we let $\tilde{\mathcal{O}}(\cdot), \tilde{\Omega}(\cdot)$ represent the same meaning with $\mathcal{O}(\cdot), \Omega(\cdot)$ except for ignoring log factors. For a random variable x we will denote by f_x , and P_x its corresponding density function and probability measure, respectively. For a c.d.f. F we will use S to denote $1 - F$. Given a function $h(x, y)$ we write $\mathbb{E}_x[h(x, y)] = \int h(x, y)dP_x(x)$. We say that a function S is α -Hölder (continuous) for some constant $\alpha \in (0, 1]$ if $|S(u) - S(v)| \leq L|u - v|^\alpha$ for all u, v in its domain.

²Alternatively, estimating $1 - F_0$ using antitonic regression.

³In their original work, [Tullii et al. \(2024\)](#) establish a probability bound $1 - 1/T$ on the event that the regret is upper-bounded by $\tilde{O}((dT)^{2/3})$. However, based on correspondence with the authors, we found that the actual bound is $1 - 1/\log^{2/3}(T)$. This correction follows from substituting their parameters choices, $\alpha \propto 1/(T + T^2 + T^{2+1/3})$ and $|\mathcal{K}| \propto 1/\epsilon \propto (T/[d^2 \log^2(T)])^{1/3}$, into the probability tail bound $1 - \alpha(1 + T^2|\mathcal{K}|)$ stated in their Lemma 2.

Table 1: Comparison of customer valuation model-based contextual dynamic pricing algorithms with stochastic contexts under the same assumptions on θ_0 and similar smoothness assumptions on F_0 . Notes:
 (★): This rate holds with probability at least $1 - \frac{1}{\log^{2/3}(T)}$ for $T \rightarrow \infty$, differently from the other rates that hold in expectation. We defer to a complete discussion in Section 1.1).
 (§): $\nu(\alpha)$ is defined in Equation (2).

2 Problem Setting

We consider the pricing problem where a seller has a single product for sale at each time period $t = 1, 2, \dots, T$. Here T is the total number of periods (i.e. length of the horizon) and may be unknown to the seller. The *market value of the product* at time t is denoted by v_t and is unknown to the seller. At each period t , the seller posts a *price* $p_t \in [p_{\min}, p_{\max}]$ for $0 \leq p_{\min} < p_{\max} < \infty$. If $p_t \leq v_t$, a sale occurs, and the seller collects a revenue of p_t . Otherwise, no sale occurs and no revenue is obtained. Let y_t be the response variable that indicates whether a sale has occurred at period t :

$$y_t = \mathbf{1}\{v_t \geq p_t\},$$

and let $p_t y_t$ the collected revenue at time t . We model the market value v_t as a linear function of the product's observable i.i.d features $x_t \in \mathcal{X} \subset \mathbb{R}^d$

$$v_t = \theta_0^\top x_t + z_t, \quad (3)$$

where $\theta_0 \in \mathbb{R}^d$ is an unknown parameter (which includes the intercept term), and z_t are i.i.d sequence of idiosyncratic noise drawn from an unknown distribution F_0 with mean 0 and bounded support

$$\mathcal{U} \triangleq (\inf\{z \in \mathbb{R} : F_0(z) > 0\}, \sup\{z \in \mathbb{R} : F_0(z) < 1\}). \quad (4)$$

We assume that the first entry in x_t equals 1 to account for the intercept term in θ_0 . The overall procedure is summarized in Box 1. The expected revenue for any offered price p given x_t is

$$r_t(p) \triangleq \mathbb{E}_{z_t} (p \mathbf{1}\{v_t > p\} \mid x_t) = p P_{z_t} (v_t > p \mid x_t) = p S_0(p - \theta_0^\top x_t).$$

The optimal price p_t^* at time t is defined by a maximizer of the expected revenue function at the round,

$$p_t^* \in \operatorname{argmax}_{p \in [p_{\min}, p_{\max}]} p S_0(p - \theta_0^\top x_t). \quad (5)$$

Note that $p_t^* = p_t^*(x_t)$, depends on x_t . The regret at step t is defined by the difference between the expected revenues from the optimal price p_t^* and the offered price p_t : $r_t(p_t^*) - r_t(p_t)$. In other words, we consider the problem of maximizing revenue as minimizing the following maximum regret

$$R(T) \triangleq \mathbb{E} \left[\sum_{t=1}^T p_t^* \mathbf{1}\{p_t^* \leq v_t\} - p_t \mathbf{1}\{p_t \leq v_t\} \right],$$

where the expectation is taken with respect to the idiosyncratic noise z_t , the covariates x_t , and the offered prices p_t that depend on the specific policy.

Box 1: Contextual Pricing Dynamic

For each sales round $t = 1, \dots, T$:

- (1) The seller observes a context vector $x_t \in \mathbb{R}^d$.
- (2) The seller offers a price p_t based on x_t and the previous sales records $\{(x_\tau, p_\tau, y_\tau)\}_{\tau=1}^{t-1}$.
- (3) Simultaneously, the customer evaluates the product at v_t , which is not known to the seller.
- (4) The seller observes $y_t = \mathbf{1}\{v_t \geq p_t\}$, indicating whether the product was sold.

As the firm's goal is to design a policy that sets prices p_t as close as possible to the optimal prices p_t^* defined in Equation (5), we first estimate (θ_0, S_0) and then we plug in the estimate as in Equation (6) to get an estimated optimal price p_t . Accurate estimation of (θ_0, S_0) thereby ensures that the resulting policy incurs low regret.

3 Proposed Algorithm

We employ an epoch-based design (also known as the doubling trick) that segments the given horizon T into several clusters of rounds, called *epochs* or *episodes*, and executes identical pricing policies on a per-epoch basis. Let $\mathcal{J}_1 = \{0, 1, \dots, \tau_1 - 1\}$ be the first episode, where τ_1 is a prefixed constant. For $k = 2, \dots, K = \lceil \log(T/\tau_1) + 1 \rceil$, define $\tau_k = \tau_1 2^{k-1}$, and $\mathcal{J}_k = \{\tau_k - \tau_1, \dots, \tau_{k+1} - \tau_1 - 1\}$ the set of times in the k -th episode.

We partition \mathcal{J}_k into two sub-phases, $\mathcal{J}_k = E_k \cup E'_k$, where E_k represents the *exploration phase*, dedicated to collecting data for estimating the parameters (θ_0, S_0) , while E'_k denotes the *exploitation phase*, during which we apply the optimal prices based on the estimated parameters $(\hat{\theta}_k, \hat{S}_k)$. The length of the exploration phase, $|E_k|$, is set to $\lceil d^{\alpha/2+\alpha} \tau_k^{\nu(\alpha)} \rceil$, chosen to minimize the expected regret $R(T)$. Specifically, as we show in the proof of Theorem 4.11, if $|E_k| = d^\xi \tau_k^\eta$ for some $\xi, \eta \in (0, 1)$, then $R(T)$ is minimized if ξ and η satisfy the condition $d^\xi \tau_k^\eta = \lceil d^{\alpha/2+\alpha} \tau_k^{\nu(\alpha)} \rceil$. E_k is further divided into two equal-sized intervals I_k and \tilde{I}_k . In I_k we collect data to estimate θ_0 . In \tilde{I}_k we collect data to estimate S_0 . The details are stated in Algorithm 1, and a picture of a general episode \mathcal{J}_k is shown in Figure 1. In the following portion of this section, we examine the details of exploration-exploitation for a fixed episode k .

Estimation of θ_0 . For all $t \in I_k$ the seller observe x_t , deploy $p_t \sim \text{unif}(p_{\min}, p_{\max})$ and observes $y_t = \mathbf{1}\{p_t \leq v_t\}$. Let $H = p_{\max} - p_{\min}$ and estimate

$$\hat{\theta}_k = \text{OLS}\{(x_t, Hy_t)\}_{t \in I_k} = \arg \min_{\theta} \frac{1}{|I_k|} \sum_{t \in I_k} (Hy_t - \theta^\top x_t)^2.$$

Estimation of S_0 . For $t \in \tilde{I}_k$, the seller observe x_t , sample $w_t \sim \text{unif}(\mathcal{U})$, propose a price $p_t = w_t + \hat{\theta}_k^\top x_t$ and observes $y_t = \mathbf{1}\{p_t \leq v_t\}$. Estimate

$$\hat{S}_k = \text{Antitonic}\{(w_t, y_t)\}_{t \in \tilde{I}_k} = \arg \min_{S \in \mathcal{S}} \sum_{t \in \tilde{I}_k} (y_t - S(w_t))^2,$$

where \mathcal{S} is the set of non-increasing function in \mathbb{R} .

Exploitation. For every $t \in E'_k$, observe x_t , set

$$p_t \in \arg \max_{p \in [p_{\min}, p_{\max}]} p \hat{S}_k(p - \hat{\theta}_k^\top x_t), \quad (6)$$

and get reward $p_t \mathbf{1}\{p_t \leq v_t\}$.

3.1 Complexity of the antitonic regression

The algorithmic complexity for estimating S_0 is $\mathcal{O}(d^{\alpha/2+\alpha} T^{\nu(\alpha)})$. Indeed by Grotzinger & Witzgall (1984); Tibshirani et al. (2011) the computational complexity for the antitonic estimator is $\mathcal{O}(n)$, where n is the sample size. In our case, the estimation of S_0 happens in (half of) the exploration phase which has length proportional to $d^{\alpha/2+\alpha} \tau_K^{\nu(\alpha)} = d^{\alpha/2+\alpha} 2^{K\nu(\alpha)}$, then, using that $K \propto \log_2(T)$, we have $n \propto d^{\alpha/2+\alpha} T^{\nu(\alpha)}$.

Algorithm 1 Semi-Parametric Pricing

Input: The length of the first epoch, τ_1 ; the Hölder exponent α of S_0 and the corresponding $\nu(\alpha)$ defined in Equation (2); the minimum and maximum of price search range, p_{\min} and p_{\max} , $H = p_{\max} - p_{\min}$; \mathcal{U} defined in Equation (4).

for epoch $k = 1, 3, \dots$ **do**

$\tau_k \leftarrow \tau_1 2^{k-1}$, length of episode k

$a_k \leftarrow \lceil d^{\alpha/2+\alpha} \tau_k^{\nu(\alpha)} / 2 \rceil$, length of exploration phase

$I_k \leftarrow \{\tau_k - \tau_1, \dots, \tau_k - \tau_1 + a_k - 1\}$

$\tilde{I}_k \leftarrow \{\tau_k - \tau_1 + a_k, \dots, \tau_k - \tau_1 + 2a_k - 1\}$

$E_k \leftarrow I_k \cup \tilde{I}_k$ indexes of the exploration phase

$E'_k \leftarrow \{\tau_k - \tau_1 + 2a_k, \dots, \tau_{k+1} - \tau_1 - 1\}$ indexes of the exploitation phase.

for $t \in I_k$ **do**

Observe x_t

Set $p_t \sim \text{unif}(p_{\min}, p_{\max})$.

Get $y_t \leftarrow \mathbf{1}\{p_t \leq v_t\}$

end for

$\hat{\theta}_k \leftarrow \text{OLS}\{(x_t, Hy_t)\}_{t \in I_k}$

for $t \in \tilde{I}_k$ **do**

Observe x_t

Sample $w_t \sim \text{unif}(\mathcal{U})$

Set $p_t \leftarrow w_t + \hat{\theta}_k x_t$

Get $y_t \leftarrow \mathbf{1}\{p_t \leq v_t\}$

end for

$\hat{S}_k \leftarrow \text{Antitonic}\{(w_t, y_t)\}_{t \in \tilde{I}_k}$

for $t \in E'_k$ **do**

Observe x_t

Set price p_t as defined in Equation (6).

Get $y_t \leftarrow \mathbf{1}\{p_t \leq v_t\}$

end for

end for

Figure 1: Picture of a general episode \mathcal{J}_k , $k = 1, 2, \dots, K$.

4 Regret Analysis

Before proceeding with the regret analysis we need to discuss the convergence rates of $\hat{\theta}_k$ to θ_0 and \hat{S}_k to S_0 . We present our main theorems and proofs. We defer to the Appendix for the missing proofs.

4.1 Estimation of θ_0

Assumption 4.1 (Bounded parameter space). The parameter $\theta_0 \in \mathbb{R}^d$ is an interior point of Θ and the parameter space Θ is a compact convex set.

Assumption 4.2 (Bounded i.i.d. contexts). (a) $x_t \in \mathcal{X} \subset \mathbb{R}^d$ is i.i.d. drawn a distribution that does not involve θ_0 and F_0 , and for all $x_t \in \mathcal{X}$, $\|x_t\|_2 \leq R_{\mathcal{X}}$ for some unknown $R_{\mathcal{X}} > 0$. (b) There exists reals $c_{\min}, c_{\max} > 0$, s.t. $c_{\min} \mathbb{I}_d \preceq \Sigma \preceq c_{\max} \mathbb{I}_d$, where $\Sigma \triangleq \mathbb{E} x_t x_t^\top$ and \mathbb{I}_d the $d \times d$ identity matrix.

Assumptions 4.1 and 4.2 are standard in the dynamic pricing literature Javanmard & Nazerzadeh (2019); Xu & Wang (2022); Luo et al. (2022); Fan et al. (2021). Combined with the fact that $\{p_t\}_{t \in I_k}$ are i.i.d. uniform, these conditions ensure the convergence of $\hat{\theta}_k$ to θ_0 .

Lemma 4.3. [Fan et al. (2021, Lemma 4.1)] Let $n_k \triangleq |I_k|$ for simplicity of notation. Under Assumptions 4.1 and 4.2, there exist $c_0, c_1 > 0$ depending only on absolute constants given in assumptions, such that for any episode k , as long as $n_k \geq c_0 d$, with probability at least $1 - Q_{n_k}$, with $Q_{n_k} \triangleq 2e^{-c_1 c_{\min}^2 n_k / 16} + \frac{2}{n_k}$, it holds that

$$\|\hat{\theta}_k - \theta_0\|_2 \leq C_{\theta_0} \sqrt{d \log n_k / n_k} \triangleq R_{n_k},$$

where $C_{\theta_0} \triangleq \frac{8 \max\{R_{\mathcal{X}}, 1\} (R_{\mathcal{X}} R_{\theta_0} + p_{\max} - p_{\min})}{c_{\min}}$.

4.2 Estimation of S_0 via antitonic regression

In this section, we provide a uniform convergence result of \hat{S}_k to S_0 . For simplicity of notation, we re-index \tilde{I}_k as $\mathcal{T} = \{1, 2, \dots, n\}$, and we denote θ_k by θ , which was estimated using data $\{(p_t, x_t, y_t)\}_{t \in I_k}$ independent of \mathcal{T} . In this section, all the results must be considered as conditioned on $\theta = \hat{\theta}_k$. We report in Box 2 a more detailed explanation of the estimation of S_0 during the exploration phase in \mathcal{T} as expounded in the box highlighted in Algorithm 1.

Box 2: Sample collection for estimating S_θ

For each $t \in \mathcal{T}$ do:

- (1) Observe x_t .
- (2) The customer samples z_t and evaluate $v_t = \theta_0^\top x_t + z_t$, unknown to the firm.
- (3) The firm samples $w_t \sim \text{unif}(\mathcal{U})$ independent of everything else and defines $p_t = w_t + \theta^\top x_t$.
- (4) Observe $y_t = \mathbf{1}\{p_t \leq v_t\}$.

This produces a set of data points $\{(p_t, x_t, y_t)\}_{t \in \mathcal{T}}$ that we are going to use for estimating S_0 . To estimate S_0 we would need to know θ_0 in advance, indeed remember that $\mathbb{E}(y_t | p_t, x_t) = S_0(p_t - \theta_0^\top x_t)$, which design points $\{p_t - \theta_0^\top x_t\}_{t \in \mathcal{T}}$ depend on θ_0 . However, our knowledge is limited to an approximation θ of θ_0 , and the observable design points are $p_t - \theta^\top x_t = w_t$. This implies that we are only able to estimate $S_\theta(u) \triangleq \mathbb{E}(y_t | w_t = u)$. Conditional on w_t we can consider (or pretend for the purpose of estimation) the y_t as coming from a sample in the ordinary current status model, where the data has the form $(w_t, y_t) \stackrel{i.i.d.}{\sim} (w, y)$, the observation times have uniform density f_w and where $y_t = 1$ with probability $S_\theta(w_t)$ at observation w_t .

Remark 4.4 (The choice of the design points w_t). The choice of the distribution for w_t is motivated by the fact that when the density of design points is uniform, we obtain convergence guarantees for the estimator of S_0 . Specifically, as mentioned by Mösching & Dümbgen (2020), if the density of the design points is bounded away from zero – which holds for the uniform distribution – then $\{w_t\}_{t \in \mathcal{T}}$ are “asymptotically dense” within any interval contained in \mathcal{U} (defined in Equation (4)). Ensuring that the design points have a density bounded away from zero is a sufficient condition for the convergence result in Theorem 4.8 (see Lemma A.2 for further details). However, this choice is not restrictive; any distribution whose density is bounded away from zero in \mathcal{U} would still satisfy the convergence result. The only consequence of using a non-uniform density is that the regret $R(T)$ will depend on the multiplicative constant $C_2 = \inf_{u \in \mathcal{U}} f_w(u)$, which may be different from $1/|\mathcal{U}|$ if f_w is not the uniform density in \mathcal{U} . Furthermore, since each episode \mathcal{J}_k is independent of any other episode $\mathcal{J}_{k'}$ for $k \neq k'$, it is possible to select a different density $f_w^{(k)}$ for each episode k , provided that it remains bounded away from zero in \mathcal{U} . An interesting extension of our work would be to adaptively update the design density $f_w^{(k)}$ based on the previous design $f_w^{(k-1)}$ in an *optimal* manner, namely that $f_w^{(k)}$ converges to the optimal design density as $k \rightarrow \infty$, that is the density that minimizes the integrated mean square error. This approach, known as *sequential optimal design*, has been extensively studied in the literature (see, e.g., Müller (1984); Zhao & Yao (2012); Bracale et al. (2024)). A key advantage of an optimal design algorithm is that it dynamically allocates more data to regions where the estimation of S_0 is less accurate, thereby progressively improving its precision. However, it is important to note that while this adaptive approach can optimize the multiplicative constant in the regret bound, it does not affect the rate of the regret itself.

Remark 4.5 (The difference between the conditional distributions of $y|(p, x)$ and $y|w$). We want to highlight the difference between the conditional distributions of $y|(p, x)$ and $y|w$. The first is independent of θ , indeed we have that

$$\mathbb{E}_z[y|p, x] = \mathbb{E}[\mathbf{1}\{p \leq \theta_0^\top x + z\}|p, x] = S_0(p - \theta_0^\top x),$$

while, the distribution of $y|w$ depends on θ because $y = \mathbf{1}\{p \leq v\}$ where $p = w + \theta^\top x$, and, since data (w, y) is generated as in Box 2, we have that

$$\begin{aligned} S_\theta(u) &= \mathbb{E}_z(y | w = u) = \mathbb{E}_{(p, x)}(\mathbb{E}_z(y | p, x) | w = u) = \mathbb{E}_{(p, x)}(S_0(p - \theta_0^\top x) | w = u) \\ &= \mathbb{E}_{(p, x)}(S_0(p - \theta^\top x + \theta^\top x - \theta_0^\top x) | w = u) = \mathbb{E}_x(S_0(u + (\theta - \theta_0)^\top x) | w = u) \\ &= \int S_0(u + (\theta - \theta_0)^\top x) dP_{x|w=u}(x) = \int S_0(u + (\theta - \theta_0)^\top x) dP_x(x), \end{aligned} \quad (7)$$

where the first equality is by definition, in the second we use the tower property and in the last equality, we use that w_t is sampled independently of x_t .

Proposition 4.6. S_θ is non-increasing for every $\theta \in \mathbb{R}^d$. Moreover, if S_0 is α -Hölder with $\alpha \in (0, 1]$, then S_θ is α -Hölder uniformly in $\theta \in \mathbb{R}^d$ and $|S_\theta(u) - S_0(u)| \lesssim \|\theta - \theta_0\|_2^\alpha$ uniformly in $u \in \mathbb{R}$.

Proposition 4.6 is crucial because it tells us that we can estimate S_θ under the antitonic constraint and that S_θ is close to S_0 as long as θ is close to θ_0 , which will be used to prove Theorem 4.11. Guided by Proposition 4.6, we estimate S_θ using antitonic regression, denoted as

$$\hat{S}_\theta \triangleq \operatorname{argmin}_{S \in \mathcal{S}} \sum_{t \in \mathcal{T}} (y_t - S(w_t))^2, \quad (8)$$

where \mathcal{S} is the set of non-increasing functions in \mathbb{R} . The minimizer \hat{S}_θ is a piecewise constant function with jumps at a subset of $\{w_t : t \in \mathcal{T}\}$. The order statistics on which \hat{S}_θ is based are the order statistics of the values w_t and the values of the corresponding y_t . To be more specific, let $u_1 < u_2 < \dots < u_m$ the different value of the observed $\{w_t\}_{t \in \mathcal{T}}$. For $j = 1, \dots, m$ set

$$o_j = \#\{t : w_t = u_j\}, \quad \hat{y}_j = \frac{1}{o_j} \sum_{i: w_i = u_j} y_i.$$

For every $1 \leq r \leq s \leq m$ let

$$o_{rs} \triangleq \sum_{j=r}^s o_j = \#\{t : u_r \leq w_t \leq u_s\}, \quad \hat{y}_{rs} = \frac{1}{o_{rs}} \sum_{j=r}^s o_j \hat{y}_j.$$

It is well known that $\hat{S}_\theta = (\hat{S}_\theta(u_1), \hat{S}_\theta(u_2), \dots, \hat{S}_\theta(u_m))$ may be represented by the following minimax and maximin formulae, see Robertson et al. (1988): for $1 \leq j \leq m$

$$\hat{S}_\theta(u_j) = \min_{r \leq j} \max_{s \geq j} \hat{y}_{rs} = \max_{s \geq j} \min_{r \leq j} \hat{y}_{rs}.$$

The \hat{S}_θ is also known as the antitonic regression on data $\{(w_t, y_t)\}_{t \in \mathcal{T}}$, and we will denote it as

$$\hat{S}_\theta = \text{Antitonic}\{(w_t, y_t)\}_{t \in \mathcal{T}}.$$

We are now prepared to demonstrate the convergence of \hat{S}_k to S_0 . To establish this result, we require that S_θ is α -Hölder for some $\alpha \in (0, 1]$ uniformly in θ . According to Proposition 4.6, this condition is satisfied provided we make the following assumption:

Assumption 4.7. $|S_0(u) - S_0(v)| \leq C_1|u - v|^\alpha$ for some $\alpha \in (0, 1]$, $C_1 > 0$ and for all $u, v \in \mathbb{R}$.

Theorem 4.8. Let $\{(w_t, y_t)\}_{t \in \mathcal{T}}$ be as defined in Box 2 and let Assumption 4.7 hold. Then for every $\kappa > 0$ and $\gamma > 2$ there exists $n_0 = n_0(\gamma, \kappa, \alpha) \in \mathbb{N}$ and $C = C(C_1, |\mathcal{U}|, \kappa, \alpha) > 0$ (where \mathcal{U} is defined in Equation (4)) such that

$$\mathbb{P} \left\{ \sup_{u \in \mathcal{U}_n} |\hat{S}_\theta(u) - S_\theta(u)| \leq C \rho_n^{\alpha/(2\alpha+1)} \right\} \geq 1 - \frac{1}{n^{\gamma-2}}, \quad n \geq n_0$$

where $\rho_n = \log(n)/n$ and $\mathcal{U}_n = \{u \in \mathcal{U} : [u \pm \delta_n] \subset \mathcal{U}\}$, with $\delta_n = \kappa \rho_n^{1/(2\alpha+1)}$.

Remark 4.9. Our Theorem 4.8 parallels Theorem 3.3 in Mösching & Dümbgen (2020), with the key distinction being the nature of the observed response variable. While Mösching & Dümbgen (2020) directly observes the response variable (which corresponds to our valuation v_t), we observe the binary indicator $y_t = \mathbf{1}\{p_t \leq v_t\}$. This difference simplifies our proof, as it only requires establishing a concentration inequality for $|\hat{y}_{rs} - \bar{S}_{rs}(\theta)|$, where

$$\bar{S}_{rs}(\theta) \triangleq \frac{1}{o_{rs}} \sum_{j=r}^s o_j S_\theta(w_j).$$

In our setting, this concentration inequality can be readily obtained using Hoeffding’s inequality uniformly over θ . Specifically, as demonstrated in Lemma A.1, for any constant $D > 1$, $\mathbb{P}\{M_n(\theta) \leq (D \log n)^{1/2}\}$ is at least $1 - (n^{1/2}/n^D)^2$, where $M_n(\theta) \triangleq \max_{1 \leq r \leq s \leq m} o_{rs}^{1/2} |\hat{y}_{rs} - \bar{S}_{rs}(\theta)|$.

4.3 Regret Upper Bound

We are ready to establish an upper bound on the expected regret for our Algorithm 1. In contrast to Fan et al. (2021), which assumes the optimal price is unique, our analysis only requires that at least one optimal price exists within the interval (p_{\min}, p_{\max}) .

Assumption 4.10. For any $(x, \theta) \in \mathcal{X} \times \Theta$ at least one maximizer of $p \mapsto pS_0(p - x^\top \theta_0)$ over $[0, \infty)$ lies inside (p_{\min}, p_{\max}) .

Theorem 4.11. Suppose that Assumptions 4.1, 4.2, 4.7 and 4.10 hold. For sufficiently large T the cumulative regret of Algorithm 1 is

$$R(T) = \begin{cases} T^{\frac{2}{2+\alpha}} d^{\frac{\alpha}{\alpha+2}} \log^{\frac{\alpha}{2\alpha+1}}(dT), & \alpha \in (0, 1/2) \\ T^{\frac{2\alpha+1}{3\alpha+1}} d^{\frac{\alpha}{\alpha+2}} \log^{\frac{\alpha}{2}}(dT), & \alpha \in [1/2, 1]. \end{cases}$$

5 Simulations

We first perform simulations for theoretical validation in Section 5.1 and a simulation to compare our algorithm with the minimax algorithm by Tullii et al. (2024) and Fan et al. (2021) algorithm in Section 5.2.

5.1 Simulation for theoretical validation

To this end, we replicate the simulation settings used by Fan et al. (2021). We set $\mathcal{U} = (-1/2, 1/2)$ (known), the feature dimension $d = 3$ (known), the distribution of $X_t \sim \text{Unif}(-\sqrt{2/3}, \sqrt{2/3})^{\times d}$ (unknown), and the coefficient $\theta_0^\top = (\alpha_0, \beta_0^\top)$ (unknown), where $\alpha_0 = 3, \beta_0 = (2/3, 2/3, 2/3)$. We also choose $p_{\min} = 0$ and $p_{\max} = 5$ (known). For $F_0 : \mathcal{U} \rightarrow \mathbb{R}$ we consider different choices: $\alpha < 1$: $F_{0,\alpha}(z) = 1/2 + (1/2)^{1-\alpha} \text{sign}(z)|z|^\alpha$ for $z \in \mathcal{U}$, for $z > 1/2$, for $\alpha \in \{1/3, 1/2, 3/4\}$. $\alpha = 1$: we use 4 choices of F_0 : a Gaussian $N(0, 1)$ truncated at \mathcal{U} , the c.d.f. used by Fan et al. (2021) with density $f_0(z) = 6(\frac{1}{4} - z^2)\mathbf{1}\{z \in \mathcal{U}\}$, a Laplace with location 0 and scale 0.2 truncated at \mathcal{U} , and a Cauchy with location 0 and scale 0.2 truncated at \mathcal{U} .

We start with $\tau_1 = 100$ and compute $K = 8$ total episodes. At every time t we follow Algorithm 1 to compute p_t , with the additional computation of the oracle p_t^* and the corresponding cumulative regret $\text{Reg}(t) = \sum_{j=1}^t p_j^* S_0(p_j^* - \theta_0^\top x_j) - p_t S_0(p_t - \theta_0^\top x_t)$. We repeated the experiment 36 times and we computed the mean and the 95% confidence interval in a $\log_2 - \log_2$ plot. As illustrated in Figure 2, we validate our approach by comparing the estimated slope of the linear regression of $\log_2(t)$ versus $\log_2(\text{Reg}(t))$ with the theoretical upper bound rate. Due to space constraints, the plot corresponding to the F_0 used by Fan et al. (2021) with density $f_0(z) = 6(\frac{1}{4} - z^2)\mathbf{1}\{z \in \mathcal{U}\}$ is provided in Appendix B.

5.2 Comparison with Tullii et al. (2024)

We first recall the brief discussion in Section 1.1 about the Tullii et al. (2024) regret upper bound $\tilde{\mathcal{O}}(T^{2/3})$ under Lipschitz assumption on F_0 , which holds in probability and the tail probability is sub-linear in T (more precisely the upper bound holds with probability at least $1 - 1/\log^{2/3}(T)$), which does not imply the same regret upper bound in expectation. Then, their regret upper bound is not directly comparable with our

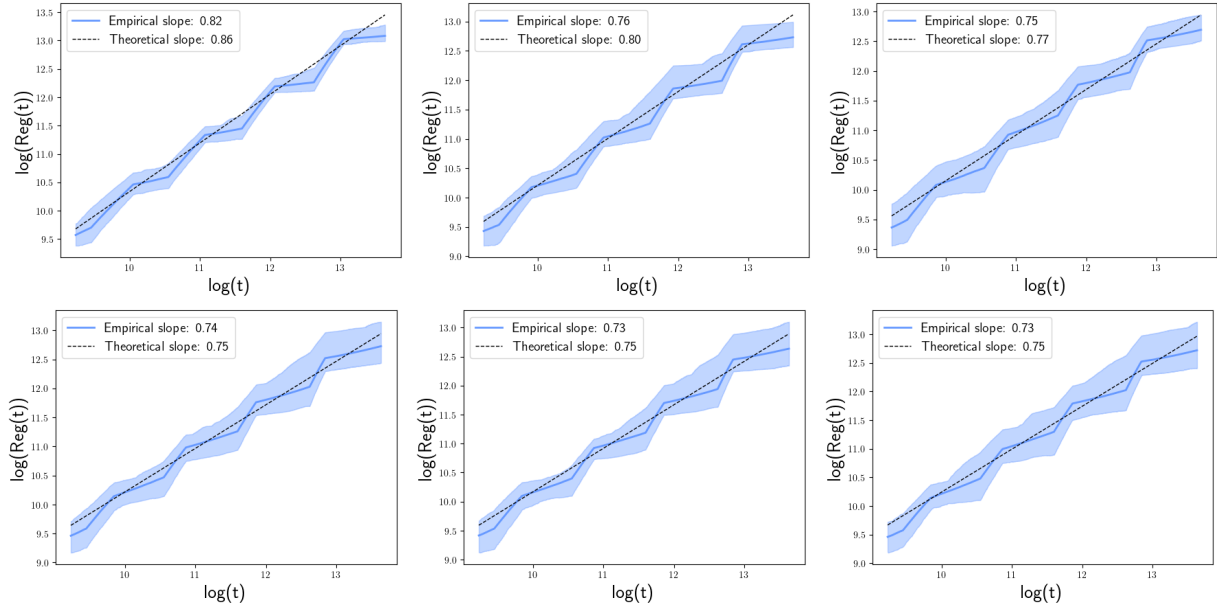

Figure 2: This plot shows the total expected regret (blue line) with $F_{0,\alpha}$, for $\alpha \in \{1/3, 1/2, 3/4\}$ in the first row, in the second we have the Gaussian, Laplace, and Cauchy c.d.f. (from the left to the right). We repeated the simulation 36 times and displayed the corresponding 95% confidence intervals. The plot is in \log_2 - \log_2 scale to show the regret rate (empirical slope): a slope of η indicated an $\mathcal{O}(T^\eta)$ regret. The black dashed line corresponds to our theoretical regret upper bound.

order-of- $T^{3/4}$ regret the upper bound, which holds in expectation. For this reason we perform the following simulations.

In their work, Tullii et al. (2024, Supplementary Material A) compared their VAPE method to the kernel-based method by Fan et al. (2021) that is: they built a dataset of 5 contexts belonging to \mathbb{R}^3 generated by a canonical Gaussian distribution and subsequently normalized. Throughout the run, the contexts are chosen from this set uniformly at random, while the noise term is picked from a Gaussian distribution truncated between -1 and 1 with mean 0 and variance 0.1 . Similarly, also the parameter θ_0 is a normalized vector initially drawn from a Gaussian distribution. Note that for this simulation, the error distribution is twice differentiable (i.e. smoother than what Tullii et al. (2024) and us allow in our theory), then Fan et al. (2021) is applicable with smoothness parameter $m = 2$. Tullii et al. (2024) showed that the algorithm by Fan et al. (2021), has stronger performance.

We apply our antitonic regression-based algorithm with $\alpha = 1$, using the same code and simulation setting provided by Tullii et al. (2024, Supplementary Material A). The algorithm has been tested on time horizons $T \in [500, 1000, 2000, 4000, 8000]$. We computed the regret 36 times and the corresponding 95% confidence interval. In Figure 3 we show the results. Although the work by Fan et al. (2021) applies to distributions of the error that are at least twice differentiable – which is the case in this simulation – their algorithm has weaker performance than ours in this setting. Comparing our antitonic method with the VAPE algorithm by Tullii et al. (2024) (which have the same assumption on F_0 , i.e. Lipschitzianity of F_0) the empirical performance of VAPE is worse than our method up to very large time horizons ($T = 8000$), achieving smaller regret.

Figure 3: Regret comparison in the simulation setting of Tullii et al. (2024).

Table 2: Dataset description

Variable	Description
v_t : act_rate_d	Final transaction price.
$x_{t,1}$: mkt_rate_d	Typical rate of similar unit in the primary market area.
$x_{t,2}$: sqft	Square footage of unit.
$x_{t,3}$: unit_type	Type of unit (bedroom, studio, or other).
$x_{t,4}$: med_home	Median home value of primary market area.

6 Real Application

This study applies our method to a real data set obtained by Welltower Inc to simulate the dynamic pricing process. The dataset consists of various characteristics and the transaction price for units in the United States (see Table 2 for more details). In our experiments, we present each rental unit to the dynamic pricing algorithm in a sequential fashion to simulate the dynamic pricing game. The unique aspect of the dataset is it includes the exact transaction price, which allows us to evaluate the regret of the algorithm directly.

This dataset doesn't contain the variable y_t , i.e. whether the sales occurred. Our knowledge is limited to the final transaction prices **act_rate_d**. To overcome this we make the following adjustment: at each time point t , we consider the transaction price **act_rate_d** as the customer valuation v_t , which we treat as unobserved; a price p_t is posted by the firm, which finally collects the data point (x_t, y_t) where $y_t \triangleq \mathbf{1}\{v_t \geq p_t\}$. Here the vector x_t contains all the variables in Table 2 except **act_rate_d**, and 1 in the first entry to account for the intercept. As we assume $v_t = \theta_0^\top x_t + z_t$ for some unknown θ_0 and unknown c.d.f. F_0 of z_t , we validate this linear validation model. To this end, we perform a linear model using data (x_t, v_t) : the p-value of the F statistics is close to 0 and the slopes of all the variables are statistically significant at a significance level of 0.05 (see Table 4). The residuals and the associated empirical distribution function (an estimate of F_0) are depicted in Figure 4, from which we notice that \mathcal{U} is approximatively $(-17, 12)$. Moreover p_{\min} and p_{\max} are the maximum and minimum values of v_t .

Figure 4: Residuals

Prior to implementing the methods, we conducted cross-validation to tune the UCB algorithm's parameters λ and C_2 , as defined in Luo et al. (2022). We searched over a grid with $(\lambda, C_2) \in \{0.1, 0.5, 1, 1.5, 2, 5\} \times \{5, 10, 15, 20, 30\}$. After selecting the optimal parameters, we ran the algorithm for each method. The initial episode length was set to $\tau_1 = 150$, with subsequent episodes doubling in length according to $\tau_k = \tau_1 2^{k-1}$,

Figure 5: Revenue comparison

for a total of $K = 4$ episodes. Each algorithm then chooses its exploration phase according to its rule. We conducted 36 iterations, randomly shuffling the data before each run. For our algorithm, we set $\alpha = 1$.

Figure 5 showcases the (empirical) revenue $\text{Rev}(t) = \sum_{j=1}^t p_t y_t$, obtained using our antitonic method (blue line), the UCB method by Luo et al. (2022) (green line), the kernel method by Fan et al. (2021) (red line) and the VAPE algorithm by Tullii et al. (2024) (black line). Higher lines indicate better performance. We present three plots corresponding to different values of the smoothness parameter m , which affects only the kernel method. We let the antitonic, UCB, and VAPE methods remain the same across all three plots, while the kernel method’s performance changes with varying m . Overall, our antitonic method generally outperforms the other approaches. The kernel method by Fan et al. (2021) also performs well and tends to improve as the smoothness parameter m increases. Despite tuning its parameters, the UCB method by Luo et al. (2022) performs poorly, while as far as the VAPE algorithm by Tullii et al. (2024) shows worse performance than our method and kernel-based method.

7 Conclusions

We introduced a novel method for estimating the market noise distribution F_0 by leveraging its natural shape constraint: monotonicity. Our analysis led to an expected upper bound on the total regret of order $\tilde{O}(T^{\nu(\alpha)} d^{\alpha/2+\alpha})$, where $\nu(\alpha)$ is defined in Equation (2), matching certain previous rates in T and enjoying the additional advantage of being tuning parameter-free. Compared to existing methods such as Tullii et al. (2024); Fan et al. (2021); Luo et al. (2022), our proposed algorithm shows stronger empirical performance in both simulations and real data applications.

An interesting direction for future research is the study of lower bounds on the expected regret under the Hölder condition on S_0 and an investigation into whether our rate matches this bound. In the special case when $\alpha = 1$, Xu & Wang (2022) established a lower bound of $\Omega(T^{2/3})$ for the expected regret under a Lipschitz condition on S_0 . However, no existing algorithm has achieved this bound in expectation—Tullii et al. (2024) attained it with high probability but not in expectation (see Section 1.1). A natural question is whether it is possible to close this gap by designing an algorithm that achieves the lower bound in expectation or by refining the bound itself to be tighter. Another promising extension, particularly for practical applications, is the incorporation of optimal design strategies, as discussed in Remark 4.4. This could significantly improve the multiplicative constants in the regret, leading to more efficient algorithms.

A Missing Proofs

A.1 Proof of Proposition 4.6

Proof. By Equation (7) we have $S_\theta(u) = \int S_0(u + (\theta - \theta_0)^\top x) dP_x(x)$, from which we note that S_θ is non-increasing, because S_0 is non-increasing. Moreover if S_0 is α -Hölder,

$$\begin{aligned} |S_\theta(u) - S_\theta(v)| &= \int |S_0(u + (\theta - \theta_0)^\top x) - S_0(v + (\theta - \theta_0)^\top x)| dP_x(x) \\ &\leq \int C_1 |u - v|^\alpha dP_x(x) = C_1 |u - v|^\alpha, \end{aligned}$$

and

$$\begin{aligned} |S_\theta(u) - S_0(u)| &= \int |S_0(u + (\theta - \theta_0)^\top x) - S_0(u)| dP_x(x) \\ &\leq \int C_1 |(\theta - \theta_0)^\top x|^\alpha dP_x(x) \\ &\leq C_1 R_{\mathcal{X}}^\alpha \|\theta - \theta_0\|_2^\alpha, \end{aligned}$$

where in the last inequality we used Cauchy-Schwartz and that $\|x\|_2 \leq R_{\mathcal{X}}$. \square

A.2 Proof of Theorem 4.8

We first need to Lemmas: Lemma A.1 and Lemma A.2.

Lemma A.1. *Let*

$$\bar{S}_{rs}(\theta) \triangleq \frac{1}{o_{rs}} \sum_{j=r}^s o_j S_\theta(w_j),$$

and

$$M_n(\theta) \triangleq \max_{1 \leq r \leq s \leq m} o_{rs}^{1/2} |\hat{y}_{rs} - \bar{S}_{rs}(\theta)|.$$

Then for any constant $D > 1$,

$$\mathbb{P} \left(M_n(\theta) \leq (D \log n)^{1/2} \right) \leq 1 - \left(\frac{n+1}{n^D} \right)^2.$$

Proof. First, the by Hoeffding's inequality, since y_j are independent random variables taking values $\{0, 1\}$ with mean $S_\theta(w_t)$, for every $\eta > 0$ we have

$$\mathbb{P} \left[\sqrt{o_{rs}} |\hat{y}_{rs} - \bar{S}_{rs}(\theta)| \geq \eta \right] \leq 2e^{-2\eta^2}.$$

Note that M_n is the maximum of the $\binom{m+1}{2}$ quantities

$$o_{rs}^{1/2} |\hat{y}_{rs} - \bar{S}_{rs}(\theta)|.$$

Consequently,

$$\begin{aligned} \mathbb{P} (M_n(\theta) \geq \eta_n) &\leq \sum_{1 \leq r \leq s \leq m} \mathbb{P} \left(o_{rs}^{1/2} |\hat{y}_{rs} - \bar{S}_{rs}(\theta)| \geq \eta_n \right) \\ &\leq 2 \binom{m}{2} \exp(-2\eta_n^2) \\ &\leq \exp(2 \log(n+1) - 2\eta_n^2) \\ &\leq \exp(2 \log((n+1)/n^D)) = \left(\frac{n+1}{n^D} \right)^2, \end{aligned}$$

for arbitrary $\eta_n \geq 0$. But the right hand side converges to zero as $n \rightarrow \infty$ if $\eta_n = (D \log n)^{1/2}$ for some $D > 1$. \square

Before proceeding with the technical Lemma A.2, let's define

$$\rho_n \triangleq \frac{\log n}{n},$$

and $\lambda(\cdot)$ the Lebesgue measure, and denote by $P_n(\cdot)$ the empirical measure of the design points w_t , that means

$$P_n(B) \triangleq \frac{1}{n} \# \{t \in \mathcal{T} : w_t \in B\} \quad \text{for } B \subset \mathcal{U}.$$

Lemma A.2. *Let w_1, w_2, \dots, w_n i.i.d. points with density f_w that satisfies $\inf_{u \in \mathcal{U}} f_w(u) \geq C_2$ for some universal constant $C_2 > 0$ (which is the case for the uniform distribution), then for a given constant $\kappa > 0$, and for any $\gamma > 2$, there exists $n_0 = n_0(\gamma, \kappa, \alpha) \in \mathbb{N}$ and a sequence $\epsilon_n = \epsilon_n(\gamma, \kappa, \alpha) > 0$, $\epsilon_n \rightarrow 0$ such that*

$$\mathbb{P}(A_{n,\gamma}) > 1 - \frac{1}{2(n+2)^{\gamma-2}}, \quad n \geq n_0$$

where $A_{n,\gamma}$ is the event

$$\inf \left\{ \frac{P_n(\mathcal{U}_n)}{\lambda(\mathcal{U}_n)} : \mathcal{U}_n \subset \mathcal{U}, \lambda(\mathcal{U}_n) \geq \delta_n \triangleq \kappa \rho_n^{1/(2\alpha+1)} \right\} \geq C_2(1 - \epsilon_n).$$

Proof. This is immediately derived from the proof of the more general result by Mösching & Dümbgen (2020, Section 4.3) which can be stated as follows: let $\delta_n > 0$ such that $\delta_n \rightarrow 0$ while $n\delta_n/\log(n) \rightarrow \infty$ (as $n \rightarrow \infty$). Then for every $\gamma > 2$, there exists $n_0 = n_0(\gamma, \delta_n)$ and $\epsilon_n = \epsilon_n(\gamma, \delta_n) > 0$, $\epsilon_n \rightarrow 0$ such that

$$\mathbb{P} \left(\inf \left\{ \frac{P_n(\mathcal{U}_n)}{P(\mathcal{U}_n)} : \mathcal{U}_n \subset \mathcal{U}, P(\mathcal{U}_n) \geq \delta_n \right\} \geq 1 - \epsilon_n \right) > 1 - \frac{1}{2(n+2)^{\gamma-2}}, \quad n \geq n_0,$$

where $P(\cdot)$ is the probability measure of the design points w_t , that is

$$P(B) \triangleq \int_B f_w(w) dw, \quad \text{for } B \subset \mathcal{U},$$

and

$$\epsilon_n \triangleq \max \left(c_n/\delta_n, \sqrt{2c_n/\delta_n} \right) + (n\delta_n)^{-1} \rightarrow 0,$$

where $c_n \triangleq \gamma \log(n+2)/(n+1)$. The value n_0 is the smallest integer n that satisfies $\epsilon_n < 1$. \square

Now we prove Theorem 4.8.

Proof. Let n be sufficiently large so that $\mathcal{U}_n \neq \emptyset$ and such that the event $A_{n,\gamma}$ in Lemma A.2 occurs. Since f_w is the uniform distribution, the value C_2 defined in Lemma A.2 corresponds to $1/|\mathcal{U}|$. For $u \in \mathcal{U}_n$ the indices

$$\begin{aligned} r(u) &\triangleq \min \{j \in \{1, \dots, m\} : u_j \geq u - \delta_n\}, \\ j(u) &\triangleq \max \{j \in \{1, \dots, m\} : u_j \leq u\}, \end{aligned}$$

are well-defined, because $[u - \delta_n, u]$ is a subinterval of I of length δ_n . Note that by Lemma A.2 this interval contains at least one observation u_j . Moreover,

$$\begin{aligned} r(u) &\leq j(u), \\ u - \delta_n &\leq u_{r(u)} \leq u_{j(u)} \leq u, \\ o_{r(u)j(u)} &= o_n([u - \delta_n, u]) \geq C_2(1 - \epsilon_n)n\delta_n, \end{aligned}$$

where ϵ_n is defined as in Lemma A.2. Consequently, with $M_n(\theta)$ as in Lemma A.1, we have

$$\begin{aligned}
\widehat{S}_\theta(u) - S_\theta(u) &\leq \widehat{S}_\theta(u_{j(u)}) - S_\theta(u) \\
&= \min_{r \leq j(u)} \max_{s \geq j(u)} \widehat{y}_{rs} - S_\theta(u) \\
&\leq \max_{s \geq j(u)} \widehat{y}_{r(u)s} - S_\theta(u) \\
&\leq o_{r(u)j(u)}^{-1/2} M_n(\theta) + \max_{s \geq j(u)} \bar{S}_{r(u)s} - S_\theta(u) \\
&\leq (C_2(1 - \epsilon_n)n\delta_n)^{-1/2} M_n(\theta) + S_\theta(u_{r(u)}) - S_\theta(u) \\
&\leq (C_2(1 - \epsilon_n)n\delta_n)^{-1/2} M_n(\theta) + C_1\delta_n^\alpha.
\end{aligned}$$

In the first step, we used antitonicity of $u \mapsto \widehat{S}_\theta(u)$, and in the second last step we used antitonicity of $u \mapsto S_\theta(u)$, and the last step utilizes that by Assumption 4.7. But on the event $\{M_n(\theta) \leq (D \log n)^{1/2}\}$, the previous considerations implies that

$$\sup_{u \in \mathcal{U}_n} (\widehat{S}_\theta(u) - S_\theta(u)) \leq (C_2(1 - \epsilon_n)n\delta_n)^{-1/2} (D \log n)^{1/2} + C_1\delta_n^\alpha = C\rho_n^{\alpha/(2\alpha+1)},$$

where $C = \sqrt{\kappa D/C_2} + C_1\kappa^\alpha$, and we recall that $C_2 = 1/|\mathcal{U}|$ and D is any real value strictly greater than 1. But $\sup_{u \in \mathcal{U}_n} (S_\theta(u) - \widehat{S}_\theta(u)) \leq C\rho_n^{\alpha/(2\alpha+1)}$ happens in $A_{n,\gamma} \cap \{M_n(\theta) \leq (D \log n)^{1/2}\}$ which has probability

$$\begin{aligned}
\mathbb{P}(A_{n,\gamma} \cap \{M_n(\theta) \leq (D \log n)^{1/2}\}) &= 1 - \mathbb{P}(A_{n,\gamma}^c \cup \{M_n(\theta) \geq (D \log n)^{1/2}\}) \\
&\geq 1 - \mathbb{P}(A_{n,\gamma}^c) - \mathbb{P}(M_n(\theta) \geq (D \log n)^{1/2}) \\
&= \mathbb{P}(A_{n,\gamma}) + \mathbb{P}(M_n(\theta) \leq (D \log n)^{1/2}) - 1 \\
&\geq 1 - \frac{1}{2(n+2)^{\gamma-2}} - \left(\frac{n+1}{n^D}\right)^2 \\
&\geq 1 - \frac{1}{(n+2)^{\gamma-2}} \geq 1 - \frac{1}{n^{\gamma-2}},
\end{aligned}$$

where we used that by Lemma A.1, for any fixed $D > 1$ we have $\mathbb{P}(M_n(\theta) \leq (D \log n)^{1/2}) \geq 1 - (\frac{n+1}{n^D})^2$ and by Lemma A.2 for any $\gamma > 2$ we have $\mathbb{P}(A_{n,\gamma}) > 1 - \frac{1}{2(n+2)^{\gamma-2}}$. The last two inequalities come from choosing $\gamma = D$ sufficiently large.

Analogously one can show that on $\{M_n \leq (D \log n)^{1/2}\}$,

$$\sup_{u \in \mathcal{U}_n} (S_\theta(u) - \widehat{S}_\theta(u)) \leq (n\delta_n)^{-1/2} (D \log n)^{1/2} + C_1\delta_n^\alpha = C\rho_n^{\alpha/(2\alpha+1)},$$

with the same constant C and with the same probability tail. \square

A.3 Proof of Theorem 4.11

Fix $k \geq 2$ and define $n_k = |I_k|$ and $\tilde{n}_k = |\tilde{I}_k|$ and $a_k = |E_k| = n_k + \tilde{n}_k$. Let $S_0(p | x) \triangleq S_0(p - \theta_0^\top x)$ and $\widehat{S}_k(p | x) \triangleq \widehat{S}_k(p - \theta_k^\top x)$. For the exploration phase $\mathbb{E}[\sum_{t \in E_k} r_t(p_t^*) - r_t(p_t)] \leq p_{\max}|E_k| \lesssim |E_k|$. Now fix $t \in E'_k$

$$\begin{aligned}
&r_t(p_t^*) - r_t(p_t) \\
&= p_t^* S_0(p_t^* | x_t) - p_t S_0(p_t | x_t) \\
&= \left\{ p_t^* S_0(p_t^* | x_t) - p_t^* \widehat{S}_k(p_t^* | x_t) \right\} + \underbrace{\left\{ p_t^* \widehat{S}_k(p_t^* | x_t) - p_t \widehat{S}_k(p_t | x_t) \right\}}_{\leq 0 \text{ by Equation (6)}} + \left\{ p_t \widehat{S}_k(p_t | x_t) - p_t S_0(p_t | x_t) \right\} \\
&\leq p_{\max} \left| S_0(p_t^* | x_t) - \widehat{S}_k(p_t^* | x_t) \right| + p_{\max} \left| \widehat{S}_k(p_t | x_t) - S_0(p_t | x_t) \right| \\
&= R_{k,t}(p_t^*) + R_{k,t}(p_t),
\end{aligned} \tag{9}$$

where $R_{k,t}(q) \triangleq |\widehat{S}_k(q - \widehat{\theta}_k^\top x_t) - S_0(q - \theta_0^\top x_t)|$ for $q \in \{p_t^*, p_t\}$, $t \in E'_k$.

Lemma A.3. *If Assumptions in Theorem 4.11 hold, for k sufficiently large we have $\mathbb{E}(R_{k,t}(q)) \lesssim \left(\log \widetilde{n}_k / \widetilde{n}_k\right)^{\alpha/2\alpha+1} + (d \log n_k / n_k)^{\alpha/2}$ for $q \in \{p_t^*, p_t\}$ with $t \in E'_k$.*

Let $k \geq k_0$ for k_0 be sufficiently large as in Lemma A.3. Summing up for all $t \in E'_k$, yields that

$$\mathbb{E} \left[\sum_{t \in E'_k} r_t(p_t^*) - r_t(p_t) \right] \lesssim |E'_k| \left[\left(\log \widetilde{n}_k / \widetilde{n}_k\right)^{\alpha/2\alpha+1} + (d \log n_k / n_k)^{\alpha/2} \right].$$

Merging with the exploration phase of episode k we get

$$\mathbb{E} \left[\sum_{t \in \mathcal{J}_k} r_t(p_t^*) - r_t(p_t) \right] \lesssim |E_k| + |E'_k| \left[\left(\log \widetilde{n}_k / \widetilde{n}_k\right)^{\alpha/2\alpha+1} + (d \log n_k / n_k)^{\alpha/2} \right].$$

Using that $n_k = \widetilde{n}_k = \frac{1}{2}a_k = \frac{1}{2}|E_k| = \frac{1}{2}d^\xi(\tau_1 2^{k-1})^\nu \propto d^\xi 2^{k\nu}$ for $\xi, \nu > 0$ to be determined such that they minimize the total regret, and that $|E'_k| \leq |\mathcal{J}_k| = \tau_1 2^{k-1} \propto 2^k$ we get that the RHS of the last inequality is

$$\begin{aligned} \mathbb{E} \left[\sum_{t \in E'_k} r_t(p_t^*) - r_t(p_t) \right] &\lesssim d^\xi 2^{k\nu} + 2^k \left[\left(\frac{\log(d^\xi 2^{k\nu})}{d^\xi 2^{k\nu}}\right)^{\alpha/2\alpha+1} + \left(\frac{d \log(d^\xi 2^{k\nu})}{d^\xi 2^{k\nu}}\right)^{\alpha/2} \right] \\ &\lesssim d^\xi 2^{k\nu} + 2^k \left(\frac{\log(d^\xi 2^{k\nu})}{d^\xi 2^{k\nu}}\right)^{\alpha/2\alpha+1} + 2^k \left(\frac{d \log(d^\xi 2^{k\nu})}{d^\xi 2^{k\nu}}\right)^{\alpha/2} \\ &\lesssim d^\xi 2^{k\nu} + d^{-\frac{\xi\alpha}{2\alpha+1}} 2^{k(1-\frac{\nu\alpha}{2\alpha+1})} [k + \log(d)]^{\frac{\alpha}{2\alpha+1}} + d^{\frac{\alpha}{2}(1-\xi)} 2^{k(1-\frac{\nu\alpha}{2})} [k + \log(d)]^{\frac{\alpha}{2}}. \end{aligned}$$

The exponents of the factor d are $\xi, -\frac{\xi\alpha}{2\alpha+1}$ and $\frac{\alpha}{2}(1-\xi)$. As the second exponent is always negative we equalize the first and the third exponent, i.e. $\xi = \frac{\alpha}{2}(1-\xi)$ to get $\xi^* = \frac{\alpha}{\alpha+2}$. The exponents of the exponential factor 2^k are $\nu, 1 - \frac{\nu\alpha}{2\alpha+1}$ and $1 - \frac{\nu\alpha}{2}$. Equalizing the first two factors, we get $\nu^* = \frac{2\alpha+1}{3\alpha+1}$, however $\nu^* > (1 - \frac{\nu^*\alpha}{2})$ for $\alpha > 1/2$, is equal for $\alpha = 1/2$ and less for $\alpha < 1/2$. Then for $\alpha \geq 1/2$ we equalizing the first and last factors, obtaining $\nu = 1 - \frac{\nu\alpha}{2}$ to get $\nu^* = \frac{2}{2+\alpha}$.

Case $\alpha > 1/2$. The expected regret in episode k , $\mathbb{E} [\sum_{t \in \mathcal{J}_k} r_t(p_t^*) - r_t(p_t)]$ is upper bounded by

$$2^k \frac{2\alpha+1}{3\alpha+1} (d^{\frac{\alpha}{\alpha+2}} + d^{-\frac{\alpha^2}{(2\alpha+1)(\alpha+2)}} [k + \log(d)]^{\frac{\alpha}{2\alpha+1}} + d^{\frac{\alpha}{\alpha+2}} [k + \log(d)]^{\frac{\alpha}{2}}) \lesssim 2^k \frac{2\alpha+1}{3\alpha+1} d^{\frac{\alpha}{\alpha+2}} [k + \log(d)]^{\frac{\alpha}{2}},$$

where we used that $\frac{\alpha}{2\alpha+1} < \frac{\alpha}{2}$ for $\alpha \in (1/2, 1]$. Putting together the phases we get

$$R(T) = \mathbb{E} \left[\sum_{k=k_0}^K \sum_{t \in \mathcal{J}_k} r_t(p_t^*) - r_t(p_t) \right] \lesssim 2^K \frac{2\alpha+1}{3\alpha+1} d^{\frac{\alpha}{\alpha+2}} [K + \log(d)]^{\frac{\alpha}{2}} \lesssim T^{\frac{2\alpha+1}{3\alpha+1}} d^{\frac{\alpha}{\alpha+2}} \log^{\frac{\alpha}{2}}(dT),$$

where we used that $K = \lceil \log(T/\tau_1) + 1 \rceil$.

Case $\alpha \leq 1/2$. The expected retreat in episode k , $\mathbb{E} [\sum_{t \in \mathcal{J}_k} r_t(p_t^*) - r_t(p_t)]$, is upper bounded by

$$2^k \frac{2}{2+\alpha} (d^{\frac{\alpha}{\alpha+2}} + d^{-\frac{\alpha^2}{(2\alpha+1)(\alpha+2)}} [k + \log(d)]^{\frac{\alpha}{2\alpha+1}} + d^{\frac{\alpha}{\alpha+2}} [k + \log(d)]^{\frac{\alpha}{2}}) \lesssim 2^k \frac{2}{2+\alpha} d^{\frac{\alpha}{\alpha+2}} [k + \log(d)]^{\frac{\alpha}{2\alpha+1}},$$

where we used that $\frac{\alpha}{2\alpha+1} \geq \frac{\alpha}{2}$ for $\alpha \in (0, 1/2]$. Putting together the phases we get

$$R(T) = \mathbb{E} \left[\sum_{k=k_0}^K \sum_{t \in \mathcal{J}_k} r_t(p_t^*) - r_t(p_t) \right] \lesssim 2^K \frac{2}{2+\alpha} d^{\frac{\alpha}{\alpha+2}} [K + \log(d)]^{\frac{\alpha}{2\alpha+1}} \lesssim T^{\frac{2}{2+\alpha}} d^{\frac{\alpha}{\alpha+2}} \log^{\frac{\alpha}{2\alpha+1}}(dT),$$

where we used that $K = \lceil \log(T/\tau_1) + 1 \rceil$, which concludes the proof.

A.4 Proof of Lemma A.3

Let $n_k = |I_k|$ and $\tilde{n}_k = |\tilde{I}_k|$ and $t \in E'_k$. Define the event $\mathcal{E}_k = \{\|\hat{\theta}_k - \theta_0\| \leq R_{n_k}\}$ where we recall

$$R_{n_k} \propto \sqrt{\frac{d \log n_k}{n_k}},$$

as defined in Lemma 4.3, and

$$R_{k,t}(q) = |\hat{S}_k(q - \hat{\theta}_k^\top x_t) - S_0(q - \theta_0^\top x_t)|, \quad q \in \{p_t, p_t^*\}.$$

Recall that

$$\hat{\theta}_k = \text{OLS}\{(x_t, y_t)\}_{t \in I_k}, \quad \hat{S}_k = \text{Antitonic}\{(w_t, y_t)\}_{t \in \tilde{I}_k},$$

and define $S_k = S_{\hat{\theta}_k}$, where by definition in Equation (7)

$$S_k(u) = S_{\hat{\theta}_k}(u) = \mathbb{E}_x[S_0(u + (\hat{\theta}_k - \theta_0)^\top x)].$$

Now let $q \in \{p_t, p_t^*\}$ for some $t \in E'_k$. We can write

$$R_{k,t}(q) = R_{k,t}(q)\mathbb{I}(\mathcal{E}_k) + R_{k,t}(q)\mathbb{I}(\mathcal{E}_k^c).$$

Analyzing the $R_{k,t}(q)\mathbb{I}(\mathcal{E}_k^c)$:

By Lemma 4.3 we have $\mathbb{E}[R_{k,t}(q)\mathbb{I}(\mathcal{E}_k^c)] \leq 2\mathbb{P}(\mathcal{E}_k^c) = Q_{n_k} = 2e^{-c_1 c_{\min}^2 n_k / 16} + \frac{2}{n_k}$.

Analyzing the $R_{k,t}(q)\mathbb{I}(\mathcal{E}_k)$:

$R_{k,t}(q)$ is less or equal than two times

$$\underbrace{|\hat{S}_k(q - \hat{\theta}_k^\top x_t) - S_k(q - \hat{\theta}_k^\top x_t)|\mathbb{I}(\mathcal{E}_k)}_{=A} + \underbrace{|S_k(q - \hat{\theta}_k^\top x_t) - S_k(q - \theta_0^\top x_t)|\mathbb{I}(\mathcal{E}_k)}_{=B} + \underbrace{|S_k(q - \theta_0^\top x_t) - S_0(q - \theta_0^\top x_t)|\mathbb{I}(\mathcal{E}_k)}_{=C} \quad (10)$$

Analyzing A on \mathcal{E}_k : Define the event $\mathcal{S}_k = \{\sup_{u \in \mathcal{U}} |\hat{S}_k(u) - S_k(u)| \leq C \rho_{n_k}^{\alpha/(2\alpha+1)}\}$, where $\rho_n = \log(n)/n$. For n_k sufficiently large, by Theorem 4.8 we have that

$$\begin{aligned} \mathbb{E}(A) &= \mathbb{E}(A\mathbb{I}(\mathcal{S}_k \cap \mathcal{E}_k)) + \mathbb{E}(A\mathbb{I}(\mathcal{S}_k^c \cap \mathcal{E}_k)) \\ &\leq \mathbb{E}\left(\sup_{u \in \mathcal{U}} |\hat{S}_k(u) - S_k(u)|\mathbb{I}(\mathcal{S}_k \cap \mathcal{E}_k)\right) + 2\mathbb{P}(\mathcal{S}_k^c)\mathbb{P}(\mathcal{E}_k) \\ &\lesssim C \left(\frac{\log \tilde{n}_k}{\tilde{n}_k}\right)^{\alpha/(2\alpha+1)} \mathbb{P}(\mathcal{S}_k \cap \mathcal{E}_k) + 2\mathbb{P}(\mathcal{S}_k^c) \\ &\lesssim \left(\frac{\log \tilde{n}_k}{\tilde{n}_k}\right)^{\alpha/(2\alpha+1)} + 2\frac{1}{\tilde{n}_k^{\gamma-2}} \\ &\lesssim \left(\frac{\log \tilde{n}_k}{\tilde{n}_k}\right)^{\alpha/(2\alpha+1)}, \end{aligned}$$

where we chose $\gamma \geq 3$.

Analyzing B on \mathcal{E}_k : By Proposition 4.6, S_k is α -Hölder, then $\mathbb{E}[B\mathbb{I}(\mathcal{E}_k)] \lesssim \|\hat{\theta}_k - \theta_0\|_2^\alpha \leq R_{n_k}^\alpha$.

Analyzing C on \mathcal{E}_k : By Proposition 4.6 we have $|S_k(u) - S_0(u)|\mathbb{I}(\mathcal{E}_k) \lesssim \|\hat{\theta}_k - \theta_0\|_2^\alpha \leq R_{n_k}^\alpha$.

Combining the terms $R_{k,t}(q)\mathbb{I}(\mathcal{E}_k^c)$ and $R_{k,t}(q)\mathbb{I}(\mathcal{E}_k)$ from Equation (10): we get

$$\sup_q R_{k,t}(q) \lesssim \left(\frac{\log \tilde{n}_k}{\tilde{n}_k}\right)^{\alpha/(2\alpha+1)} + \left(\frac{d \log n_k}{n_k}\right)^{\alpha/2}.$$

B Additional Plots of Section 5.1

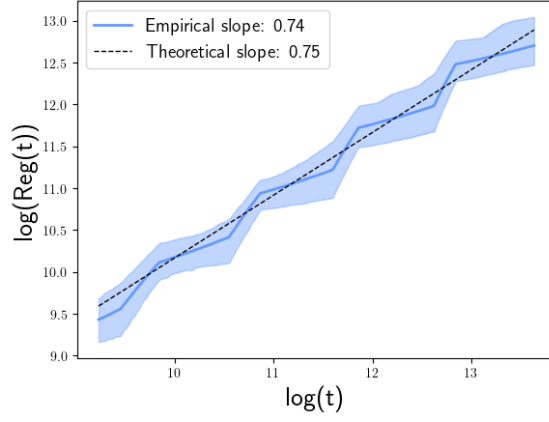

Figure 6: This plot was generated using as true F_0 the one considered in [Fan et al. \(2021\)](#) with density $f_0(z) = 6 \left(\frac{1}{4} - z^2\right) \mathbf{1}\{z \in (-1/2, 1/2)\}$. We repeated the simulation 36 times and the corresponding 95% confidence interval. The plot is in \log_2 - \log_2 scale to show the regret rate (empirical slope): a slope of η indicated an $\mathcal{O}(T^\eta)$ regret. The black dashed line corresponds to our theoretical regret upper bound of $3/4$. The estimated slope is very close to that value.
