

SFESS: SCORE FUNCTION ESTIMATORS FOR k -SUBSET SAMPLING

Anonymous authors

Paper under double-blind review

ABSTRACT

Are score function estimators a viable approach to learning with k -subset sampling? Sampling k -subsets is a fundamental operation in machine learning that is not amenable to differentiable parametrization, impeding gradient-based optimization. Prior work has focused on relaxed sampling or approximate pathwise gradients but dismissed score function estimators due to their high variance. Inspired by the success of score function estimators in variational inference and reinforcement learning, we revisit them within the context of k -subset sampling. Specifically, we demonstrate how to efficiently compute the k -subset distribution’s score function using a discrete Fourier transform, and reduce the estimator’s variance with control variates. The resulting estimator provides *both* exact samples and unbiased gradient estimates while being applicable to non-differentiable downstream models, unlike existing methods. We validate our approach in multiple experimental settings and find that comparable results can be achieved to recent state-of-the-art relaxed and approximate pathwise gradient methods, across all tasks.

1 INTRODUCTION

Subsets are essential in tasks such as feature selection (Bahin et al., 2019; Huijben et al., 2019; Yamada et al., 2020), optimal sensor placement (Manohar et al., 2018), learning to explain (Chen et al., 2018), stochastic k -nearest neighbors (Grover et al., 2019), and system identification (Brunton et al., 2016). Therefore, understanding and effectively manipulating subsets is an important step in improving machine methods that model discrete phenomena.

A cornerstone of modern machine learning is efficient optimization, typically achieved through differentiable models optimized via stochastic gradient descent. However, not all operations are differentiable, necessitating approximate differentiation to leverage gradient-based optimization. This includes discrete sampling, and thus k -subset sampling which is not amenable to the reparametrization trick (Kingma & Welling, 2014).

Differentiable optimization of Bernoulli and categorical distributions have been extensively studied (Bengio et al., 2013; Jang et al., 2017; Maddison et al., 2017; Dimitriev & Zhou, 2021; De Smet et al., 2023; Liu et al., 2023). These distributions are less structured than subset distributions and do not share their combinatorially large support. Still, the methods employed in their optimization serve as a blueprint for more structured distributions. Existing approaches for differentiable subset sampling (Xie & Ermon, 2019; Ahmed et al., 2023; Pervez et al., 2023) use either relaxed sampling methods or approximate pathwise gradient estimators. While these methods are effective, they produce relaxed samples (which cannot be used in all settings) and biased gradient estimates respectively (see fig. 1). This paper seeks to address these limitations by revisiting score function estimators (Glynn, 1990; Williams, 1992; Kleijnen & Rubinstein, 1996), a technique well-established in reinforcement learning (Sutton et al., 1999) and variational inference (Ranganath et al., 2014), but overlooked for subset sampling. In this work, we cover the aforementioned research gap by posing the following question:

Can we enjoy the benefits of score function estimators and obtain similar results to recent relaxed and approximate pathwise gradient estimators in k -subset sampling?

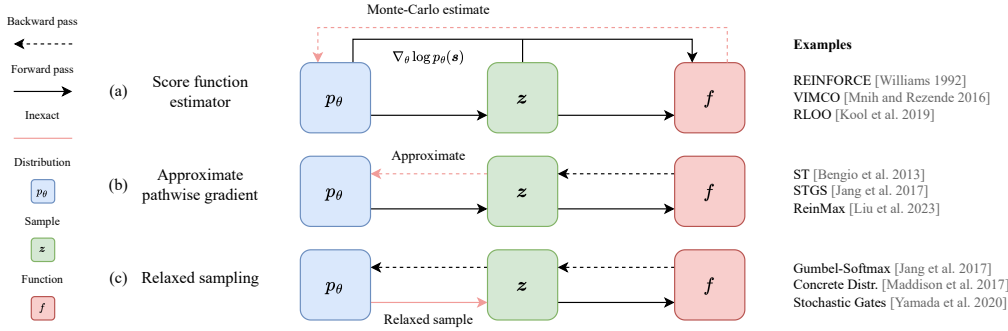

Figure 1: **Gradient estimation for discrete distributions.** Three prominent approaches to gradient estimation for discrete distributions: (a) approximate score function estimator, (b) pathwise gradient estimator, and (c) relaxed sampling. The examples listed estimate the gradients of Bernoulli samples, categorical samples, or both. We propose a score function estimator for k -subset sampling to complement existing methods based on approximate pathwise derivatives and relaxed sampling (see section 5). Because it does not use the pathwise gradient, it is applicable in cases when f is non-differentiable.

We propose score function estimators for k -subset sampling (SFESS) as a *complement* to existing methods. Our proposed approach fundamentally differs from prior works on k -subset sampling (see table 1), offering both exact samples and unbiased gradient estimates. Furthermore, it does not assume differentiable downstream models, broadening the possible applications of k -subset sampling to cases when the downstream model’s gradient is unavailable or computationally expensive.

In addition to the complementary advantages of our proposed approach, our research question holds significant relevance to the field, as previous work advises against the use of score function estimators for k -subset selection due to their high variance (Xie & Ermon, 2019; Niepert et al., 2021; Ahmed et al., 2023). Thus, illustrating the potential of this family of methods could facilitate further progress in a direction that is currently overlooked in the field.

To realize our proposal, we develop an efficient method for computing the score function based on the discrete Fourier transform (DFT) for computing the Poisson binomial distributions’ probability density function (Fernandez & Williams, 2010). Furthermore, we use control variates to significantly reduce the high variance of the vanilla score function estimator. In summary, our contributions are the following:

- **Research gap.** We identify and address a significant research gap in k -subset sampling where score function estimators are not being considered despite their conceptual simplicity, desirable properties, and broad applicability.
- **Approach.** We propose a score function estimator for the k -subset distribution featuring an efficient DFT-based score function calculation and reduced variance using multi-sample control variates.
- **Results.** We validate our approach in multiple experimental settings and find comparable results to state-of-the-art relaxed and approximate pathwise gradient methods, signifying the potential of score function estimators for k -subset selection.

2 PROBLEM STATEMENT AND MOTIVATION

The gradient estimation problem We are interested in learning with k -subset sampling using the following gradient:

$$\nabla_{\theta} \mathbb{E}_{p_{\theta,k}(z)} [f(z)], \quad (1)$$

where $p_{\theta,k}$ is a parameterized distribution over subsets with size k and f is a downstream function of the subset samples. In practice, f will often be a parameterized function with additional inputs besides z . The discrete distribution over subsets is not amenable to the reparametrization trick (Kingma & Welling, 2014) which motivates the development of alternative gradient estimators for eq. (1).

Table 1: **Method comparison.** Comparison of methods for learning with k -subset sampling based on the criteria: producing exact (k -hot) samples, having unbiased gradient estimates (a desirable property in statistical estimators), compatibility with non-differentiable objectives f , and being free from parameters requiring tuning (e.g. relaxation temperature, which may require multiple training runs to adjust). Insensitive parameters like the number of samples used for variance reduction are not considered tuned.

Method	Exact samples	Unbiased	Non-differentiable f	Tuning-free

Figure 2: **Toy problem comparison.** Bias and variance (left) and error (right) of gradient estimates in a toy problem (Ahmed et al., 2023) with known ground-truth gradients. All methods use single sample estimates, except SFESS + VR, where control variates are computed using 32 samples. Estimates are computed using 10,000 samples, with error bars (1 std) from 10 repetitions with different random seeds.

Existing approaches and their limitations Existing approaches to learning with k -subset sampling generally fall into one of two categories: relaxed sampling or approximate gradient methods. Approximate pathwise gradient methods directly modify the gradient calculation. The best-known example is the straight-through estimator (Bengio et al., 2013) which treats the sampling as an identity function during the backward pass. Recently, Liu et al. (2023) showed that straight-through estimation works as a first-order approximation of the gradient for Bernoulli and categorical samples. However, these approximate estimators tend to produce biased gradients. Relaxed sampling methods replace the distribution with a relaxed distribution so that the reparametrization trick (Kingma & Welling, 2014) can be used to obtain a gradient. These are gradients of the relaxed samples, not the original discrete distribution. Regardless, these gradients can be used to train a model that is used with discrete samples at test time. Although this approach can often be effective, there are two main limitations: (1) it requires the use of relaxed samples in place of discrete samples (which may not be possible depending on f), and (2) the model trained with relaxed sampling is not guaranteed to generalize to discrete samples at test time. Figure 1 shows the forward- and backward-passes of the two approaches and how they differ from score function estimators. For in-depth reviews of Monte-Carlo gradient estimators and the Gumbel-max trick, we refer the reader to Mohamed et al. (2020) and Huijben et al. (2023) respectively.

Why use black-box gradient estimates? A natural question to ask is what potential benefits black-box gradient estimates like score function estimators provide. Although discarding the pathwise gradient theoretically reduces the dimensionality of gradient information by one (Metz et al., 2021; Liu et al., 2023), it also allows for non-differentiable downstream functions. Interestingly, Metz et al. (2021) find that the variance of black-box estimates is not necessarily higher than for pathwise estimators. Furthermore, black-box estimators have been used extensively in settings like variational inference (Ranganath et al., 2014) and reinforcement learning (Sutton et al., 1999) where they form the basis for algorithms like PPO (Schulman et al., 2017). In table 1 we summarize the desirable properties of our proposed method and compare it to existing methods.

¹NCPSS draws k -hot samples, but relaxes the subset size k such that k varies slightly.

3 METHOD

We are interested in devising a black-box gradient estimator for k -subset sampling with efficacy similar to the existing techniques. Here, we describe our method including how to compute the score function and reduce its variance with control variables. The resulting algorithm is presented in alg. 2 along with Gumbel top- k sampling (Kool et al., 2019b) in alg. 1 for k -subset sampling.

Overview We are interested in sampling subsets z of size k given a set of n variables. We consider the following conditional distribution:

$$p_{\theta,k}(z) = p_{\theta}(b \mid \sum_{i=1}^n b_i = k) = \frac{\prod_{i=1}^n p_{\theta}(b_i)}{p_{\theta}(\sum_{i=1}^n b_i = k)} \mathbb{1}[\sum_{i=1}^n b_i = k], \quad (2)$$

where $b \in \{0, 1\}^n$ is independently Bernoulli distributed with parameters $\theta \in [0, 1]^n$ and $\mathbb{1}[\cdot]$ denotes the indicator function. This equation induces a particular distribution over the $\binom{n}{k}$ possible subsets using only n parameters.

Previous work has explored approximate derivatives of this distribution’s samples (Xie & Ermon, 2019; Ahmed et al., 2023). In this work, we instead consider score function estimators that are *exact* in expectation. Hence, we want to compute the score function defined on the region where $\sum_{i=1}^n b_i = k$,

$$\nabla_{\theta} \log p_{\theta,k}(z) = \sum_{i=1}^n \nabla_{\theta} \log p_{\theta}(b_i) - \nabla_{\theta} \log p_{\theta}(\sum_{i=1}^n b_i = k). \quad (3)$$

Computing the first term is easy, since each $p_{\theta}(b_i)$ is Bernoulli distributed. The second term appears more challenging. Importantly, it follows a Poisson binomial distribution, a generalized binomial distribution where the samples are not necessarily identically distributed. Several efficient methods for computing the Poisson binomial’s density function have been developed, including approximate and recursive methods (Le Cam, 1960; Wadycki et al., 1973; Ahmed et al., 2023). We follow Fernandez & Williams (2010) and compute it using a DFT (Cooley & Tukey, 1965)—leveraging its $\mathcal{O}(n \log n)$ time-complexity and efficient implementation on modern hardware². The gradient of the log probability is computed using automatic differentiation.

Now, being able to compute the score function in eq. (3), we can write the following score function estimator:

$$\begin{aligned} \nabla_{\theta} \mathbb{E}_{p(x)} \mathbb{E}_{p_{\theta,k}(z)} [f(z, x)] &= \mathbb{E}_{p(x)} \mathbb{E}_{p_{\theta,k}(z)} [\nabla_{\theta} \log p_{\theta,k}(z) f(z, x)] \\ &\approx \frac{1}{NM} \sum_{i=1}^N \sum_{j=1}^M \nabla_{\theta} \log p_{\theta,k}(z^{(j)}) f(z^{(j)}, x^{(i)}), \end{aligned} \quad (4)$$

where N samples $x^{(i)} \sim p(x)$ are sampled from the training data and M k -subset samples $z^{(j)} \sim p_{\theta,k}(z)$ are used in the Monte-Carlo estimate of the expectations in eq. (4). For completeness, we derive the standard score function estimator in appendix A.

Efficiently computing the score function The second term of eq. (3) follows a Poisson binomial distribution. The likelihood of which can be written as:

$$p_{\theta}(\sum_{i=1}^n b_i = k) = \sum_{b \in \{0,1\}^n} \mathbb{1}[\sum_{i=1}^n b_i = k] p_{\theta}(b). \quad (5)$$

Naïvely computing the likelihood using eq. (5) requires iterating all 2^n binary vectors b which is prohibitively expensive. Instead, we look for a more efficient method. Fernandez & Williams (2010) derive this closed-form expression using the discrete Fourier transform:

$$p_{\theta}(\sum_{i=1}^n b_i = k) = \frac{1}{n+1} \text{DFT}_k \left(\prod_{i=1}^n p_{\theta}(b_i) e^{2\sqrt{-1}\pi/(n+1)} + (1 - p_{\theta}(b_i)) \right). \quad (6)$$

Note that this expression is solely a function of θ and k which means we can cache any repeated calls when computing eq. (3) with different subsets z with the same size k . This is a common occurrence in e.g. instancewise feature selection (Chen et al., 2018), where a new z is evaluated for each example x .

²We use the Nvidia cuFFT implementation in PyTorch. See appendix B for pseudocode.

Algorithm 1 Subset sampling using Gumbel top- k **Require:** Subset parameters θ and size k

- 1: Sample noise $g_i \sim \text{Gumbel}(0, 1)$ for $i \in [n]$
- 2: Compute $z \leftarrow \text{ArgTopK}(\log \theta + g, k)$ ▷ A k -hot vector
- 3: **return** z

Algorithm 2 SFESS + VR: Score function estimator for k -subset sampling with variance reduction**Require:** Initial subset parameters θ and size k , training data \mathcal{D} batch size N , and number of variance reduction samples M

- 1: **repeat**
- 2: Sample data $x^{(i)} \sim \mathcal{D}$ for $i \in [N]$
- 3: Sample subsets $z^{(j)} \sim p_{\theta,k}(z)$ for $j \in [M]$ ▷ Or conditionally with e.g. $p_{\theta,k}(z|x)$
- 4: Compute the Poisson-Binomial likelihood $\log p_{\theta} \left(\sum_{i=1}^n b_i^{(j)} = k \right)$ using eq. (6)
- 5: Compute the score function $\nabla_{\theta} \log p_{\theta,k}(z^{(j)})$ using eq. (3) and autodiff
- 6: Evaluate $f(x^{(i)}, z^{(j)})$ for $i, j \in [N] \times [M]$
- 7: Optimize parameters θ using the variance-reduced gradients in eq. (7)
- 8: **until** convergence ▷ Number of steps, threshold, etc.
- 9: **return** θ

Reducing variance with control variates The vanilla score function estimator generally suffers from high variance. While many variance reduction techniques have been proposed (Mnih & Gregor, 2014; Gu et al., 2016; Tucker et al., 2017; Shi et al., 2022), we choose to employ control variates using multiple samples (Mnih & Rezende, 2016; Kool et al., 2019a) in this work due to its simplicity, unbiasedness, and lack of additional assumptions. In section 4, we will see that this straightforward approach proves highly effective. The estimator with reduced variance is shown below:

$$\begin{aligned} \nabla_{\theta} \mathbb{E}_{p(x)} \mathbb{E}_{p_{\theta,k}(z)} [f(z, x)] &\approx \frac{1}{NM} \sum_{i=1}^N \sum_{j=1}^M \nabla_{\theta} \log p_{\theta,k}(z^{(j)}) \\ &\cdot \left(f(z^{(j)}, x^{(i)}) - \frac{1}{M-1} \sum_{k \neq j} f(z^{(k)}, x^{(i)}) \right). \end{aligned} \quad (7)$$

Conditional distributions and parameterized f Conditional k -subset distributions $p_{\theta}(z|x)$ are a useful extension of the model presented above that do not change the gradient estimator (the estimated gradients are simply backpropagated through the conditioning variable). Similarly, parameterized functions f are easily incorporated and optimized alongside the k -subset distribution’s parameters. We investigate both conditional distribution and neural-network parameterized functions in our experiments (section 4).

4 EXPERIMENTS

In this section, we validate our proposed estimator in three main experimental settings: feature selection, variational autoencoders (VAE), and stochastic k -nearest-neighbors (k -NN). In this set of problems, the k -subset distribution is used in various ways: as the first operation in feature selection, as the mid-point bottleneck in a VAE, and in computing the final loss in stochastic k -NN.

We use MNIST (LeCun et al., 1998) and FASHION MNIST (Xiao et al., 2017) with the canonical train and test splits. We withhold 10,000 samples from the train set for validation. For all training, we use a batch size of 128 and train for 50,000 steps using the Adam optimizer (Kingma & Ba,

Figure 3: **Variance reduction and gradient error.** The cosine difference of the true gradient and the estimated gradient using SFESS + VR with different numbers of variance reduction samples (shown in parentheses) on the toy problem with known gradients. No VR corresponds to the vanilla SFESS estimator. Estimates are computed using 10,000 samples, with error bars (1 std) from 10 repetitions with different random seeds.

2015) with a learning rate of $1e-4$ and parameters $\beta_1 = 0.9$ and $\beta_2 = 0.999$. We compare our proposed method with variance reduction (SFESS + VR) using 32 variance reduction samples to relaxed subset sampling (GS) and its straight-through variant (STGS) (Xie & Ermon, 2019), implicit maximum likelihood estimation (I-MLE) (Niepert et al., 2021), SIMPLE (Ahmed et al., 2023), and SFESS without variance reduction. For ST and STGS we use the relaxation temperature $\tau = 0.5$, which gave the best overall results out of $\tau \in \{0.1, 0.5, 1.0\}$. For I-MLE, we set both the input and target noise temperature to 1.0. As noted in table 1, SIMPLE and our method have no hyperparameters in need of tuning.

4.1 TOY PROBLEM

First, we consider a simple toy setting with known ground-truth gradients. We adapt the toy problem in Ahmed et al. (2023)³ where the gradient estimator is used to minimize $\mathbb{E}_{p_\theta(z)}[\|z - \theta^*\|^2]$ where θ^* are the ground-truth parameters sampled from a standard normal distribution. Using $n = 10$ and $k = 5$ lets us enumerate all $\binom{10}{5} = 256$ subsets and compute the ground-truth gradient. Figure 2 shows the estimated bias, variance, and error ($1 - \text{cosine similarity}$ compared to ground-truth) of the different estimators. Figure 3 shows the decreasing error of SFESS + VR as the number of variance reduction samples increases.

4.2 FEATURE SELECTION

Sampling a subset of inputs and estimating the gradients (Baln et al., 2019; Huijben et al., 2019; Yamada et al., 2020) is an intuitive approach to differentiable feature selection. By being differentiable, the selection can be jointly optimized alongside a downstream network. We consider feature selection for reconstruction and where a reconstruction network ($28^2 \rightarrow 200 \rightarrow 28^2$ dense ReLU network) predicts the full set of input features inputs masked by the sampled subset and both the subset parameters and reconstruction network are optimized using the reconstruction loss (binary cross entropy). Table 2 shows our results and fig. 4 the convergence of the validation loss.

4.3 VARIATIONAL AUTOENCODERS

Variational Autoencoders (Kingma & Welling, 2014) with latent variables distributed over k -subsets has been used as a benchmark in previous work on learning with k -subset sampling (Niepert et al., 2021; Ahmed et al., 2023). We use the approximate ELBO and network architecture of Niepert et al. (2021). The encoder ($28^2 \rightarrow 512 \rightarrow 256 \rightarrow nd$ dense ReLU network) encodes the input. The outputs are reshaped to $(d \times d)$. Then, d k -subset sample of length n are drawn and decoded by the decoder ($d^2 \rightarrow 256 \rightarrow 512 \rightarrow 28^2$ dense ReLU network). The loss is the sum of a reconstruction loss (binary cross entropy) and the KL-divergence between each latent distribution and a uniform prior. Examples of the encoding and decoding results are shown in fig. 8. Table 3 shows our results and fig. 5 the convergence of the validation loss. Finally, the wall-clock time is shown in fig. 7.

³Code available at <https://github.com/UCLA-StarAI/SIMPLE>.

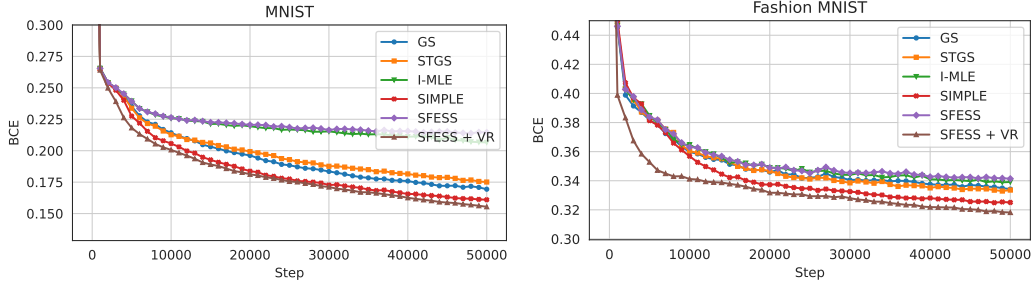

Figure 4: **Feature selection validation loss.** Convergence of BCE on the validation set for feature selection with $k = 30$ selections (see appendix C for $k = 50$) averaged over 5 repetitions with different random seeds. The results follow the trend in the toy experiment (see fig. 2).

Figure 5: **VAE validation loss.** Convergence of BCE + KL-divergence on the validation set with $d = 20$, $n = 20$, and $k = 10$ (see appendix C for $d = 10$, $n = 10$, and $k = 5$) averaged over 5 repetitions with different random seeds. The effect of variance reduction on SFESS is evident—going from a failure to learn useful representations to second best among the methods tested.

Table 2: **Feature selection results.** BCE on the test split. The parameters n and k are the number of inputs and the number of selections respectively. The means and standard deviations are computed from 5 repetitions with different random seeds. The best mean result is shown in **bold** and the second best mean result is underlined.

4.4 STOCHASTIC k -NEAREST-NEIGHBORS

Our final experiment is stochastic k -NN (Grover et al., 2019). Here, we learn an embedding that optimizes the classification accuracy of k -NN. During training, we sample a query point $\{\mathbf{x}_q, \mathbf{y}_q\}$ and a batch of neighbors $\{\mathbf{x}_n^i, \mathbf{y}_n^i\}_{i=1}^n$ (we use $n = 128$ in our experiments) and encode them using an encoder f_θ ($28^2 \rightarrow 512 \rightarrow 256 \rightarrow d$ dense ReLU network). Then, we compute the Euclidean distance from the query point embedding to all neighbor candidates' embeddings $\{\|\mathbf{f}_\theta(\mathbf{x}_q) - \mathbf{f}_\theta(\mathbf{x}_n^i)\|\}_{i=1}^n$

Table 3: **VAE results.** BCE + KL-divergence on the test set. The parameters d , n , and k are the number of latent subsets, their dimensionality, and size respectively. The means and standard deviations are computed from 5 repetitions with different random seeds. The best mean result is shown in **bold** and the second best mean result is underlined.

and sample a k -subset of neighbors using the distances as unnormalized logits. Finally, the negated proportion of the k -subset with the same label as the query point is used as a loss. The algorithm is slightly different at test time: we use the entire training set as candidate neighbors and compute the k -nearest-neighbors deterministically instead of sampling a k -subset. Table 4 shows the results. The convergence of accuracy on the validation set is shown in appendix C. Embeddings of the validation sets are shown in fig. 6.

5 RELATED WORK

In this section, we provide an overview of existing methods for k -subset sampling. Table 1 shows a qualitative comparison of the methods’ different properties.

Relaxed Subset Sampling (Xie & Ermon, 2019) extends the Gumbel-Softmax distribution to distributions over subsets. Despite its elegance, relaxed subset sampling inherits the biased gradient estimation of the Gumbel-Softmax estimator. Furthermore, the top- k sampling procedure sequentially applies the softmax function k times, which limits scalability with respect to k and potentially degrades performance (Pervez et al., 2023). The temperature parameter $\tau \in \mathbb{R}_{\geq 0}$ controls the relaxation strength. The relaxed samples approach uniform as $\tau \rightarrow \inf$ and k -hot as $\tau \rightarrow 0$.

SIMPLE (Ahmed et al., 2023) approximates the pathwise gradient of the sample using its exact marginals, achieving both lower bias and variance than ST Gumbel-Softmax top- k .

Figure 6: **Stochastic k -NN embeddings.** Two-dimensional embeddings ($d = 2$) of the MNIST (left) and FASHION MNIST (right) validation sets learned by optimizing the stochastic k -NN objective with $k = 10$ for 30,000 training steps. The resulting embeddings form clusters of the same class. Note that some of the samples placed between clusters are indeed ambiguous examples.

Neural Conditional Poisson Subset Sampling (NCPSS) (Pervez et al., 2023) relaxes k -subset sampling in a manner different from relaxed subset sampling (Xie & Ermon, 2019), allowing subset sizes slightly smaller and larger subsets than k . Then, pathwise gradient estimates are used for differentiable optimization. The authors show that NCPSS is more scalable than relaxed subset sampling and that the subset size k can be optimized alongside the distribution’s parameters.

Implicit Maximum Likelihood Estimation (I-MLE) (Niepert et al., 2021) uses a perturb-and-MAP approach that is applicable to general optimization problems, with subset sampling as a special case.

Other methods In some settings, a subset distribution can be modeled as either the concatenation of n Bernoulli variables or the sum of k categorical variables. This way, a host of gradient estimates for Bernoulli and categorical variables can be used (Yamada et al., 2020; Paulus et al., 2021; Dimitriev & Zhou, 2021; Shi et al., 2022; De Smet et al., 2023; Liu et al., 2023). However, neither option directly models k -subset sampling. Bernoulli variables require some constraint (e.g. a loss term) limiting the subset size, and a sum of categoricals requires nk parameters and runs the risk of duplicate inclusions (Nilsson et al., 2024). Finally, there are techniques for relaxed sampling of other structures like permutation matrices, trees, or graphs (Paulus et al., 2020).

6 CONCLUSION

In this work we identified a research gap to explore the viability of score-function estimators for learning with k -subset sampling. We devised a simple approach and showed its efficacy in a variety of tasks achieving comparable results to existing state-of-the-art. This is a significant finding not only due to the complementary properties and wider applicability of our approach but also due to its dismissal in the current literature. We believe our work will serve the field by opening up a new viable direction for further research.

Figure 7: **Wall-clock time.** The average wall clock time of a single training step (forward + backward) of the methods in table 3 (MNIST with batch size 128). Despite drawing 32 samples for variance reduction, the increase in wall time from SFESS to SFESS + VR is minor.

Figure 8: **VAE reconstruction.** The top row shows images from the MNIST validation set. The middle row shows their learned embeddings as 10 k -subsets with 10 elements and $k = 5$. Finally, the bottom row shows the reconstructions.

A DERIVING THE SCORE FUNCTION ESTIMATOR

In this appendix, we derive the score function estimator (Williams, 1992) which provides a Monte-Carlo estimate of the objective’s gradient. We adapt the proof from Mohamed et al. (2020) (with annotations added):

$$\nabla_{\theta} \mathbb{E}_{p_{\theta}(z)}[f(z)] = \nabla_{\theta} \sum_z p_{\theta}(z) f(z) \quad \text{By definition of } \mathbb{E} \quad (8)$$

$$= \sum_z \nabla_{\theta} p_{\theta}(z) f(z) \quad \text{Interchange gradient and summation}$$

$$= \sum_z p_{\theta}(z) \nabla_{\theta} \log p_{\theta}(z) f(z) \quad \text{By log derivative rule}$$

$$= \mathbb{E}_{p_{\theta}(z)}[f(z) \nabla_{\theta} \log p_{\theta}(z)] \quad \text{By definition of } \mathbb{E} \quad (9)$$

$$\approx \frac{1}{N} \sum_{i=1}^N f(z^{(i)}) \nabla_{\theta} \log p_{\theta}(z^{(i)}) \quad \text{Monte-Carlo estimate} \quad (10)$$

By the law of large numbers, the Monte-Carlo estimator in eq. (10) converges to the expected value in eq. (9) as $N \rightarrow \infty$, which is exactly the value of the true gradient in eq. (8). Hence, the estimator is an unbiased estimator of the true gradient.

B SCORE FUNCTION CALCULATION

A key component of SFESS is calculating the score function. The unconditional independent Bernoulli distribution is renormalized by the Poisson-Binomial distribution. This renormalization factor is calculated following Fernandez & Williams (2010). Listing 1 outlines this calculation in pseudocode.

Listing 1 PyTorch-style pseudocode for calculating the Poisson-Binomial PMF (Fernandez & Williams, 2010).

```
import torch
import cmath

def poibin_prob(theta, k):
    n = theta.size(0)
    i = torch.arange(n + 1).unsqueeze(-1)
    c = cmath.exp(2j * torch.pi / (n + 1))
    prod = torch.prod(theta * c**i + (1 - theta), dim=1)
    probs = torch.fft.fft(prod).real / (n + 1)
    return probs[k]
```

C ADDITIONAL LOSS CURVES

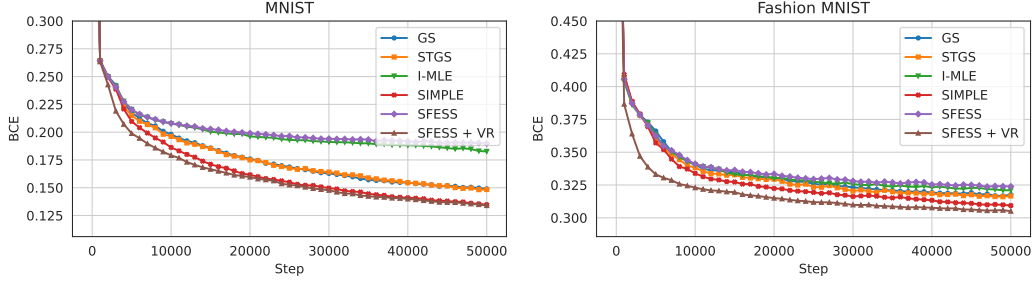

Figure 9: **Feature selection validation loss.** Convergence of BCE on the validation set for feature selection with for $k = 50$ averaged over 5 repetitions with different random seeds. The results follow the trend in the toy experiment (see fig. 2).

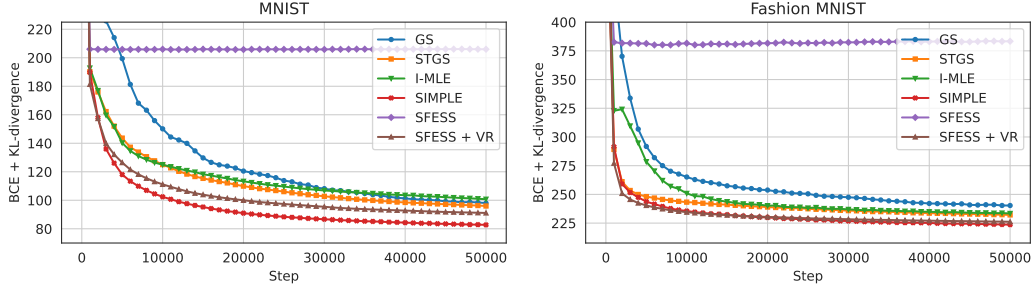

Figure 10: **VAE validation loss.** Convergence of BCE + KL-divergence on the validation set with $d = 10$, $n = 10$, and $k = 5$ averaged over 5 repetitions with different random seeds. The effect of variance reduction on SFESS is evident—going from a failure to learn useful representations to second best among the methods tested.

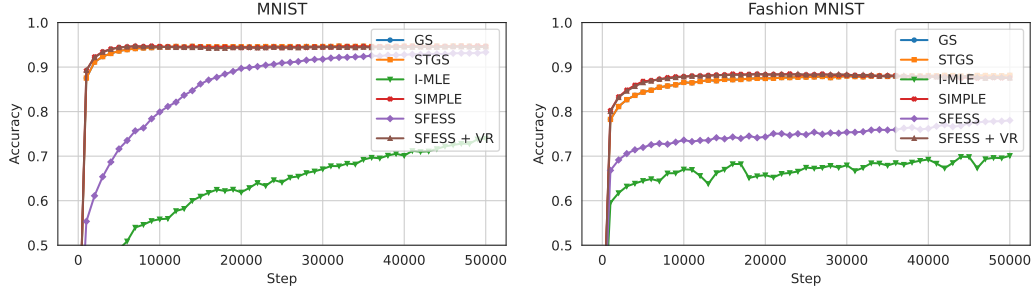

Figure 11: **k -NN validation accuracy.** Convergence of accuracy on the validation set with $d = 2$, $n = 128$, and $k = 10$ averaged over 5 repetitions with different random seeds. All methods except I-MLE and SFESS quickly converge to similar minima.
