
Data Feedback Loops: Model-driven Amplification of Dataset Biases

Rohan Taori¹ Tatsunori B. Hashimoto¹

Abstract

Datasets scraped from the internet have been critical to large-scale machine learning. Yet, its success puts the utility of future internet-derived datasets at potential risk, as model outputs begin to replace human annotations as a source of supervision. In this work, we formalize a system where interactions with one model are recorded as history and scraped as training data in the future. We then analyze its stability over time by tracking changes to a test-time bias statistic (e.g. gender bias of model predictions). We find that the degree of bias amplification is closely linked to whether the model’s outputs behave like samples from the training distribution, a behavior which we characterize and define as uniform faithfulness. Experiments in three conditional prediction scenarios – image classification, visual role-labeling, and language generation – demonstrate that models that exhibit a sampling-like behavior are more faithful and thus more stable. Based on this insight, we propose an intervention to help mitigate and stabilize unstable feedback systems.

1. Introduction

Due to the successes of large-scale training in machine learning (He et al., 2016; Brown et al., 2020; Radford et al., 2021), datasets derived from publicly available internet data have become indispensable to the machine learning community. For example, without relying on internet scraping, it would be cost-prohibitive to manually construct key datasets such as ImageNet (Deng et al., 2009), The Pile (Gao et al., 2020), or YFCC100M (Thomee et al., 2016). While the internet has served as a large, easily-accessible source of human generated data in the past, the growing deployment of machine learning systems puts this procedure at risk. As models begin to create and annotate a significant fraction of

internet content, the utility of the internet as a data source may decrease rapidly.

As an example in visual role-labeling, consider a classifier trained on public photos and their associated tags, as depicted in Figure 1. Instead of manually tagging photos, some users may instead choose to auto-tag their photos with the model. These photos, now stored in internet history, may be scraped as training data for an updated iteration of the image-tagging model. Any systematic biases introduced by the model, such as consistently mislabeling female doctors as nurses as in Figure 1, are now encoded into the training data. This *data feedback* gradually degrades the quality of the internet as a data source, since supervision becomes driven by model outputs rather than human annotation.

Issues arising from training data that includes previously model-generated content have already been encountered in machine translation (Venugopal et al., 2011) and speech recognition (Radford et al., 2022). These concerns are especially important in situations where model predictions may exacerbate existing toxicity, harm, or other biases (Gehman et al., 2020; Zhao et al., 2017). In such cases, a viable strategy for model developers is to weigh the benefit of updating their model to new internet content versus the cost of amplifying biases via such model-induced feedback. However, it is not yet understood when and to what degree data feedback is an issue in practice.

In this work, we define the data feedback setting and carefully study how model biases change under feedback. In particular, we ask: Are there conditions that stabilize bias amplification? We answer this in the affirmative, finding that learning algorithms with stability guarantees produce models with a bias similar to their current input distributions – a property we call uniform faithfulness. Importantly, this form of faithfulness is achieved in realistic experimental settings. Sampling from a generative model is one natural way to reach this, as they directly approximate the input distribution and thus are more likely to be faithful and stable. Surprisingly, however, we find that many prediction algorithms that do not explicitly perform sampling (such as image classifiers) can also be faithful, owing to a conjectured phenomenon called Distributional Generalization (Nakkiran & Bansal, 2020).

Formally, we quantify the stability of data feedback with a

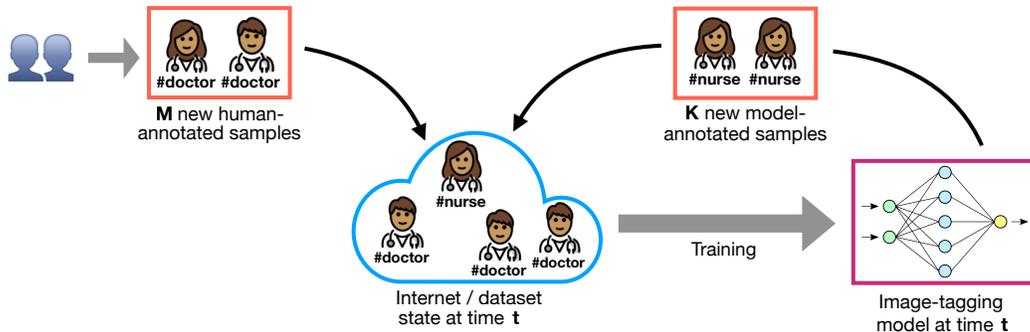

Figure 1: A simple example of data feedback. An image-tagging model is trained on an initial set of images from the internet. Some users auto-tag new images with the model when posting them online, while others continue to manually tag their images. After some time, the model may be updated by re-scraping the internet and re-training on the updated data, which now includes feedback from previous: model predictions.

bias metric $\phi(x, \hat{y})$, where $\hat{y} = f_t(x)$ are predictions from the model at time t . For example, the predictions \hat{y} are image tags or sentence completions, and the bias metrics ϕ are gender bias or sentence toxicity. Our intuitive, theoretical result shows that if the model is uniformly faithful with error level δ , then the total bias amplification for all time is bounded by $\frac{m+k}{m} \delta$, where m and k refer to the number of new human-annotated samples and model-annotated samples between deployments respectively.

Empirically, we demonstrate the utility of our bias amplification bounds in three different natural experiment settings:

1. First, we define a simple data feedback setting in CIFAR (Krizhevsky, 2009), where the label distribution is skewed and feedback has the potential to amplify label shift. In this case, we show the feedback dynamics are stable and consistent with our theoretical bounds.
2. Next, we show that data feedback can significantly amplify gender biases in a visual semantic role labeling task (Yatskar et al., 2016). Our bounds predict that the dynamics may be unstable since the initial faithfulness error is large, which is mirrored by the rapid increase in gender bias of the deployed models.
3. Third, we examine data feedback for language generation on a toxic prompts dataset (Gehman et al., 2020) and demonstrate that toxicity and repetition amplify, with sampling-based generation schemes enjoying substantially higher stability than beam search methods.

Finally, based on these observations, we design an intervention to stabilize beam search methods by leveraging the sampling-like behavior of interpolating classifiers (Nakkiran & Bansal, 2020). To do this, we simply overfit the language model to its training set, which significantly stabilizes the model’s toxicity and repetition.

Before we discuss these main experimental results, we first briefly discuss related work, detail the data feedback setting, and describe how uniform faithfulness is related to sampling and how it leads to bounds on bias amplification.

2. Related Work

Performative prediction. The general problem of model-induced feedback in machine learning has been previously studied as performative prediction and strategic classification (Perdomo et al., 2020; Hardt et al., 2016), where future data distributions can change arbitrarily in response to the deployed model. In this context, existing work has focused on methods that optimize towards equilibria of the system (Brown et al., 2022). The generality of the problem setting allows for complex human interactions in-the-loop; however, it is for this reason that experimental evaluation has been limited, and most analyses have focused on convex settings with experiments on Gaussian data or simple synthetic data such as loan applications or credit risk (Izzo et al., 2021; Miller et al., 2021).

In contrast, motivated by the image tagging example in Section 1, we consider a more restricted form of feedback, in which new data examples are gathered only from either the “true” human-annotated distribution or outputs of the currently deployed model. This restriction allows us to analyze feedback stability in more realistic experimental settings and derive bounds on stability.

Bias amplification. Machine learning models have a tendency to amplify at test-time biases that exist in their training data, a problem known as bias amplification (Dinan et al., 2019; Leino et al., 2019; Hall et al., 2022). For example, image classifiers have skewed gender predictions, beyond what exists in the training data (Zhao et al., 2017; Wang et al., 2019). In our work, we build on this literature by studying the multi-step amplification of bias via feedback.

Algorithm 1 Data Feedback Procedure

Input: Human-annotated distribution P_0
 Training algorithm \mathcal{A}
 Number of initial human-annotated samples n_0
 Number of human-annotated samples per round m
 Number of model-annotated samples per round k
Output: Model deployments over time: f_0, f_1, f_2, \dots
 1: $\mathcal{S}_0 = \{(x_i, y_i)\}_{i=1}^{n_0}$, with $(x_i, y_i) \stackrel{\text{iid}}{\sim} P_0(x, y)$.
 2: Deploy $f_0 \sim \mathcal{A}(\mathcal{S}_0)$.
 3: **for** $t \in \{1, \dots, \infty\}$ **do**
 4: $\mathcal{S}_t = \mathcal{S}_{t-1} \cup \{(x_i, y_i)\}_{i=1}^m \cup \{(x_j, f_{t-1}(x_j))\}_{j=1}^k$
 where $(x_i, y_i) \stackrel{\text{iid}}{\sim} P_0(x, y)$ and $x_j \stackrel{\text{iid}}{\sim} P_0(x)$.
 5: Deploy $f_t \sim \mathcal{A}(\mathcal{S}_t)$.

Feedback in healthcare. The data feedback setting is most related to feedback loops previously studied in binary, tabular healthcare data (Adam et al., 2022; 2020). In these works, false positives are explicitly added to the training set over time, and the focus is on methods that mitigate the impact of the errors. In contrast, our work builds the tools necessary to predict bias amplification ahead of time and can be used in more general settings (e.g. image classification or language modeling).

Additional discussion relating to recommender systems, semi-supervised learning, domain adaptation, and more can be found in Appendix A.

3. Defining Data Feedback and Model Bias

Our work considers feedback effects in the conditional prediction setting. In the standard conditional prediction or supervised learning framework, the goal is to learn a function $f \in \mathcal{F}, f : \mathcal{X} \rightarrow \mathcal{Y}$ from a collection of samples $\{(x_i, y_i)\} \stackrel{\text{iid}}{\sim} P_0(x, y)$. $P_0(x, y)$ represents a fixed human-annotated example distribution (e.g. human-tagged images or human-written prompts and completions). Motivated by the example in Figure 1 where the dataset changes over time, we instead consider a series of supervised learning problems from time $t = 0 \dots \infty$. At each time, we learn a new model f_t using the latest available internet data.

At $t = 0$, before any data feedback, only human-annotated samples are available on the internet. Thus, the initial model f_0 is trained on n_0 i.i.d. samples from $P_0(x, y)$, and we call this initial dataset $\mathcal{S}_0 = \{(x_i, y_i)\}_{i=1}^{n_0}$, with $(x_i, y_i) \stackrel{\text{iid}}{\sim} P_0(x, y)$. The corresponding model is defined as $f_0 \sim \mathcal{A}(\mathcal{S}_0)$, where $\mathcal{A} : (\mathcal{X} \times \mathcal{Y})^* \rightarrow \mathcal{F}$ refers to a potentially stochastic learning algorithm, which in our experiments is a neural network trained on the cross entropy loss with SGD.

For any $t \geq 1$, we assume that data on the internet grows in

two ways. Humans naturally continue to interact with the internet and generate data, creating m new samples following the original distribution $P_0(x, y)$. Another k samples are generated by humans interacting with the newest model f_{t-1} (e.g. users auto-tag new images). The dataset, derived from accumulated online content, thus evolves as

$$\mathcal{S}_t = \mathcal{S}_{t-1} \cup \{(x_i, y_i)\}_{i=1}^m \cup \{(x_j, f_{t-1}(x_j))\}_{j=1}^k,$$

with $(x_i, y_i) \stackrel{\text{iid}}{\sim} P_0(x, y)$ and $x_j \stackrel{\text{iid}}{\sim} P_0(x)$, where $P_0(x)$ denotes the marginal over the covariates. The model is then updated by re-training on the growing dataset, $f_t \sim \mathcal{A}(\mathcal{S}_t)$. Formally, the data feedback model we instantiate in our experiments is defined in Algorithm 1.

Our overall goal is to analyze the behavior of f_t over time. Concretely, we are concerned with *bias amplification*, tracked via a particular bias statistic $\phi : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}$. We will measure the expected difference between the bias of the initial, human-annotated distribution $P_0(x, y)$ and the bias of the model f_t . Thus, in both our theoretical and empirical analyses, we will measure amplification as

$$\left| \mathbb{E}_{f_t} \left[\mathbb{E}_{(x,y) \sim P_0(x,y)} [\phi(x, y) - \phi(x, f_t(x))] \right] \right|$$

over time t . The expectation in this bias term, $\mathbb{E}_{f_t}[\cdot]$, is an expectation over all random objects up to time t , which includes random draws in each dataset \mathcal{S}_t and random draws of the model f_t .

One important aspect of this setting is that all covariates are sampled from the same distribution $P_0(x)$, which remains fixed over time. This assumption is natural in situations similar to Figure 1, where predictions of the image-tagging model may not influence the types of photos taken. Though we make this choice to simplify our analysis, this setting still poses challenging tradeoffs; in Section 5.1, we show that retraining classifiers with future data improves accuracy at the cost of increasing bias.

4. Stabilizing Bias Amplification

4.1. Illustrative Example

Before the analysis, we begin with an example to emphasize how data feedback may become unstable. Consider a set of images of female healthcare workers with high inherent uncertainty – they could each be either a doctor or a nurse, depending on context cues that are not present in the image (Figure 2 left). In this case, data feedback on a dataset with twice as many nurses as doctors can rapidly destabilize.

More concretely, any Bayes optimal classifier would predict new examples only as nurse, as nurses are the majority class and the image is indistinguishable otherwise. This would exacerbate the nurse bias in the dataset (Figure 2 top). A natural solution would be to predict nurses and doctors

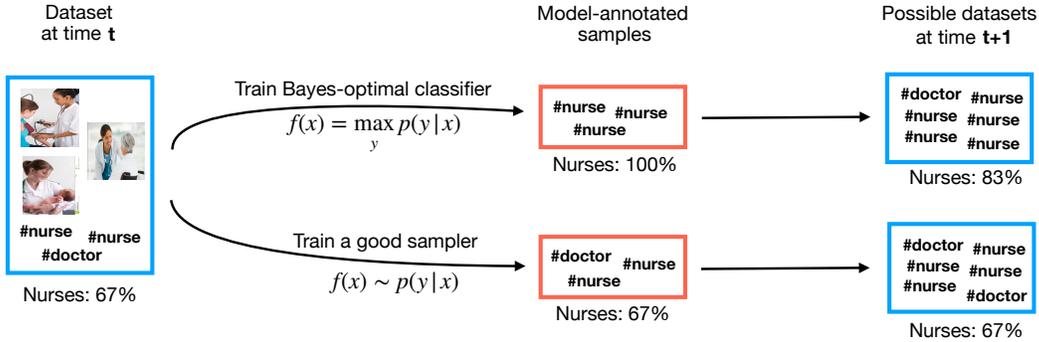

Figure 2: An example showing that models that reproduce the training distribution experience limited feedback effects. Suppose a dataset contains only indistinguishable examples, with a nurse majority (**left**). A Bayes-optimal classifier would label new examples all as nurses, since it is the majority class; this would exacerbate the nurse bias in the dataset, illustrating the potential harm of data feedback (**top**). In contrast, a model that behaves like a sampler would maintain the dataset nurse ratio during prediction, thus stabilizing any feedback effects (**bottom**). Images are from Yatskar et al. (2016).

at a rate equal to the original distribution. Specifically, a sampling-based model that reproduces the training distribution would continue to label a random $\frac{2}{3}$ of the examples as nurses. Though such a model may have lower utility, it would maintain the level of nurse bias in the dataset (Figure 2 bottom).

A training algorithm that produces models whose outputs match the bias of the training distribution is said to be uniformly faithful, and we will now formally define and connect faithfulness to stability.

4.2. Achieving Stability Through Faithfulness

Setup. We first define a few objects useful for analysis. We call the number of training samples at time t as $n_t = n_0 + t(m + k)$. A mixture of past training data, new human-annotated data, and new model-annotated data, the training data distribution at time t is

$$P_t(x, y) = \frac{n_{t-1}}{n_t} P_{t-1}(x, y) + \frac{m}{n_t} P_0(x, y) + \frac{k}{n_t} \widehat{P}_0^{f_{t-1}}(x, y),$$

where $\widehat{P}_0^{f_{t-1}}(x, y)$ denotes the model-annotated distribution, which is the *relabeling* of examples in distribution $P_0(x, y)$ by model f_{t-1} . Samples are drawn from $\widehat{P}_0^{f_{t-1}}(x, y)$ by first sampling a covariate $x \sim P_0(x)$ and then returning the annotated pair $(x, f_{t-1}(x))$.

Additionally, for ease of analysis in this section only, we study the case where the dataset \mathcal{S}_t is drawn fresh from its distribution $P_t(x, y)$ at every time, i.e. $\mathcal{S}_t = \{(x_i, y_i)\}_{i=1}^{n_t}$ where $(x_i, y_i) \stackrel{\text{iid}}{\sim} P_t(x, y)$ ¹.

¹This differs from the procedure in Algorithm 1 where \mathcal{S}_t concatenates new samples with the prior timestep’s dataset. We make this simplifying assumption only for the theoretical analysis in this section, and we expect this difference to be small as the sample size grows large. More details are provided in Appendix B.1.

Uniform Faithfulness. In the previous nurses versus doctors example, we discovered that a model that faithfully represented the training data distribution was more stable under data feedback. Now, we formalize what it means to faithfully represent the data distribution: We say a learning algorithm is *uniformly faithful* if the bias of the model is similar to the bias of its training distribution.

Definition 1 (Uniform Faithfulness). *A learning algorithm $\mathcal{A}: (\mathcal{X} \times \mathcal{Y})^n \rightarrow \mathcal{F}$ is $(\delta, \phi, P(x), n)$ -uniformly faithful if for any joint distribution $Q(x, y)$ with marginal $P(x)$,*

$$\left| \mathbb{E}_{\mathcal{S} \stackrel{\text{iid}}{\sim} Q^n(x, y), f \sim \mathcal{A}(\mathcal{S}), (x, y) \sim Q} [\phi(x, y) - \phi(x, f(x))] \right| \leq \delta.$$

If a learning algorithm is uniformly faithful, it means that in expectation, the bias of the trained model will be close to the bias of its input distribution. This property naturally arises in certain settings, as discussed in the next subsection.

Faithfulness holds throughout feedback: as the covariate marginal does not change does not change ($P_t(x) = P_0(x)$ for all t), if learning algorithm \mathcal{A} is uniformly faithful for the initial distribution $P_0(x)$, \mathcal{A} will also be uniformly faithful for all $P_t(x)$ (formalized in Lemma B.1). Intuitively, faithfulness helps to control bias amplification: at time t , a uniformly faithful algorithm \mathcal{A} will produce a model f_t with bias no more than δ greater than its training distribution $P_t(x, y)$. In turn, the bias of $P_t(x, y)$ is reduced when adding human-annotated samples and increased when adding model-annotated samples.

Stability. Our main feedback stability result is a direct consequence of uniform faithfulness.

Theorem 1 (Feedback Stability). *Let $\mathcal{A}: (\mathcal{X} \times \mathcal{Y})^n \rightarrow \mathcal{F}$ be a $(\delta_n, \phi, P_0(x), n)$ -uniformly faithful learning algorithm, where faithfulness error δ_n is a monotone non-increasing function of dataset size n . Then, under the data feedback*

procedure, for all time t ,

$$\begin{aligned} & \left| \mathbb{E}_{f_t} \left[\mathbb{E}_{(x,y) \sim P_0(x,y)} [\phi(x,y) - \phi(x, f_t(x))] \right] \right| \\ & \leq \left(1 + \sum_{i=1}^t \frac{k}{n_i} \prod_{j=i+1}^t \frac{n_j - m}{n_j} \right) \delta_{n_0} \leq \frac{m+k}{m} \delta_{n_0}. \end{aligned}$$

The proof is provided in Appendix B. The bound shows that, in expectation over runs of Algorithm 1, data-driven feedback can be stable even in the limit of $t \rightarrow \infty$. From inspecting the simplified upper bound, it is clear that both a larger number of human-annotated examples m and a smaller initial faithfulness error δ_{n_0} stabilize the system and minimize bias amplification. This leads to a natural question: in which situations can we expect small uniform faithfulness error?

Intuitively, models that behave like samplers will have low faithfulness error. In particular, suppose that model f_t has accurately learned the conditional distribution of $P_t(x, y)$, i.e. $d_{TV}(P_t(y|x), f_t(y|x)) \leq \delta$. Now, we perform a comparison of two prediction strategies commonly used in machine learning: sampling $y \sim f_t(y|x)$ and argmax prediction $y = \operatorname{argmax}_y f_t(y|x)$.

If labels are sampled, $y \sim f_t(y|x)$, then by definition $d_{TV}(P_t(x, y), \hat{P}_t^{f_t}(x, y)) \leq \delta$, and so f_t is δ -faithful for any metric ϕ by post-processing. However, if the top prediction $y = \operatorname{argmax}_y f_t(y|x)$ is used, f_t is not guaranteed to be δ -faithful for bias metric ϕ , similar to Figure 2.

While it is unsurprising that sampling maintains faithfulness and argmax predictions can be unfaithful, prior work has discovered that certain models which do not explicitly sample can still behave like samplers (Nakkiran & Bansal, 2020), which provides feedback stability.

4.3. Achieving Faithfulness Through Distributional Generalization

As in the example in Figure 2, when there is large uncertainty over the true labels (doctors versus nurses), one strategy for reducing bias is to sample according to the training distribution. Distributional Generalization (DG) (Nakkiran & Bansal, 2020) demonstrates that interpolating classifiers, which are argmax predictors, behave similarly; when the model has high uncertainty over the true labels, it produces outputs that mimic the training distribution.

Concretely, let $L : \mathcal{X} \rightarrow [m]$ be a partitioning of the input space into $m \in \mathbb{Z}_+$ parts, where similar points with high uncertainty are grouped together. This partitioning ‘‘coarsens’’ the input space by mapping hard-to-learn regions to single points. DG finds that at this level of coarseness, samples labeled by interpolating classifiers look like samples from the training distribution, i.e. $(L(x), f(x)) \approx (L(x), y)$ (Nakki-

ran & Bansal, 2020). That is, *within a specific partition*, the random process of drawing a sample x and labeling it with a deterministic classifier $y = f(x)$ produces a distribution similar to drawing x and then sampling a label from the true conditional $y \sim p(y|x)$.

If the bias metric ϕ was applied over this coarsened space, we may expect feedback stability as a natural consequence of model outputs behaving like samples. We now informally sketch the link between DG and uniform faithfulness (a more rigorous treatment is included in Appendices B.3 to B.5), providing the end result in Lemma 4.1.

The appropriate partitioning needed for DG is called feature distinguishability. L is a $(\delta, \mathcal{A}, P(x), n)$ -distinguishable feature if learning algorithm \mathcal{A} can accurately predict the partitioning induced by L over the input space $P(x)$ (Definition 2 in Appendix B.3). This means the learner \mathcal{A} can classify the group identity of each point with error at most δ . The core claim of DG (Conjecture 1 in Appendix B.4) is that, over the coarsened space defined by L , the learner \mathcal{A} will be δ -faithful for any metric ϕ . Thus, it is straightforward to use this property to show uniform faithfulness.

Lemma 4.1. *Suppose that bias metric ϕ is a function of a $(\delta, \mathcal{A}, P(x), n)$ -distinguishable feature L , i.e. $\phi(x, y) = T(L(x), y)$ for some bounded $T : [m] \times \mathcal{Y} \rightarrow \mathbb{R}$. Then, under DG (Conjecture 1), learning algorithm \mathcal{A} is $(\delta, \phi, P(x), n)$ -uniformly faithful.*

The proof is provided in Appendix B.5. This result, together with Theorem 1, shows that under DG, global stability can be achieved (excess bias bounded by $\frac{m+k}{m} \delta_{n_0}$ for all time) if the bias metric ϕ is a function of a δ_{n_0} -distinguishable feature on the initial dataset.

4.4. Instantiating Feedback Upper Bounds in Experiments

We have now seen two strategies for uniform faithfulness: 1) explicitly, through estimating the conditional distribution well and sampling outputs, and 2) implicitly through DG, where interpolating classifiers are stable as long as the bias metric is a sufficiently coarse statistic of the inputs.

In these settings, one more condition is needed for Theorem 1 to apply – that uniform faithfulness error δ_n , which is a generalization error, is non-increasing with dataset size n . Although not guaranteed, many learning algorithms and natural data distributions satisfy this property experimentally, especially if regularization is tuned (Nakkiran et al., 2020), as in done in practice. We therefore believe it is reasonable to assume the error to be a monotone non-increasing function of dataset size in most experimental situations.

In the next section, we will explore how our derived predictions can help estimate bias amplification in realistic data

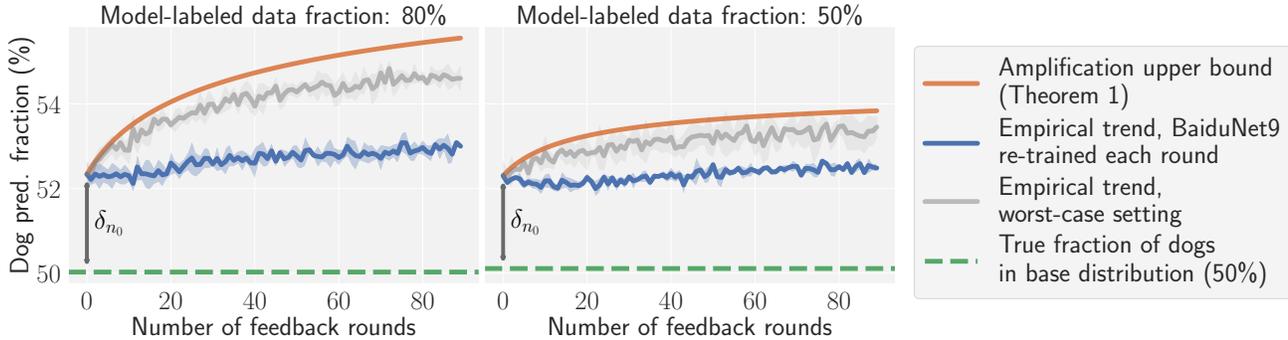

Figure 3: Results of data feedback (Algorithm 1) on CIFAR with dog imbalance. Bias is measured as the fraction of model predictions that are dogs. Empirical trends are shown with the mean and standard deviation over 3 random seeds. In the amplification bound, δ_{n_0} is estimated empirically. The gray line shows a worst-case stress set for the bound (details in Appendix D.1). **Takeaways:** The empirical curves qualitatively match the bounds, with bias amplifying more with more model-labeled samples. In all cases including the worst-case test, the orange line upper bounds the empirical behavior.

feedback settings. In order to instantiate the bound in Theorem 1, we need to know the initial uniform faithfulness error δ_{n_0} . As a practical approximation, we estimate δ_{n_0} empirically via the faithfulness error of the initial model f_0 . Although this empirical estimate is a lower bound on the uniform faithfulness error, we find that it is a useful guide, and we observe that the corresponding predictions from Theorem 1 still bound the empirical amplification.

5. Tracking Bias Amplification in Feedback Experiments

We consider three natural real-world settings that give rise to data feedback: image classification, visual role-labeling, and conditional language generation. The image classification and visual role-labeling settings are inspired by the example in Figure 1, where existing biases in image annotations may amplify. The language modeling setting is inspired by the rise of online conversational agents (Dinan et al., 2021) and assisted story writing systems (Donahue et al., 2020), for which there are real concerns about model-generated toxicity or bias (Sheng et al., 2019).

In each of these cases, we will study the behavior of data feedback in three steps: instantiate Algorithm 1, measure the empirical bias amplification, and then compare with the predictions of Theorem 1. For each setting, we describe the main experimental setup followed by the results. Extra details are in Appendix F, with ablations in Appendix G.

5.1. Image Classification

Setting up the label bias experiment.

Studying data feedback over many rounds requires very large datasets, and we use the CIFAR-5m dataset (Nakkiran et al., 2021), which contains 5 million synthetically gener-

ated examples. We re-balance the dataset to contain 50% dogs, resulting in a 9:1 imbalance ratio compared to any other class. For the bias metric ϕ , we track the fraction of the model’s predictions that are dogs. Ideally, we would like this to remain near 50%, the true data distribution level.

For the model, we train a BaiduNet9 (Li et al., 2019) on the growing dataset from scratch at each timestep, and hyperparameters are re-tuned every time. We run data feedback (Algorithm 1) with an initial dataset size $n_0 = 50k$ and new samples per round $m + k = 5k$. We report results both when 80% and 50% of new samples are model-labeled each round ($\frac{m+k}{m} = 5$ and 2 respectively).

Analyzing label bias amplification.

We show the results of running data feedback on the CIFAR-5m dataset in Figure 3 (blue trend). As predicted, the fraction of model predictions which are dogs grows faster in the setting with a greater fraction of model-labeled samples. Specifically, the bias amplifies +0.8% when $\frac{m+k}{m} = 5$ (left) and +0.3% when $\frac{m+k}{m} = 2$ (right). Theorem 1, though conservative, offers nontrivial upper bounds on bias and is consistent with the empirical results. This matches our expectations, since prior work suggests that Distributional Generalization holds for CIFAR classifiers and that the dog class is a distinguishable feature (Nakkiran & Bansal, 2020), which by Lemma 4.1 implies stability.

While in both settings the dog bias amplifies, the overall classification accuracies of the models improve throughout data feedback, a result of increasing dataset size. Specifically, as the size of the training set grows from $n_0 = 50k$ to $n_{90} = 500k$ over 90 rounds of data feedback, average classification accuracy improves +2.4% and +1.6% for the models with 50% and 80% model-labeled samples (Figure 6 in Appendix E.1). Trading off this increase in utility with greater label bias is a challenge for model developers who

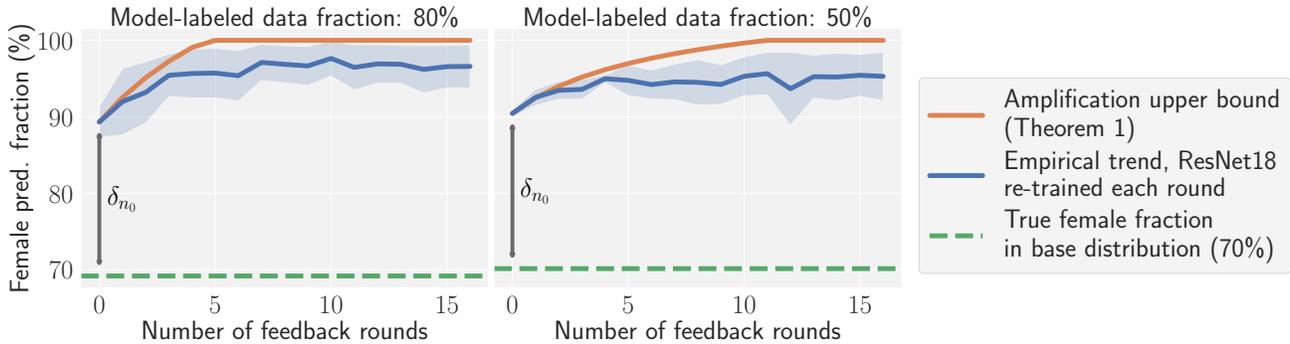

Figure 4: Results of data feedback (Algorithm 1) on the imSitu dataset. Bias is measured as the fraction of predictions that are labeled as female within the verb categories that have an existing female bias. **Takeaways:** Since the initial faithfulness error δ_{n_0} is large, the bounds quickly become vacuous (hitting the 100% female prediction fraction mark), which is mirrored by the empirical bias also reaching near 100%.

seek to update their models to new data. Our theoretical bounds take a step towards characterizing this tradeoff by upper bounding empirical bias amplification.

Finally, we discuss the source of the looseness in our bounds and present a more rigorous test of our upper bound with a worst-case setting in Appendix D.1. The results are displayed in the gray trend in Figure 3; our bounds capture the empirical behavior in this setting well.

5.2. Visual Role-labeling

Setting up the gender bias experiment.

We run data feedback on the imSitu dataset (Yatskar et al., 2016), where models are asked to predict both the verb category of an image (e.g. cooking, jumping, etc.) as well as labels for the subjects and objects (e.g. female, basketball, etc.). Zhao et al. (2017) previously found that models trained on this dataset amplify gender disparities at test-time; for example, 67% of cooking images in the dataset are labeled female, but a ResNet18 trained on the dataset will label 84% of cooking images as female. Based on this observation, we select the verb categories with an existing female gender bias, and we measure the fraction of the model’s predictions that are labeled female over these verbs.

We train the default ResNet18 (He et al., 2016) conditional random fields model from scratch at each timestep, and hyperparameters are re-tuned every time. We run data feedback (Algorithm 1) with an initial dataset size $n_0 = 50k$ and new samples per round $m + k = 5k$. We report results both when 80% and 50% of new samples are model-labeled each round ($\frac{m+k}{m} = 5$ and 2 respectively).

Analyzing gender bias amplification.

We show results of data feedback on the imSitu dataset in Figure 4. The initial faithfulness error δ_{n_0} is much larger than in the CIFAR setting; the initial trained model pre-

dicts females 90% of the time, though the dataset female fraction level is at 70%. As a result, the bound from Theorem 1 quickly becomes vacuous, hitting the 100% female prediction fraction mark. This prediction is mirrored by the empirical bias also reaching near 100% in just 16 rounds of feedback (97% and 95% female prediction fraction when 80% and 50% of samples are model-labeled, respectively).

Male prediction bias is also amplified on this task. Figure 7 in Appendix E.2 plots the male prediction bias over the verb categories with an existing male skew for these same models and finds that it amplifies quickly, similar to Figure 4. Interestingly, this implies that gender biases quickly amplify simultaneously and in both directions; for female-biased categories, predictions become more female, and for male-biased categories, predictions become more male.

5.3. Conditional Language Modeling

Setting up the toxicity and repetition bias experiment.

We use the Real Toxicity Prompts dataset (Gehman et al., 2020), which is a set of 100k sentences collected from the Open-WebText Corpus (Gokaslan & Cohen, 2019) with varying levels of toxicity. Each sentence was split into two halves, a prompt and a continuation. We use this to construct a language modeling task where a model is asked to complete a sentence given a prompt.

We measure two bias metrics on the model output: toxicity and repetition. Toxicity is measured by the fraction of model outputs classified as toxic by the Detoxify classifier (Hanu & Unitary team, 2020). We also measure a specific form of repetition bias: the average number of quotation marks in the generated text. Repetitive text is a common degeneracy of language models (Holtzman et al., 2020; Fan et al., 2018), and we count quotation marks as a simple approximation after observing that repetitive outputs in this setting commonly contained many quotes (examples in Appendix E.4).

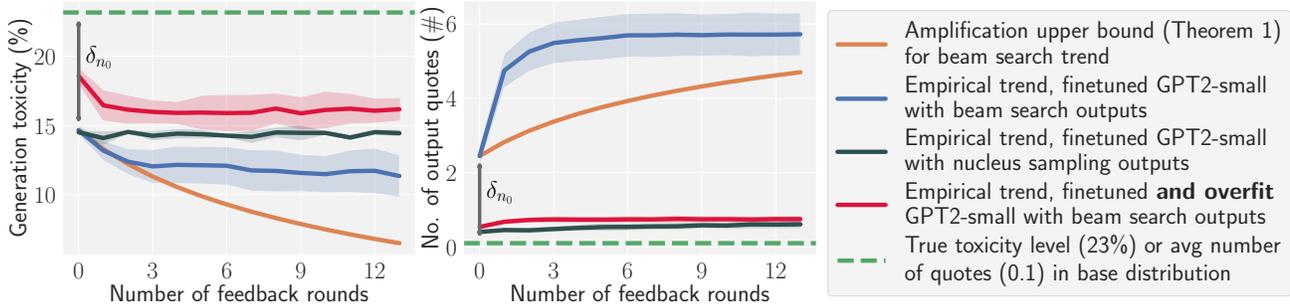

Figure 5: Results of data feedback (Algorithm 1) on the Real Toxicity Prompts dataset (Gehman et al., 2020). Bias is measured in two ways; **left**: the fraction of model outputs that are marked toxic by a separate toxicity classifier (toxicity bias), and **right**: the average number of quotation marks in the generated text (repetition bias). **Takeaways**: Nucleus sampling (black) is more stable than beam search (blue) for both bias metrics, particularly for repetition bias, demonstrating that sampling is more stable than argmax predictions. The proposed intervention of overfit beam search (red) largely resolves the issues with beam search (blue); the empirical curves behave more similarly to nucleus sampling (black) for toxicity bias and especially repetition bias, demonstrating the stabilizing effect of the intervention.

We finetune a pretrained GPT-2 small (Radford et al., 2019) at each round, with hyperparameters re-tuned every time. To generate new sentence completions, we consider two common schemes: nucleus sampling (Holtzman et al., 2020) ($\text{top}_p = 0.9$) and beam search (Graves, 2012) ($\text{num_beams} = 10$). We run data feedback (Algorithm 1) with $n_0 = 20k$, $m = 1k$, and $k = 4k$ (80% model-labeled).

Analyzing toxicity and repetition bias amplification.

Figure 5 shows the results of data feedback on the Real Toxicity Prompts dataset. Comparing beam search (blue) to nucleus sampling (black), the toxicity of the final nucleus sampling models (14.5%) did not change from their initial level. However, the toxicity of the final beam search models (11.5%) decreased by about 3% from their initial level; in this case, beam search amplified the toxicity bias downward since the initial model’s toxicity (14.5%) was lower than the dataset toxicity level (23%).

Repetition bias paints a more dramatic difference between the two. While the average number of quotes in generated text increases little for nucleus sampling (0.4 to 0.6), it amplifies significantly for beam search (2.5 to 5.7). In fact, the empirical amplification exceeds Theorem 1’s bound. This is not unexpected, as beam search models do not satisfy the preconditions, either explicitly through sampling or implicitly by satisfying Distributional Generalization (as image classifiers do). By contrast, repetition bias for nucleus sampling is within its upper bound (Figure 8 in Appendix E.3).

An intervention to stabilize toxicity and repetition bias.

We now test our understanding of bias amplification by designing an intervention to mitigate biases for beam search models. Leveraging the claim in Distributional Generalization that interpolating models behave like samplers, we

overfit the beam search model to make it interpolate the training data. We simply finetune the model for 5 times the number of gradient steps as before, increasing the test loss from 3.5 to 6.4 and dropping training loss from 3.5 to 0.4.

Figure 5 (red) shows the results of the intervention. Overfitting significantly improves the stability of the beam search model; the average number of quotes output by the final model is reduced from 5.7 to 0.8, which is closer to the nucleus sampling level at 0.6. Sample outputs of all three models are in Appendix E.4.

In Appendix D.3, we compare this intervention to prior work on mitigating feedback effects and find that our proposed solution is most effective. We also discuss the utility of the overfitting intervention in more detail in Appendix D.2; in particular, we find that the overfit model has less coherent model generations (scoring 0.26 vs 0.35) and a higher memorization rate (25% vs 11%). Whether such a utility cost is acceptable in exchange for less biased generations is context-dependent. Nevertheless, our experimental results suggest that improving faithfulness may broadly help to mitigate bias amplification, and our theoretical bounds provide a concrete way to navigate this tradeoff.

6. Limitations and Future Work

The main limitations of the current work, and corresponding potential for future work, involve assumptions in the data feedback setting:

- The base human-labeled distribution P_0 is assumed to be fixed over time. While this may be true in certain settings or on smaller time scales, reasoning about a changing base distribution is necessary for more general analyses. For example, the introduction of new

products (e.g. the iPhone) alters the distribution of pictures taken and uploaded online, and the types of topics humans write about also change over time in response to new world events. In these cases, it may be necessary to redefine bias amplification with respect to the changing base distribution and re-derive the bounds in Section 4.

- It is assumed that, in between model deployments, a constant fraction of model-annotated samples are recorded back online. However, as with the proliferation of any new technology, it is reasonable that this fraction may increase quickly over time (e.g. the deployment of ChatGPT). Additionally, the data feedback setting assumes that all model-annotated samples are recorded online. However, humans naturally use AI systems in an interactive way, posting outputs that reflect their personal preferences. Formalizing these nuances and how they affect the model-annotated distribution is important future work.
- We only consider data feedback loops for a one-model system. However, it is also increasingly likely that feedback loops occur between multiple different neural systems, such as the outputs of a machine translation system being used as inputs for an image-text similarity model. In these cases, it is important to understand how bias amplification in one system impacts the other and vice versa.

Finally, future work on potential mitigation strategies for unstable data feedback systems is also important. Watermarking model outputs (Kirchenbauer et al., 2023) is one strategy for avoiding feedback from previous model-labeled samples. Developing more effective filters, such as powerful discriminators to detect between artificially generated and human-created content (Mitchell et al., 2023) is another fruitful direction. Lastly, developing training algorithms that are uniformly faithful (Kulynych et al., 2022) is a crucial component to ensure feedback stability in the wild.

7. Conclusion

We propose a new setting called *data feedback*, where past model outputs act as training data in the future. We show that the natural decision to retrain a deployed model can increase utility while also amplifying biases. We then provide conditions for stability (namely, uniform faithfulness) and derive corresponding upper bounds on bias amplification. These bounds reliably predict model bias in experiments across image classification, visual role-labeling, and language modeling, confirming the observation that sampling-like behaviors often result in better faithfulness and greater feedback stability. Finally, we leverage our insight to design a mitigation strategy for unstable feedback systems.

8. Ethics Statement

Our work explores how certain model biases may amplify during data feedback. However, the definition of bias is not static and depends on various cultural norms. What is seen as favorable among one group may be problematic among another, and certain biases have much more important consequences than others. Our work does not take any steps towards addressing these issues, treating bias as purely a mathematical or programmatic construct.

Additionally, we highlight three points of concern regarding the proliferation of AI-generated data in future ML datasets:

- **Bias.** Data feedback loops can selectively amplify certain biases, cultural norms, or standards in existing data. This can make it harder to tune models to be unbiased in their responses, if certain standards become so amplified and polluted on the internet that they are impossible to unlearn.
- **Homogenization.** Currently, many different humans with diverse perspectives contribute data to the internet. It is likely that in the future, a much fewer number of AI systems will be responsible for generating much of the synthetic data on the internet. An unintended consequence of this is that future training on these datasets may produce models that are very similar to each other and reflect similar properties (Bommasani et al., 2022).
- **Privacy.** Large models have been found to memorize and repeat their training data (Carlini et al., 2021; 2023). It is possible that training on such generations may increase the privacy risk and the likelihood of models to reveal training data.

9. Reproducibility Statement

We release all code and data for this project at https://github.com/rtaori/data_feedback. The repository contains code for all experiments presented in the main text and appendix of this paper, with one command per figure (approximately).

All datasets we use are open-source. In addition, all model architectures and pretrained model weights we use are open-source. Appendix F discusses in detail the setup for each experiment in Section 5, including details on hyperparameter tuning, model training and evaluation, and dataset construction.

A. Additional Related Work

Recommender systems. Our work is also closely aligned with the study of feedback loops in recommendation systems (Sinha et al., 2016; Schmit & Riquelme, 2018). In this context, existing work has shown that optimizing strictly for ranking metrics such as accuracy can create echo chambers, where minority populations are crowded out and disengage from the platform (Hashimoto et al., 2018; Jiang et al., 2019). This issue arises due to the tension between improving ranking metrics and considerations of bias, fairness, or diversity (Steck, 2018; Chaney et al., 2018).

In Section 5.1, we show that a similar phenomenon exists in data feedback: retraining classifiers with future data improves classification accuracy, but at the cost of increasing its bias. In the recommendation literature, one possible successful mitigation strategy is the use of recommendations that are calibrated in proportion to user interests (Steck, 2018). Similarly, our work also heavily relies on the faithfulness of the model’s predictions to ensure the stability of data feedback.

The takeaways from this work cannot be immediately ported into the recommender systems setting, however. The big difference is that in data feedback, annotations are collected from both humans and model predictions, while the distribution of examples for which the annotations are collected remains fixed. In recommender systems, the annotation is always produced by a human, and the distribution of items for which the rating is collected is a function of the recommendation model. In recommender systems, the distribution over examples itself is changing as a function of the model, which violates the fixed covariate assumption of data feedback. In addition, annotations are only collected from humans, not a mix of humans and model predictions.

Semi-supervised learning. The semi-supervised learning setting (Ouali et al., 2020; Grandvalet & Bengio, 2004), also widely referred to as self-training, shares many similarities with the data feedback setting. Assuming access to an additional pool of unlabeled data, a self-trained model iteratively labels parts of the data and retrains on its new predictions. In contrast to data feedback, the unlabeled pool is typically fixed at the start, and the model can selectively choose which examples to use for training.

In most cases, self-training improves the utility of the overall model; however, prior work has found it may have disparate effects across population subgroups (Zhu et al., 2021). In Section 5.2, we show a similar phenomenon in data feedback; gender bias amplifies differently for male-heavy and female-heavy subgroups of the data.

Domain adaptation. Data feedback has connections to various domain adaptation settings (Farahani et al., 2021; Shu et al., 2018; Kumar et al., 2020; Lipton et al., 2018), where the changing data distributions can be viewed as shifting target domains. The major difference between the settings is that in data feedback, the model itself drives changes in the distribution, while in domain adaptation, the shift in distribution is independent of the model. Due to this difference in the problem setting, it is an open question how well domain adaptation techniques would transfer to data feedback.

Feedback loops in the wild. Prior work has documented additional examples of feedback loops in the wild, in the context of predictive policing (Ensign et al., 2017), online polarization (Dandekar et al., 2013), and affirmative action, admissions, and hiring (Coate & Loury, 1993; Liu et al., 2020).

B. Stability Analysis Proofs

B.1. Notation and Setup

First, we note that the training distribution P_t , defined recursively via $P_t = \frac{n_{t-1}}{n_t} P_{t-1} + \frac{m}{n_t} P_0 + \frac{k}{n_t} \widehat{P}_0^{f_{t-1}}$, is a random variable, as it is a function of random variables f_{t-1} and P_{t-1} and deterministic P_0 .

For ease of analysis, we study the case where the dataset \mathcal{S}_t is drawn fresh from its distribution P_t at every time, i.e. $\mathcal{S}_t \sim P_t^{n_t}$. This generative model assumes \mathcal{S}_t is a new draw from P_t at each timestep, which differs from the definition in Algorithm 1 where \mathcal{S}_t is constructed by concatenating new samples with the prior timestep's dataset. We make this simplifying assumption only for the theoretical analysis in this section since we are interested in the dependence between deployed models and training data distributions, not in the dependence introduced by the draw of each dataset. We expect this difference in definition to be small as the sample size grows large.

Second, denote $\mathbb{E}_{f_t}[\cdot] := \mathbb{E}_{P_{1:t}, f_{0:t}}[\cdot] := \mathbb{E}_{f_0, P_1, f_1, \dots, P_t, f_t}[\cdot]$ as a shorthand for the expectation over all random objects up to time t during data feedback. Here, the randomness in f_i is both over the draw in dataset S_i as well as randomness in the learning algorithm \mathcal{A} .

Third, we define the shorthand $P\phi := \mathbb{E}_{(x,y) \sim P(x,y)}[\phi(x, y)]$ as expectation of the bias metric ϕ over distribution $P(x, y)$. For clarity, as a reminder, our interest is in the expected bias amplification of a learning algorithm \mathcal{A} at time t ,

$$|P_0\phi - \mathbb{E}_{f_t}[\widehat{P}_0^{f_t}\phi]| := |\mathbb{E}_{f_t}[\mathbb{E}_{(x,y) \sim P_0}[\phi(x, y) - \phi(x, f_t(x))]]|.$$

B.2. Proof of Theorem 1

We first show that uniform faithfulness with respect to base distribution P_0 implies faithfulness at each step of data feedback.

Lemma B.1. *Let \mathcal{A} be $(\delta_n, \phi, P_0(x), n)$ -uniformly faithful, where δ_n is a function of dataset size n . Then, under data feedback, for each time t ,*

$$|\mathbb{E}_{f_t}[P_t\phi - \widehat{P}_0^{f_t}\phi | P_t]| \leq \delta_{n_t}.$$

Proof By definition of the data feedback model, the covariate marginal does not change throughout data feedback, and $P_t(x) = P_0(x)$ for all t . Thus, conditioned on a particular P_t , we have that \mathcal{A} is $(\delta_{n_t}, \phi, P_t(x), n_t)$ -uniformly faithful. Applying the uniform faithfulness definition gives $|\mathbb{E}_{f_t}[P_t\phi - \widehat{P}_t^{f_t}\phi | P_t]| \leq \delta_{n_t}$, where P_t is fixed inside the conditional expectation. Finally, we obtain the claim of the Lemma by noting that $\widehat{P}_t^{f_t} = \widehat{P}_0^{f_t}$, because \widehat{P}_t depends on P_t only through the marginal covariate distribution, which is identical between P_t and P_0 . \square

Now, are ready to prove Theorem 1.

Proof The general proof strategy is to first bound the bias amplification of model f_t in terms of the bias amplification of its training distribution P_t , and then bound the bias amplification of P_t in terms of the previous training distribution P_{t-1} . This will lead to a recursive formula that we can solve.

We begin by bounding bias amplification of f_t in terms of the bias amplification of P_t .

$$\begin{aligned} |\mathbb{E}_{f_t}[P_0\phi - \widehat{P}_0^{f_t}\phi]| &= |P_0\phi - \mathbb{E}_{P_{1:t}, f_{0:t}}[\widehat{P}_0^{f_t}\phi]| \\ &= |P_0\phi - \mathbb{E}_{P_{1:t}, f_{0:t}}[P_t\phi - P_t\phi + \widehat{P}_0^{f_t}\phi]| \\ &\leq |P_0\phi - \mathbb{E}_{P_{1:t}, f_{0:t}}[P_t\phi]| + |\mathbb{E}_{P_{1:t}, f_{0:t}}[P_t\phi - \widehat{P}_0^{f_t}\phi]| \end{aligned} \quad (1)$$

$$= |P_0\phi - \mathbb{E}_{P_{1:t}, f_{0:t-1}}[P_t\phi]| + |\mathbb{E}_{P_{1:t}, f_{0:t-1}}[\mathbb{E}_{f_t}[P_t\phi - \widehat{P}_0^{f_t}\phi | P_t]]| \quad (2)$$

$$\leq |P_0\phi - \mathbb{E}_{P_{1:t}, f_{0:t-1}}[P_t\phi]| + \delta_{n_t} \quad (3)$$

Equation (1) uses triangle inequality, Equation (2) uses the iterated expectation equality and the fact that f_t is conditionally independent of $P_{1:t-1}, f_{0:t-1}$ given P_t , and Equation (3) uses Lemma B.1.

Now, we will bound the bias amplification of P_t in terms of P_{t-1} .

$$\begin{aligned}
 |P_0\phi - \mathbb{E}_{P_{1:t}, f_{0:t-1}}[P_t\phi]| &= \left| P_0\phi - \mathbb{E}_{P_{1:t-1}, f_{0:t-1}} \left[\frac{n_{t-1}}{n_t} P_{t-1}\phi + \frac{m}{n_t} P_0\phi + \frac{k}{n_t} \widehat{P}_0^{f_{t-1}}\phi \right] \right| \\
 &= \left| \frac{n_{t-1}+k}{n_t} P_0\phi - \mathbb{E}_{P_{1:t-1}, f_{0:t-1}} \left[\frac{n_{t-1}}{n_t} P_{t-1}\phi + \frac{k}{n_t} \widehat{P}_0^{f_{t-1}}\phi \right] \right| \\
 &\leq \frac{n_{t-1}}{n_t} |P_0\phi - \mathbb{E}_{P_{1:t-1}, f_{0:t-2}}[P_{t-1}\phi]| \\
 &\quad + \frac{k}{n_t} |P_0\phi - \mathbb{E}_{P_{1:t-1}, f_{0:t-1}}[\widehat{P}_0^{f_{t-1}}\phi]| \\
 &\leq \frac{n_{t-1}}{n_t} |P_0\phi - \mathbb{E}_{P_{1:t-1}, f_{0:t-2}}[P_{t-1}\phi]| \\
 &\quad + \frac{k}{n_t} |P_0\phi - \mathbb{E}_{P_{1:t-1}, f_{0:t-2}}[P_{t-1}\phi]| + \frac{k}{n_t} \delta_{n_{t-1}} \\
 &= \frac{n_{t-1}+k}{n_t} |P_0\phi - \mathbb{E}_{P_{1:t-1}, f_{0:t-2}}[P_{t-1}\phi]| + \frac{k}{n_t} \delta_{n_{t-1}}
 \end{aligned} \tag{4}$$

Equation (4) uses triangle inequality and Equation (5) uses Equation (3).

Denoting $b_t := |P_0\phi - \mathbb{E}_{P_{1:t}, f_{0:t-1}}[P_t\phi]|$, we therefore have that $b_t \leq \frac{n_{t-1}+k}{n_t} b_{t-1} + \frac{k}{n_t} \delta_{n_{t-1}}$, with $b_0 = 0$. Unrolling the recursion, we have that

$$b_t \leq \sum_{i=1}^t \delta_{n_{i-1}} \frac{k}{n_i} \prod_{j=i+1}^t \frac{n_j - m}{n_j}.$$

Substituting the above into Equation (3), we have that

$$|\mathbb{E}_{f_t}[P_0\phi - \widehat{P}_0^{f_t}\phi]| \leq \delta_{n_t} + \sum_{i=1}^t \delta_{n_{i-1}} \frac{k}{n_i} \prod_{j=i+1}^t \frac{n_j - m}{n_j}.$$

By assumption, $\delta_{n_t} \leq \delta_{n_0}$ for all t , and so we arrive at the result

$$|\mathbb{E}_{f_t}[P_0\phi - \widehat{P}_0^{f_t}\phi]| \leq \left(1 + \sum_{i=1}^t \frac{k}{n_i} \prod_{j=i+1}^t \frac{n_j - m}{n_j} \right) \delta_{n_0}.$$

□

The simplified upper bound is a result of the following Lemma.

Lemma B.2. *For all t ,*

$$1 + \sum_{i=1}^t \frac{k}{n_i} \prod_{j=i+1}^t \frac{n_j - m}{n_j} \leq \frac{m+k}{m}.$$

Proof Let $c_t = \sum_{i=1}^t \frac{k}{n_i} \prod_{j=i+1}^t \frac{n_j - m}{n_j}$. We need to show that $c_t \leq \frac{k}{m}$ for all t , which we will do via induction:

Claim: $c_t \leq \frac{k}{m}$ for all t .

Base case: $c_1 = \frac{k}{n_1+m+k} \leq \frac{k}{m}$.

Inductive step: $c_{t+1} = \sum_{i=1}^{t+1} \frac{k}{n_i} \prod_{j=i+1}^{t+1} \frac{n_j - m}{n_j} = c_t \left(\frac{n_{t+1} - m}{n_{t+1}} \right) + \frac{k}{n_{t+1}} \leq \frac{k}{m} - \frac{k}{n_{t+1}} + \frac{k}{n_{t+1}} = \frac{k}{m}$. □

B.3. Stating Feature Distinguishability

Definition 2 (Distinguishable Feature (Nakkiran & Bansal, 2020)). *Let $L : \mathcal{X} \rightarrow [m]$ be a coarsening of the input domain \mathcal{X} into $m \in \mathbb{Z}_+$ parts. Define \widehat{P}^L as the relabeling of P by L . Then, L is a $(\delta, \mathcal{A}, P(x), n)$ -distinguishable feature if*

$$\mathbb{P}_{S=\{(x_i, l_i)\}_{i=1}^n \text{ s.t. } (x_i, l_i) \stackrel{\text{iid}}{\sim} \widehat{P}^L, f \sim \mathcal{A}(S), x \sim P(x)} [f(x) = L(x)] \geq 1 - \delta.$$

The partitioning L defines how points in P are grouped together. An appropriate partitioning is one where the learner \mathcal{A} can classify the group identity of each point with high accuracy. Additionally, note that the coarsening L does not depend on the label distribution and relies only on the marginal $P(x)$. This property is important for data feedback; if L is distinguishable for the initial distribution P_0 , it will continue to be distinguishable for all P_t .

B.4. Stating Distributional Generalization

Conjecture 1 (Feature Calibration (Nakkiran & Bansal, 2020)). *Let $T : [m] \times \mathcal{Y} \rightarrow \mathbb{R}$ be any bounded function. If L is a $(\delta, \mathcal{A}, P(x), n)$ -distinguishable feature, then for any joint distribution $Q(x, y)$ with marginal $P(x)$,*

$$|\mathbb{E}_{S \sim Q^n, f \sim \mathcal{A}(S), (x, y) \sim Q} [T(L(x), y) - T(L(x), f(x))] | \leq \delta.$$

B.5. Proof of Lemma 4.1

Proof By Conjecture 1, for any joint $Q(x, y)$ with marginal $P(x)$,

$$|\mathbb{E}_{S \sim Q^n, f \sim \mathcal{A}(S), (x, y) \sim Q} [\phi(x, y) - \phi(x, f(x))] | = |\mathbb{E}_{S \sim Q^n, f \sim \mathcal{A}(S)} [Q\phi - \widehat{Q}^f \phi] | \leq \delta.$$

□

This lemma is an immediate consequence of DG (Conjecture 1), which states that the coarsened model outputs $(L(x), f(x))$ are similar to the coarsened training data $(L(x), y)$ for all bounded tests T ; this is the basis for the statement that model outputs behave like samples, i.e. $(L(x), f(x)) \approx (L(x), y)$. The given bias metric ϕ is simply one such test.

C. Controlling Data Feedback

The data feedback framework could be adapted to cases where the model produces outputs that are less biased than the original dataset (possibly through the use of a bias-mitigating learning algorithm). While we did not focus on this case, our analysis can naturally handle this situation, as described below.

For the theoretical results, this situation would be captured by modifying Uniform Faithfulness (Definition 1) by removing the absolute value and turning the upper bound into a lower bound. This corresponds to

$$\mathbb{E}_{S \stackrel{\text{iid}}{\sim} Q^n(x, y), f \sim \mathcal{A}(S), (x, y) \sim Q} [\phi(x, f(x)) - \phi(x, y)] \leq \delta \leq 0,$$

which captures the intuition that the learner is guaranteed to be less biased than the data. The final result in Theorem 1 then follows through similarly,

$$\mathbb{E}_{f_t} [\mathbb{E}_{(x, y) \sim P_0(x, y)} [\phi(x, f_t(x)) - \phi(x, y)]] \leq \left(1 + \sum_{i=1}^t \frac{k}{n_i} \prod_{j=i+1}^t \frac{n_j - m}{n_j} \right) \delta_{n_0}.$$

This result shows that the absolute bias of the model f_t decays over time, with the shape similar to our previous amplification bound.

Verifying this result is straightforward, as the proof Appendix B.2 does not rely on whether the bounds have an absolute value or not, and we can step through the proof removing absolute values and flipping upper bounds to lower bounds (due to the change in the definition of Uniform Faithfulness) as appropriate.

For the empirical result, note that we already show that this type of *bias decay* over time can happen. Figure 5, left panel, shows that the toxicity of language model outputs decrease over time. In this case, there is no bias mitigation strategy being applied, but the combination of model training and decoding hyperparameters happens to reduce toxicity. In this case, the model with the least stable data feedback (blue line, beam search) also maximally reduces the bias over time.

We will update the camera ready manuscript with an appendix section discussing this aspect of controlling data feedback. Our work initially focused on stability, as we felt this was closer to existing systems deployments without extensive bias mitigation in place. We hope that future work builds on our analysis to create new mitigation strategies, and we agree this discussion on controlling data feedback is important for this reason.

D. Additional Main Experiments Discussion

D.1. Image classification

Observing that the theoretical bounds are loose in Figure 3, we discuss the source of this gap and where the bounds may more accurately reflect the empirical amplification. In particular, Theorem 1 assumes that faithfulness errors δ_{n_t} are decreasing with dataset size n_t and uses it to globally bound $\delta_{n_t} \leq \delta_{n_0}$ for all t , which results in conservative bounds when $\delta_{n_t} < \delta_{n_0}$. By creating an artificial setting where we expect faithfulness errors to be constant over time, i.e. $\delta_{n_t} = \delta_{n_0}$ for all t , we can test the validity of the upper bound in a worst-case situation. We construct this setting by randomly subsampling the training set at each round to the initial dataset size n_0 . Specifically, we modify Line 5 of Algorithm 1 to be

$$f_t := \mathcal{A}(\tilde{S}_t), \text{ where } \tilde{S}_t = \{z_i\}_{i \in n_0}, z_i \stackrel{\text{iid}}{\sim} S_t.$$

The empirical trends and theoretical bounds in this worst-case setting are shown in the gray line in Figure 3. There is greater empirical amplification, and the upper bounds more accurately reflect the observed amplification. This result suggests that the upper bound cannot be further improved without a better characterization of δ_{n_t} as a function of n_t , which we leave as future work ².

D.2. Language modeling

Table 1: Utility metrics of the three language models in Figure 5.

Model	Coherence score (\uparrow)	Mauve score (\uparrow)	5-gram memorization (\downarrow)
beam search	0.35	0.015	11%
nucleus sampling	0.29	0.022	2%
overfit beam search	0.26	0.018	25%

Here, we analyze the utility of the three language models considered in Figure 5. We measure two quality metrics and one generalization metric: 1) coherence score (Su et al., 2022), defined as the average similarity between prompts and corresponding model completions featurized by a sentence embedding model; 2) mauve score (Pillutla et al., 2021), defined as the difference in distributions between model-completed sentences and ground truth sentences, featurized by GPT-2; and 3) memorization, defined as the overlap between 5-grams of model outputs and the training data. These three metrics were all measured at round 0 without any data feedback.

We first compare the beam search model to the nucleus sampling model. The beam search model has higher coherence, while the nucleus sampling model has a higher mauve score and lower memorization due its more diverse outputs. In certain applications (such as machine translation), coherence may be valued more; in these cases, choosing the beam search model, with its higher repetition bias, presents a utility-bias tradeoff.

We now discuss our intervention with lowered repetition bias, the overfit beam search model. Compared to its non-overfit counterpart, the coherence of the overfit beam search model is significantly decreased. This intervention introduces a new axis to control the utility-bias tradeoff: instead of trading coherence for reduced repetition by switching from beam search to sampling, one may instead trade coherence for reduced repetition by overfitting the beam search model to different degrees.

We also analyze to what extent the overfit beam search model is matching the frequency of punctuations by simply memorizing the training data. For the overfit beam search model, 25% of model output 5-grams exist in the training data, while the rate was 11% for the non-overfit beam search model and 2% for the nucleus sampling model. Thus, while it may be that the overfit model is less diverse than the original models, it is still not simply memorizing and returning the training data.

²For example, scaling laws may model faithfulness error as a function of dataset size (Rosenfeld, 2021).

D.3. Comparing overfitting intervention to prior work

To compare our overfitting intervention to previous work on mitigating feedback effects, we implement a method from the existing literature for mitigating feedback loops in the healthcare setting (Adam et al., 2022). The method is simply to drop the lowest confidence examples for the data collected in between deployments. We run this method in the language setting, dropping between 5-50% of the lowest confidence examples, and compare the repetition and toxicity bias results with the baseline beam search and our overfitting intervention.

Table 2: Comparison of our overfitting intervention to the baseline of dropping lowest confidence examples.

Method	Repetition $t = 0$	Repetition $t = 13$	Toxicity $t = 0$	Toxicity $t = 13$
Baseline beam search	+2.3	+5.6	-8%	-11%
Drop 5% low-conf	+2.0	+4.1	-8%	-15%
Drop 10% low-conf	+2.9	+5.4	-9%	-14%
Drop 20% low-conf	+1.5	+0.8	-9%	-12%
Drop 50% low-conf	+1.6	+0.6	-7%	-12%
Overfitting intervention	+0.4	+0.6	-4%	-6%

The results are shown in Table 2. In short, the takeaways are:

- Dropping 5% or 10% of the lowest confidence examples does not significantly mitigate the repetition or toxicity bias compared to the baseline beam search and is thus ineffective.
- Dropping 20% or 50% lowest confidence examples greatly reduces repetition bias over time, roughly matching the overfitting intervention (though repetition bias does start out higher initially).
- On the other hand, dropping 20% or 50% lowest confidence examples does not mitigate the toxicity bias, which still amplifies -12%, compared to only -6% for the overfitting intervention.

Overall, our overfitting intervention is most effective at reducing both repetition and toxicity bias.

E. Additional Main Experiment Results

E.1. Image classification accuracy

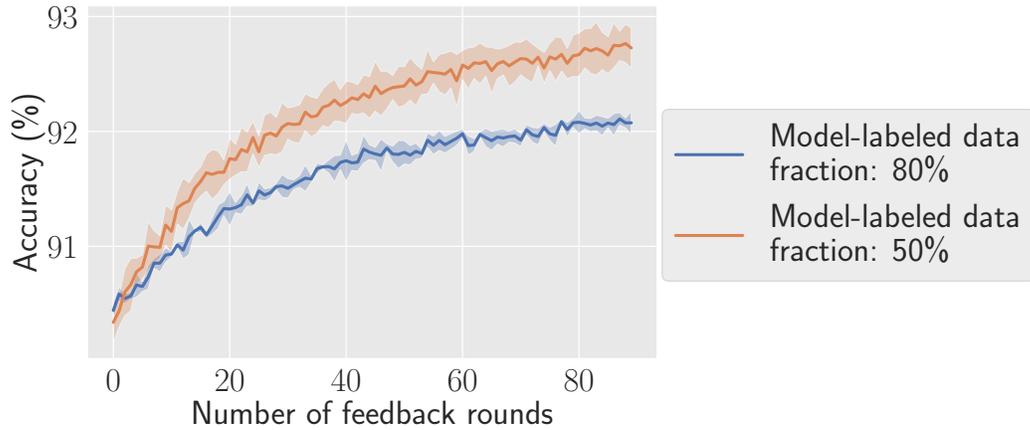

Figure 6: During data feedback, average classification accuracy improves over time as the dataset size grows. This result mirrors gains reported in the semi-supervised learning literature. When the model-labeled data fraction is smaller, the gains in accuracy are larger. All experimental settings are the same as in Figure 3.

E.2. Visual role-labeling male bias

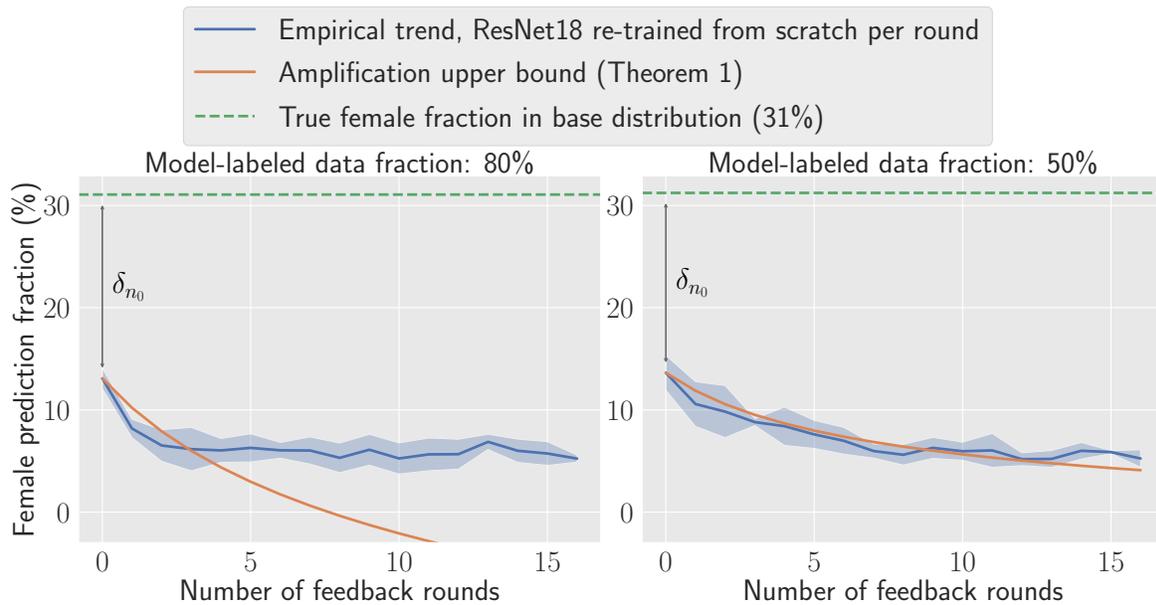

Figure 7: Male bias amplification on the imSitu dataset. Gender bias is measured over the image categories where the ground truth female frequency is between 20% and 40% (which indicates an existing male bias). All experimental settings are the same as in Figure 4. Data feedback amplifies male bias over the model predictions, pushing the empirical trend downwards below 10% female prediction fraction in just 16 rounds of feedback.

E.3. Language modeling bias amplification

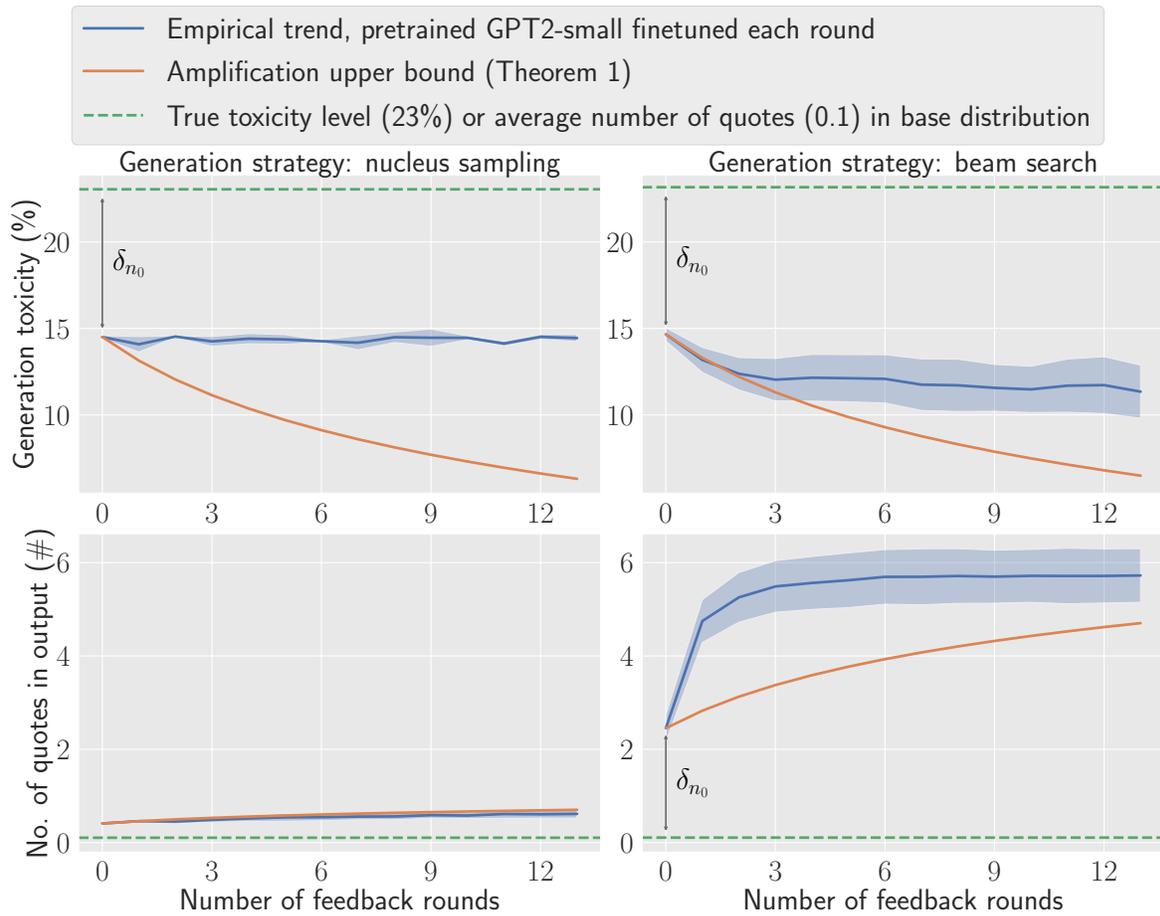

Figure 8: Simplified version of Figure 5 without the overfit beam search intervention. Repetition bias for the nucleus sampling model is within the predicted Theorem 1 upper bound (bottom left), whereas it is exceeded for the beam search model (bottom right).

E.4. Language model outputs

We provide sample model outputs for GPT2-small, generated with nucleus sampling in Table 3 and with beam search in Table 4. When generating via beam search, model completions tend to be less fluent and contain many quotation marks and non-unicode characters. Sample outputs for an overfit GPT2-small, an intervention designed to stabilize feedback, are provided in Table 5. Though still present, repetition and the overuse of quotation marks is mitigated. All outputs are random samples from the test set, and sampled from the initial round 0 model (i.e. without any data feedback).

Data Feedback Loops: Model-driven Amplification of Dataset Biases

Table 3: Randomly sampled outputs from a GPT2-small model, decoded with nucleus sampling ($t_{\text{op}_p} = 0.9$). The model is the initial round 0 model, i.e. it is finetuned on 20k examples from the Real Toxicity Prompts dataset without any data feedback. Newline and non-unicode characters are replaced by \times .

F. Details on Experiment Settings

F.1. Image classification

Datasets. For most experiments, we use the first 3 million images of the CIFAR-5m dataset, which contains 5 million examples synthetically generated by the DDPM diffusion generative model (Ho et al., 2020), which was originally trained on the CIFAR-10 train set. The examples were then labeled by a BigTransfer classifier (Beyer et al., 2022), which has 98.5% accuracy on classifying CIFAR-10 images. We create a test set by randomly selecting 50k examples on each new experiment run. For an ablation on non-synthetic data, we also use the CINIC-10 dataset (Darlow et al., 2018), which is an extension of CIFAR-10 by including downscaled ImageNet images.

Training hyperparameters. For most experiments, we train a BaiduNet9 (Li et al., 2019), which has 94% accuracy when trained on CIFAR-10. We optimize the model using stochastic gradient descent with a batch size of 512, Nesterov momentum factor of 0.9, and weight decay of 0.256. The number of epochs trained is dependent on dataset size: below 20k examples, we train for 63 epochs, then linearly scaled down to 50 epochs at 50k examples, then linearly scaled down to 38 epochs at 100k examples, then linearly scaled down to 25 epochs at 1m or more examples. We use a triangular learning rate: for the first fifth of training time, the learning rate is scaled linearly up from 0 until 0.4 and then, for the rest of training time, scaled linearly back down to 0.001. We use data augmentation standard for CIFAR-10 training: random crops, horizontal flips, and input normalization during training time, and only input normalization during test time. We train with half precision.

For the ablation training an underfit BaiduNet9, we use the following learning rate schedule: train using a learning rate of 0.1 for the first 3 epochs, then decay linearly down to 0.01 during the fourth epoch, then finally decay linearly down to 0.001 on the fifth epoch. We only train for 5 epochs regardless of dataset size for the underfit model.

For an ablation training a ResNet18, we train a ResNet18 adapted to CIFAR from this repository, and this model has 95% CIFAR test accuracy. We train for twice the number of epochs as the regular BaiduNet9 training; that equates to 100 epochs at 50k dataset size and 50 epochs at dataset size of 1m or more. We optimize the model using stochastic gradient descent with a batch size of 128, momentum factor of 0.9, and no weight decay. We use a cosine annealing schedule for the learning rate during training. We train using full precision. All other parameters remain the same.

Hyperparameter tuning. During data feedback, the model is retuned and retrained from scratch on the growing dataset at each new round. Due to the computational complexity of re-tuning hyperparameters for each data feedback experiment, we tune hyperparameters ahead of time for varying CIFAR-5m dataset sizes (in this case, the examples are not relabeled by data feedback). During data feedback, we use the dataset size to match the hyperparameter setting at each round.

For hyperparameter tuning, we trained the BaiduNet9 for [10, 20, 30, 45, 65] epochs on dataset sizes of [20k, 50k, 100k, 200k, 500k, 1m]. We then chose the earliest number of epochs at which accuracy stopped improving for each dataset size, and then interpolated the number of epochs for all dataset sizes in between. Once the optimal number of epochs was found, we then tuned the batch size and learning rate, varying batch size in [64, 128, 256, 512] and accordingly scaling the learning rate linearly; and found the maximum batch size of 512 and corresponding learning rate of 0.4 worked best across all dataset size settings.

F.2. Visual role-labeling

Dataset. The imSitu dataset provides three sets of annotations for each image. We collapse these annotations into a single label for each role in each image via majority voting. We make this design choice to fit the data feedback setting, since model-labeled data points only have one annotation per image. We also combine all data splits (train, dev, and test), and randomly sample 50 images per category (for a total of 25200 examples) to create a test set for each new experiment run.

Bias metric. We select the verb categories with an existing female gender bias, and we measure the fraction of the model’s predictions that are labeled female over these verbs. Specifically, in Figure 4, we consider the verb categories where the dataset female label ratios lie between 60% to 80%. This interval was chosen as it represented a wide range of stereotypically female activities. In Appendix G.2, we provide plots for 0-20%, 20-40%, 40-60%, and 80-100%.

Training hyperparameters. We train the default ResNet18-backed conditional random fields model (Yatskar et al., 2016), proposed as a baseline alongside the dataset. We optimize the model using Adam (Kingma & Ba, 2014) with batch size 64,

learning rate 0.00001, default betas 0.9 and 0.999, and weight decay of 0.0005. The number of epochs trained is dependent on dataset size: below 20k examples, we train for 50 epochs, then linearly scaled down to 40 epochs at 35k examples, then linearly scaled down to 35 epochs at 50k examples, then linearly scaled down to 30 epochs at 75k or more examples. We use data augmentation standard for ImageNet training: random resized crops, horizontal flips, and input normalization during training time, and resized center crop with input normalization during test time.

Hyperparameter tuning. Similar to the CIFAR setting, we tune hyperparameters ahead of time for varying dataset sizes (where the examples are not relabeled by data feedback). The optimization criterion was the average score of five metrics calculated over the given dev set: verb classification accuracy, role classification accuracy, role classification accuracy conditioned on the correct verb, and two additional similar role classification metrics (Yatskar et al., 2016). During data feedback, we then use the dataset size to match the hyperparameter setting at each round.

For hyperparameter tuning, we trained the ResNet18 CRF for [20, 30, 45, 60] epochs on dataset sizes of [20k, 50k, 75k, 100k]. We then chose the earliest number of epochs at which the average score stopped improving for each dataset size, and then interpolated the number of epochs for all dataset sizes in between. Once the optimal number of epochs was found, we then tuned the learning rate in [0.000001, 0.00001, 0.001, 0.01] and found the optimal to be 0.00001 for all dataset sizes.

F.3. Language modeling

Dataset. We use the Real Toxicity Prompts dataset (Gehman et al., 2020), which is a collection of 100k sentences from the Open-WebText Corpus (Gokaslan & Cohen, 2019) stratified along varying levels of toxicity as predicted by the Perspective API toxicity classifier³. We create a test set by randomly selecting 14442 examples on each new experiment run.

Toxicity metric. Toxicity is measured by counting the fraction of model outputs classified as toxic by the Detoxify classifier⁴, which was trained on the Jigsaw toxicity challenge datasets (team, 2018; 2019; 2020). A generation is classified toxic if the classifier’s toxicity score is greater than 0.5. We sample one output per prompt. Our metric differs from that used in the Real Toxicity Prompts paper (Gehman et al., 2020), which measures the maximum toxicity over 25 independently sampled model generations for a given prompt.

Models and tokenizers. We finetune GPT2 small, medium, and large, initialized to the pretrained models available on HuggingFace (Wolf et al., 2019). All text is tokenized using the default GPT2 tokenizer. For both nucleus sampling and beam search, model output is capped at a maximum of 20 tokens, following the settings in (Gehman et al., 2020).

Training hyperparameters. We optimize each model using AdamW (Loshchilov & Hutter, 2019) with batch size 16, default betas 0.9 and 0.999, and no weight decay. For GPT2 small, the learning rate is set to 0.00005, and for medium and large is set to 0.00001. The models are finetuned for one epoch regardless of dataset size. For the overfitting intervention, the models are finetuned for 5 epochs, and the learning rate increased by a factor of 10 (to 0.0005 for GPT-2 small and 0.0001 for GPT-2 medium and large).

Hyperparameter tuning. Similar to the CIFAR and imSitu settings, we tune hyperparameters ahead of time for varying dataset sizes (where the examples are not relabeled by data feedback). The optimization criterion is model perplexity of test set sentence continuations conditioned on their respective prompts. During data feedback, we then use the dataset size to match the hyperparameter setting at each round.

For hyperparameter tuning, we trained each GPT2 small, medium, and large model using a very dense sampling of the following hyperparameter combinations: [1, 2, 3, 5] epochs, [20k, 35k, 50k, 65k, 85k] dataset sizes, [0.000001, 0.000005, 0.00001, 0.00005, 0.0001, 0.0005, 0.001] learning rates, and [4, 8, 16, 32, 64, 128, 256] batch sizes. We found that across dataset sizes, training for 1 epoch with batch size 16, with learning rate 0.00005 for GPT2 small and 0.00001 for medium and large was optimal or very near optimal.

³<https://www.perspectiveapi.com/>

⁴Prior work (Dhamala et al., 2021) has adopted a similar method for measuring toxicity. Though toxicity classifiers have shortcomings (Kumar et al., 2021; Sap et al., 2022), this work is primarily concerned with aggregate, *relative* changes in toxicity over time to measure amplification.

G. Ablations for Experiments

G.1. Image classification

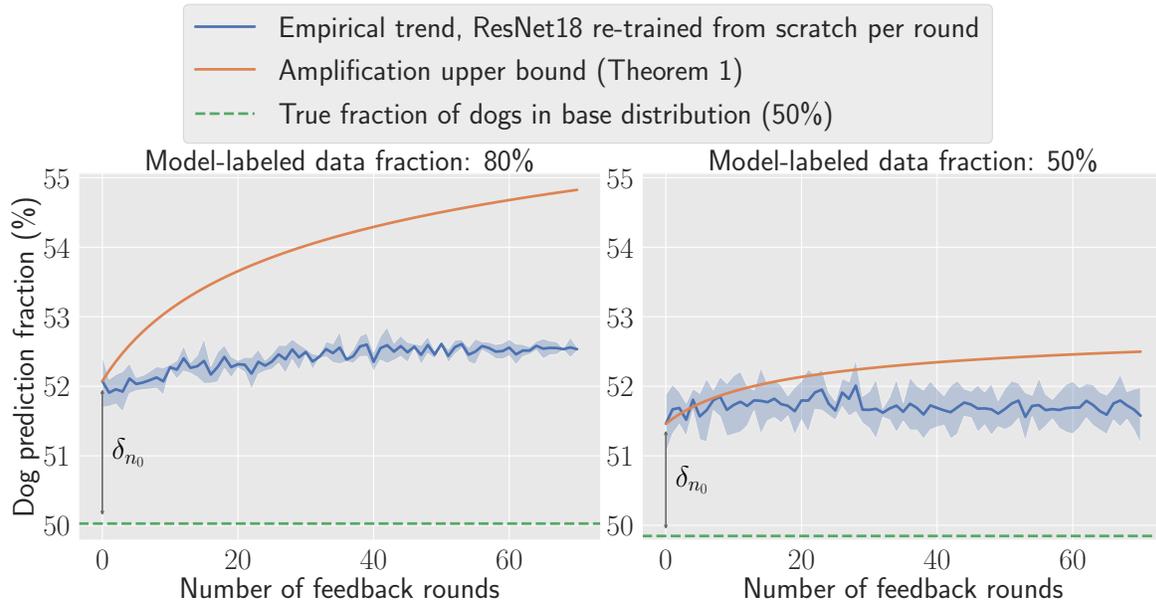

Figure 9: Label bias amplification on CIFAR. We train a ResNet18 with standard training hyperparameters (instead of a BaiduNet9). The fewer number of feedback rounds is due to computational limitations. All other experimental settings are the same as in Figure 3.

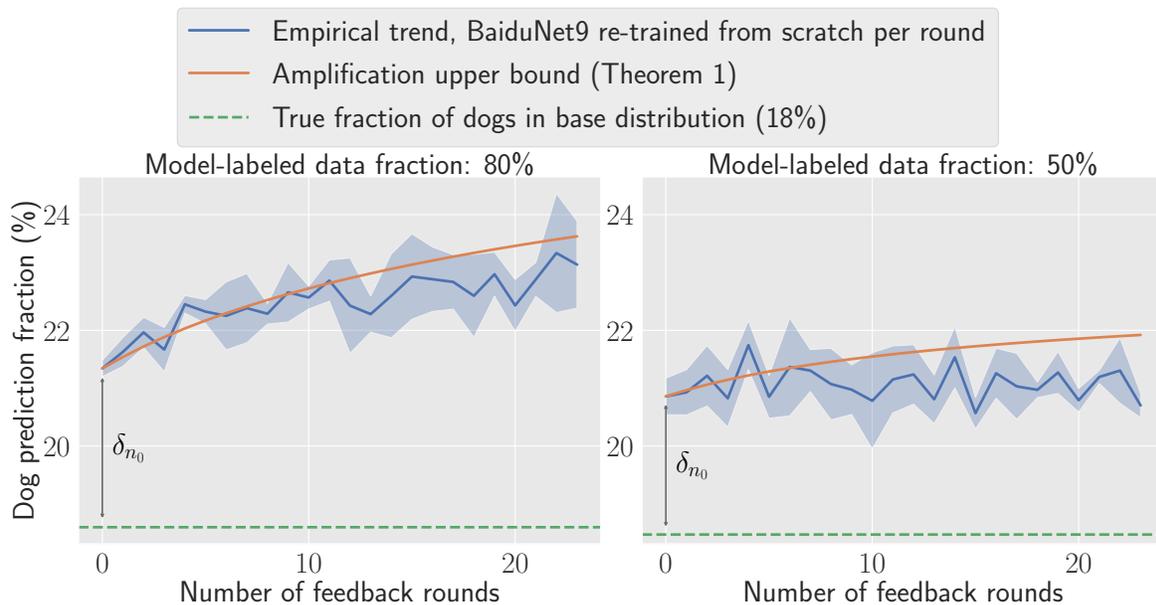

Figure 10: Label bias amplification on CINIC-10, a non-synthetic dataset. The initial dataset size is set to $n_0 = 20k$ and the dog imbalance is at a 2:1 imbalance ratio compared to any other class. The fewer number of feedback rounds is due to dataset size limitations. All other experimental settings are the same as in Figure 3.

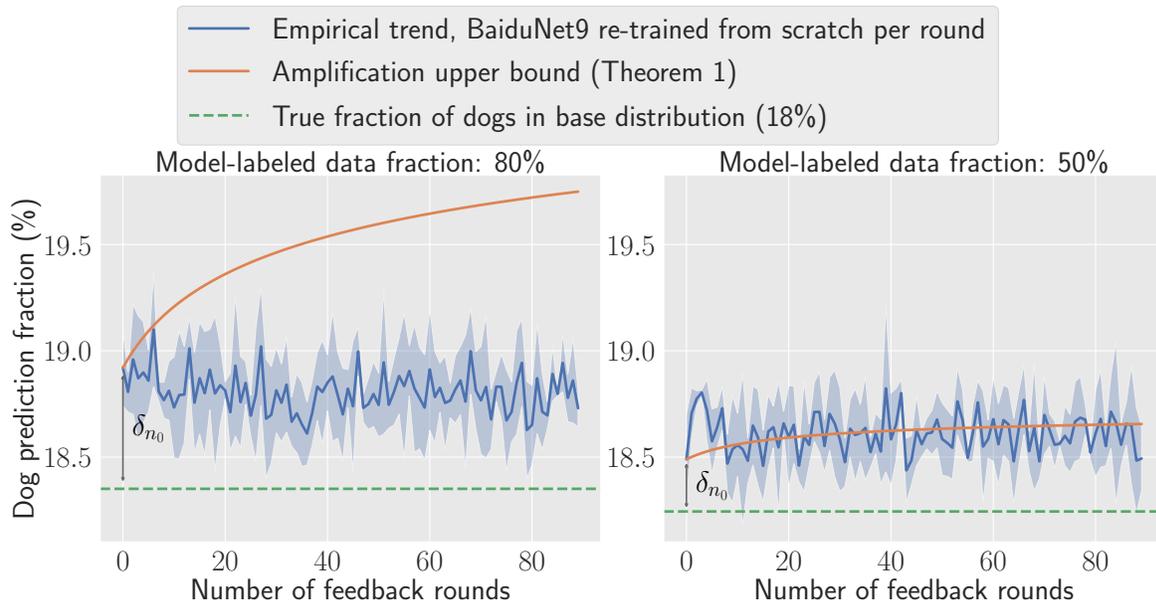

Figure 11: Label bias amplification on CIFAR. The dataset is balanced such that dogs are in a 2:1 imbalance ratio (instead of a 9:1 ratio) compared to any other class. All other experimental settings are the same as in Figure 3. Bias amplification is more modest since the initial faithfulness error is smaller. For this reason, the relative effect of run-to-run variance is larger, and therefore the bound from Theorem 1 (which only holds in expectation) is no longer a strict upper bound (see right plot).

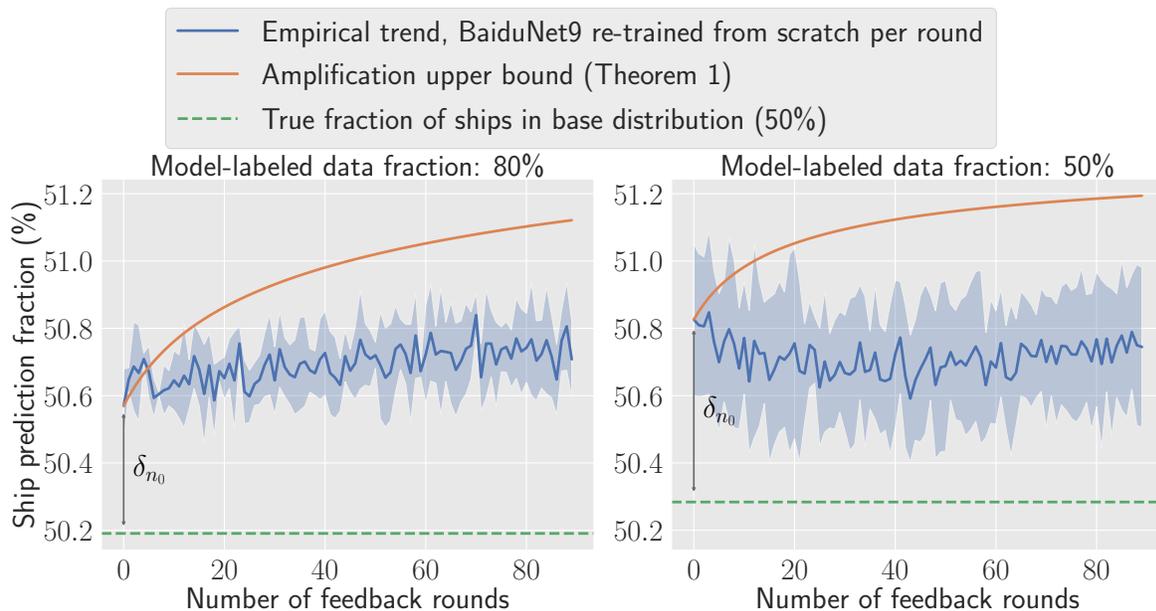

Figure 12: Label bias amplification on CIFAR. The dataset is balanced such that ships (instead of dogs) are in a 9:1 imbalance ratio compared to any other class. All other experimental settings are the same as in Figure 3. Bias amplification is more modest since the initial faithfulness error for ships is smaller.

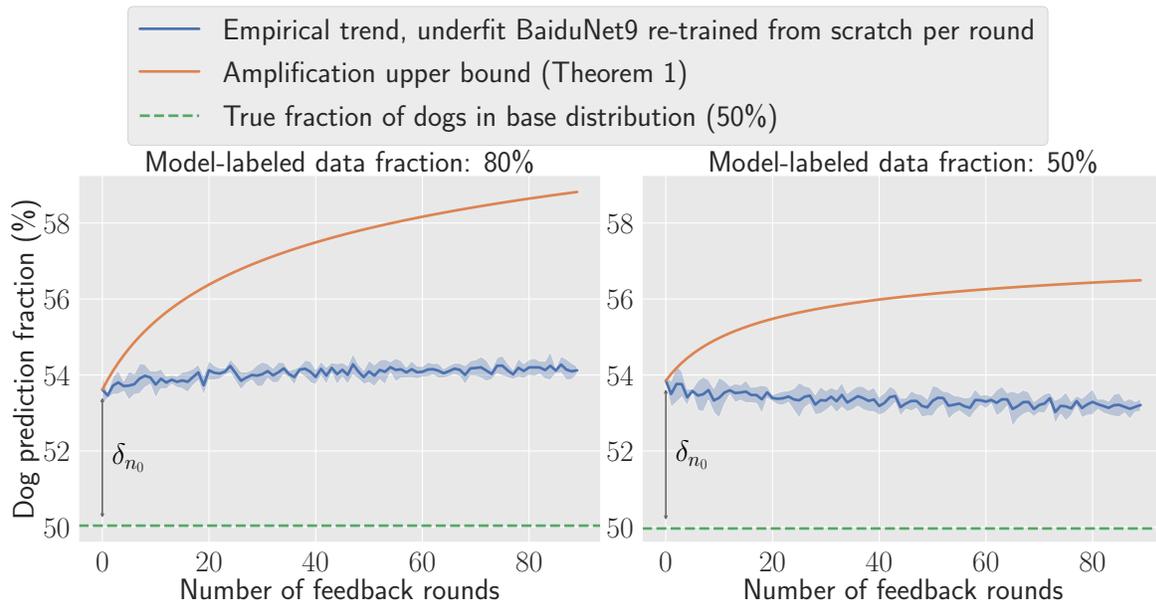

Figure 13: Label bias amplification on CIFAR. The BaiduNet9 is underfit by using a shortened training schedule. All other experimental settings are the same as in Figure 3. Bias decreases over time when the model-labeled fraction is 50%; this may be due to decreasing faithfulness error as the dataset size increases and the model is trained for a larger number of iterations, an effect which is magnified when the model is underfit.

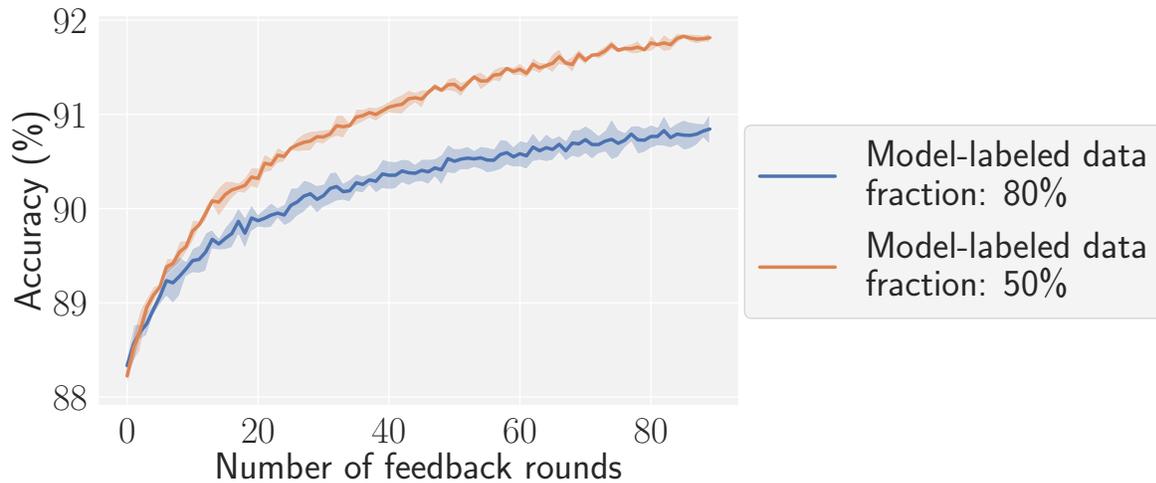

Figure 14: Average classification accuracy during data feedback for the underfit models presented in Figure 13. Compared to the non-underfit models presented in Figure 3, these models have both lower classification accuracy (comparing to Figure 6) and higher label bias (looking at Figure 13). Thus, in this setting, there does not seem to be a bias-accuracy tradeoff for well-tuned interpolating classifiers.

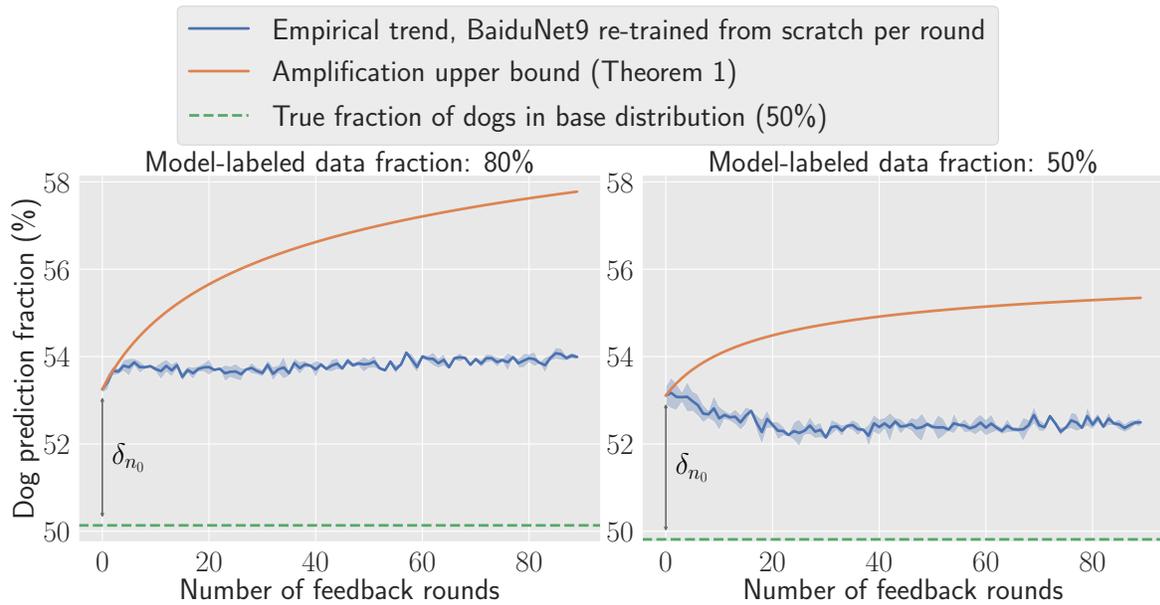

Figure 15: Label bias amplification on CIFAR. The initial dataset size is set to $n_0 = 20k$ (instead of $n_0 = 50k$). All other experimental settings are the same as in Figure 3. Bias decreases over time when the model-labeled fraction is 50%; this may be due to decreasing faithfulness error as the dataset size increases, an effect which is magnified when the initial dataset size is smaller.

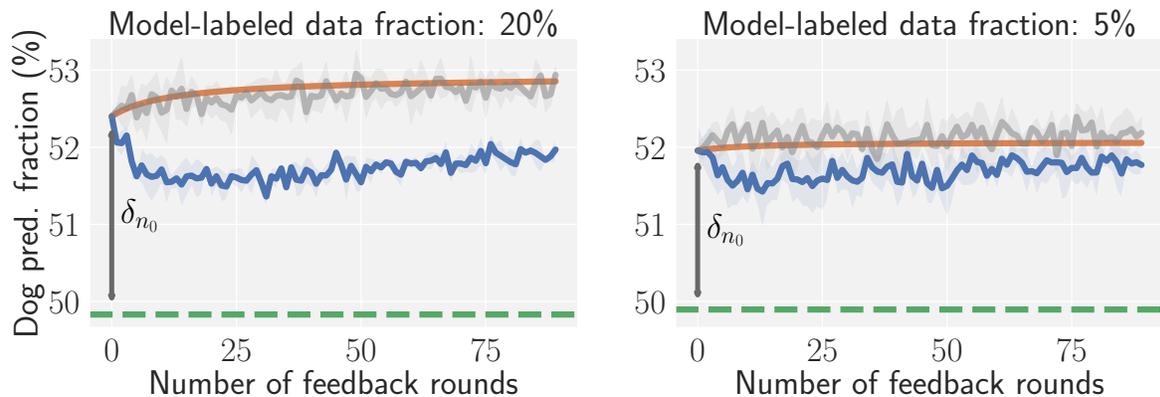

Figure 16: Label bias amplification on CIFAR. The fraction of model-labeled examples per round is either 20% (left) or 5% (right). All other experimental settings are the same as in Figure 3. Overall amplification is smaller compared to Figure 3 since the fraction of model-labeled samples is smaller. The Theorem 1 bound, which holds in expectation, provides a useful guide of amplification in the worst-case setting (in gray). The empirical trends in blue initially show a reduction in amplification, possibly due to smaller faithfulness errors as the dataset size increases, especially as a greater fraction of dataset labels come from humans compared to Figure 3.

G.2. Visual role-labeling

We show gender bias amplification plots, each covering the image categories where the female label ratio lies in one of the five intervals between 0% – 100%. Figure 17 shows amplification on the interval 0% – 20%, and Figure 7 shows amplification on the interval 20% – 40%, both of which depict male bias amplification. Figure 4 shows amplification on the interval 60% – 80%, and Figure 19 shows amplification on the interval 80% – 100%, both of which depict female bias amplification. The middle interval 40% – 60%, where existing gender ratios are balanced, is depicted in Figure 18.

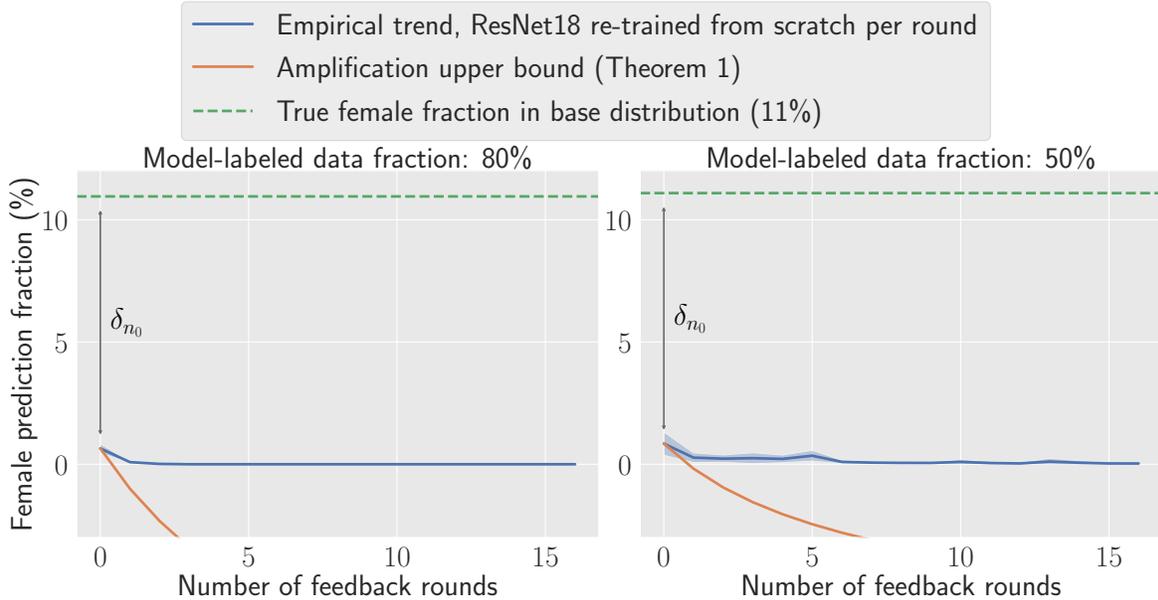

Figure 17: Gender bias amplification on the imSitu dataset. Gender bias is measured over the image categories where the ground truth female frequency is between 0% and 20%. All experimental settings are the same as in Figure 4.

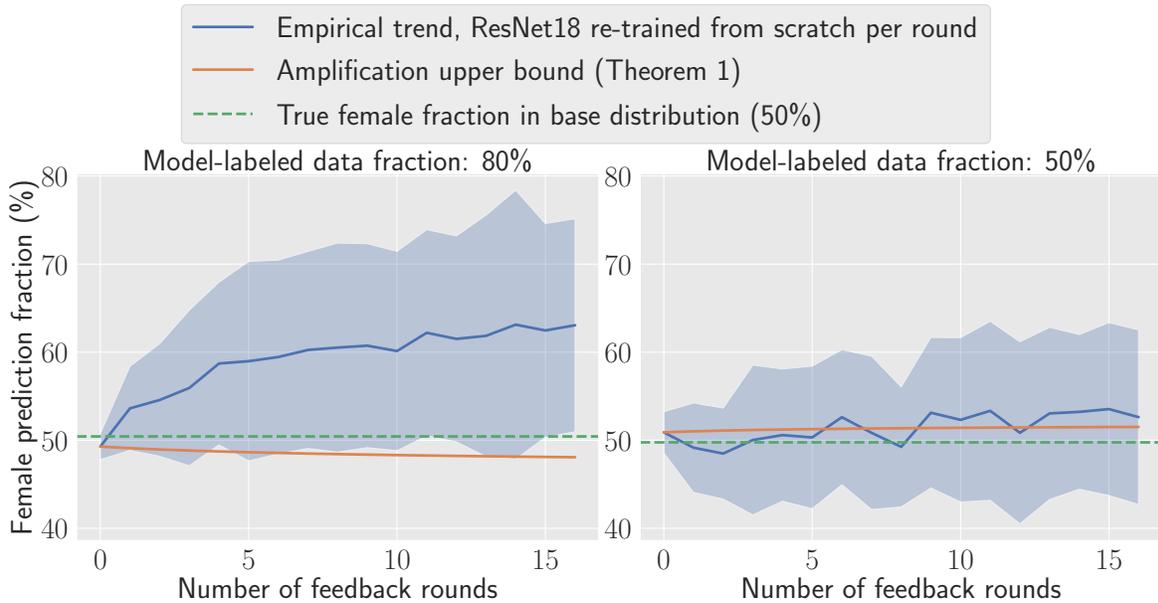

Figure 18: Gender bias amplification on the imSitu dataset. Gender bias is measured over the image categories where the ground truth female frequency is between 40% and 60%. All experimental settings are the same as in Figure 4.

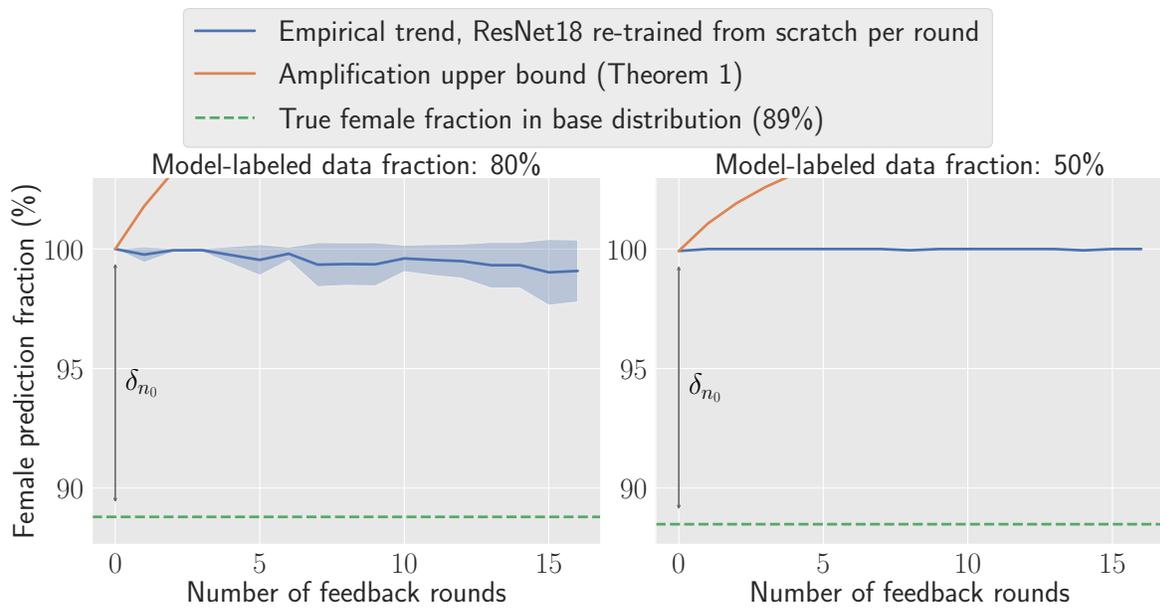

Figure 19: Gender bias amplification on the imSitu dataset. Gender bias is measured over the image categories where the ground truth female frequency is between 80% and 100%. All experimental settings are the same as in Figure 4.

G.3. Language modeling

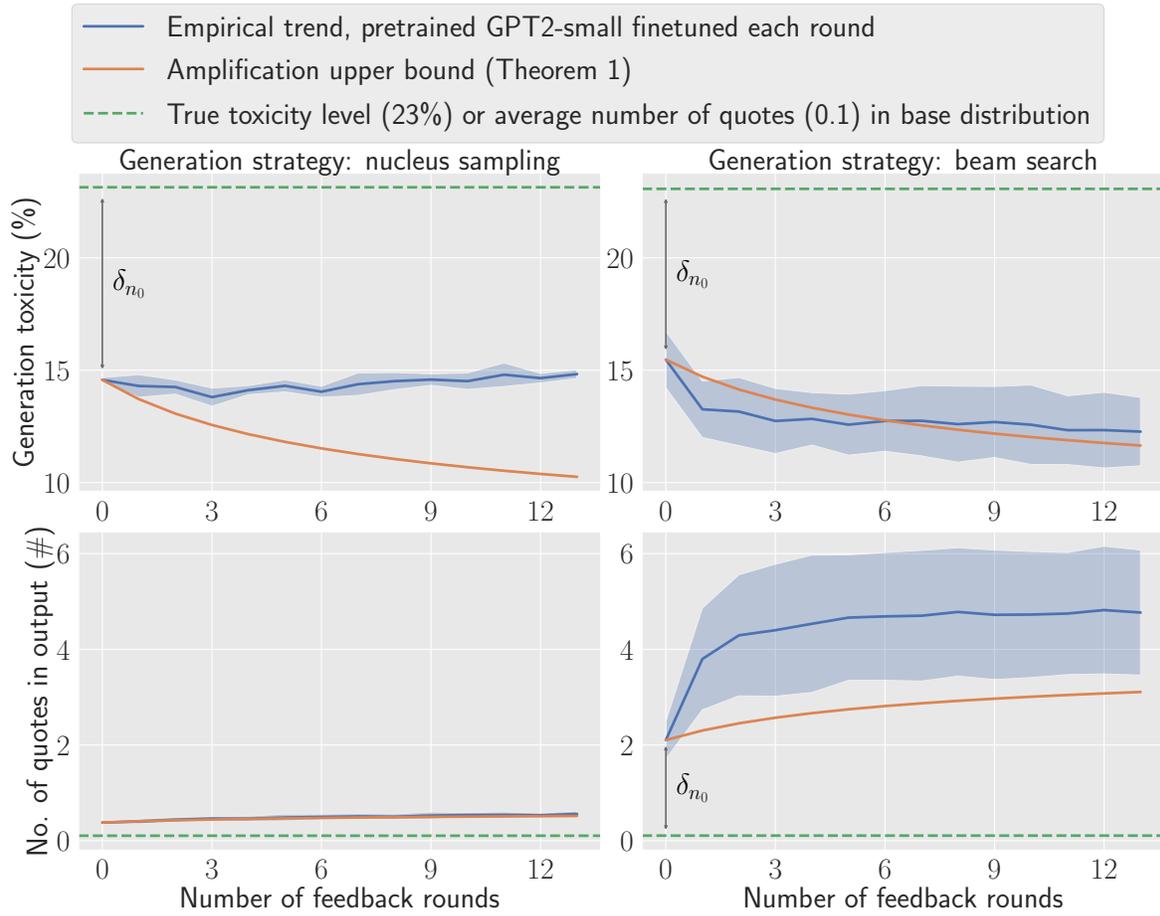

Figure 20: Toxicity and repetition amplification on Real Toxicity Prompts. Half of the new data during data feedback is model-labeled ($m = 2.5k, k = 2.5k$). All other experimental settings are the same as in Figure 5.

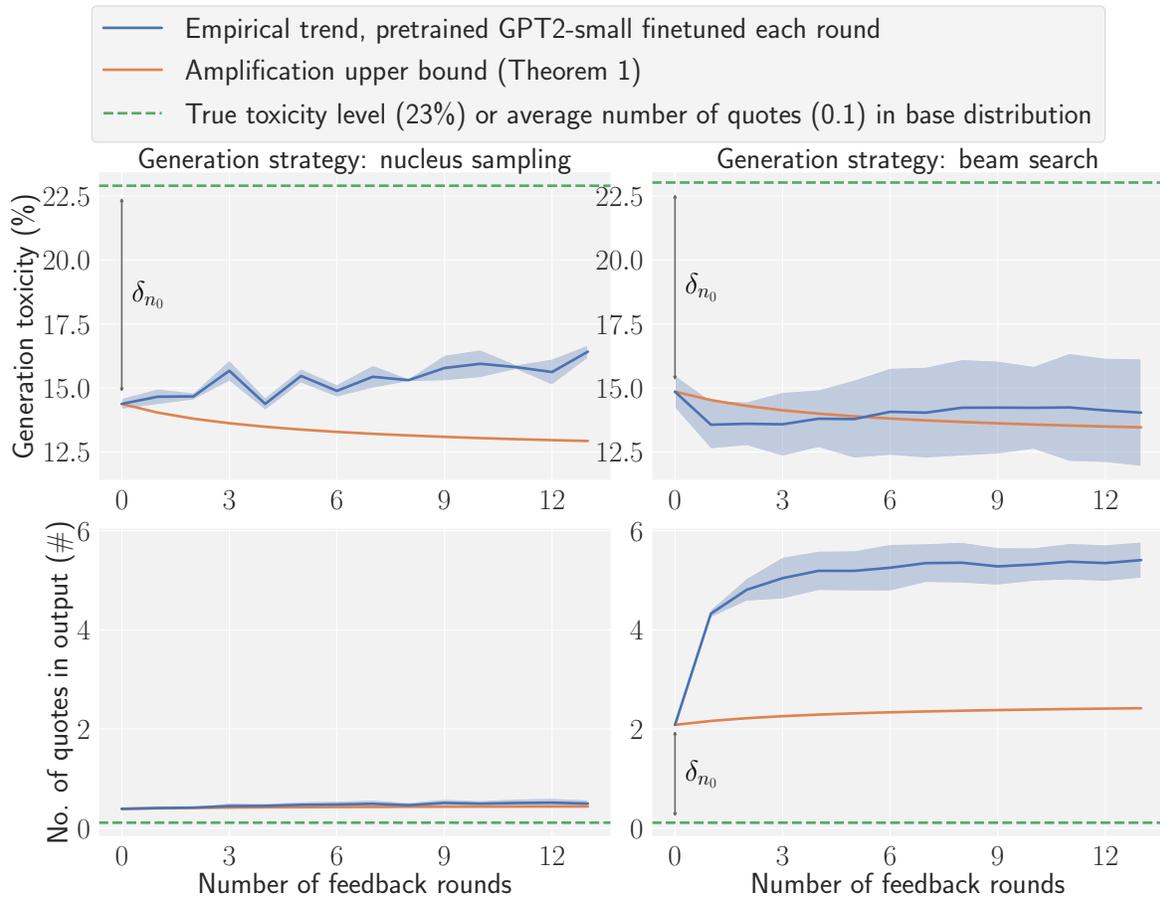

Figure 21: Toxicity and repetition amplification on Real Toxicity Prompts. 20% of the new data during data feedback is model-labeled ($m = 4k, k = 1k$). All other experimental settings are the same as in Figure 5. The beam search models still strongly amplify repetition bias. However, toxicity bias for both beam search and nucleus sampling models is mitigated compared to Figure 5.

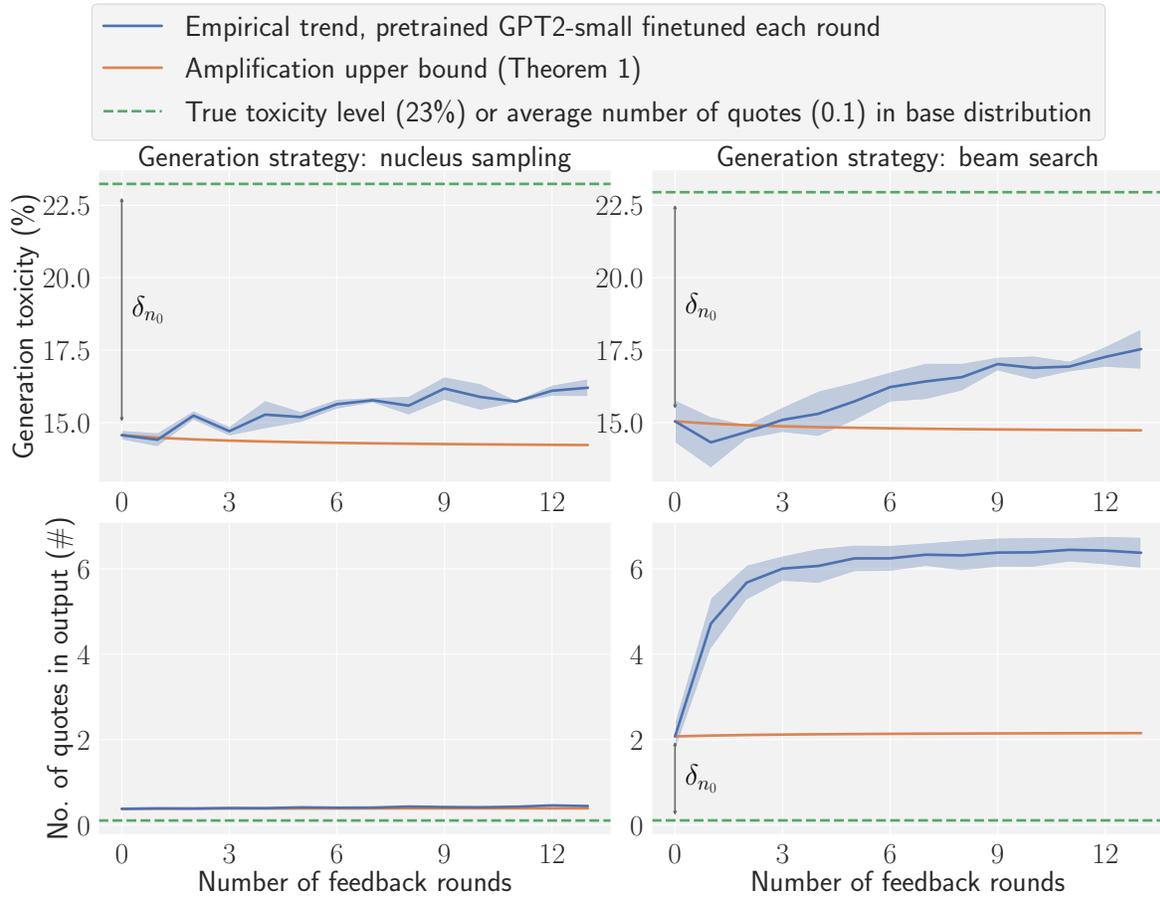

Figure 22: Toxicity and repetition amplification on Real Toxicity Prompts. 5% of the new data during data feedback is model-labeled ($m = 4.75k$, $k = 0.25k$). All other experimental settings are the same as in Figure 5. Toxicity bias for both models reduce over time, as a greater fraction of the data is human-labeled and therefore faithfulness errors decrease. However, the beam search models still strongly amplify repetition bias.

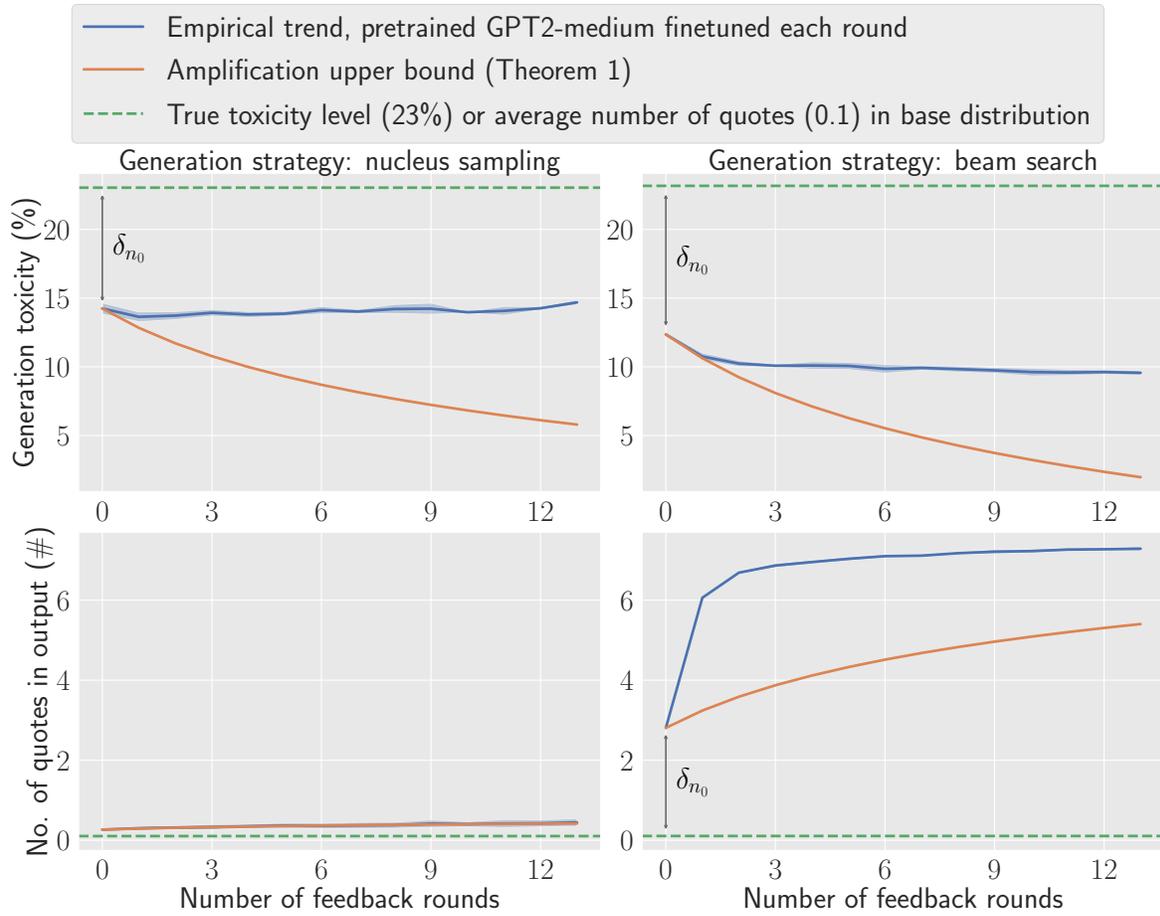

Figure 23: Toxicity and repetition amplification on Real Toxicity Prompts. The language model used is GPT2-medium. All other experimental settings are the same as in Figure 5.

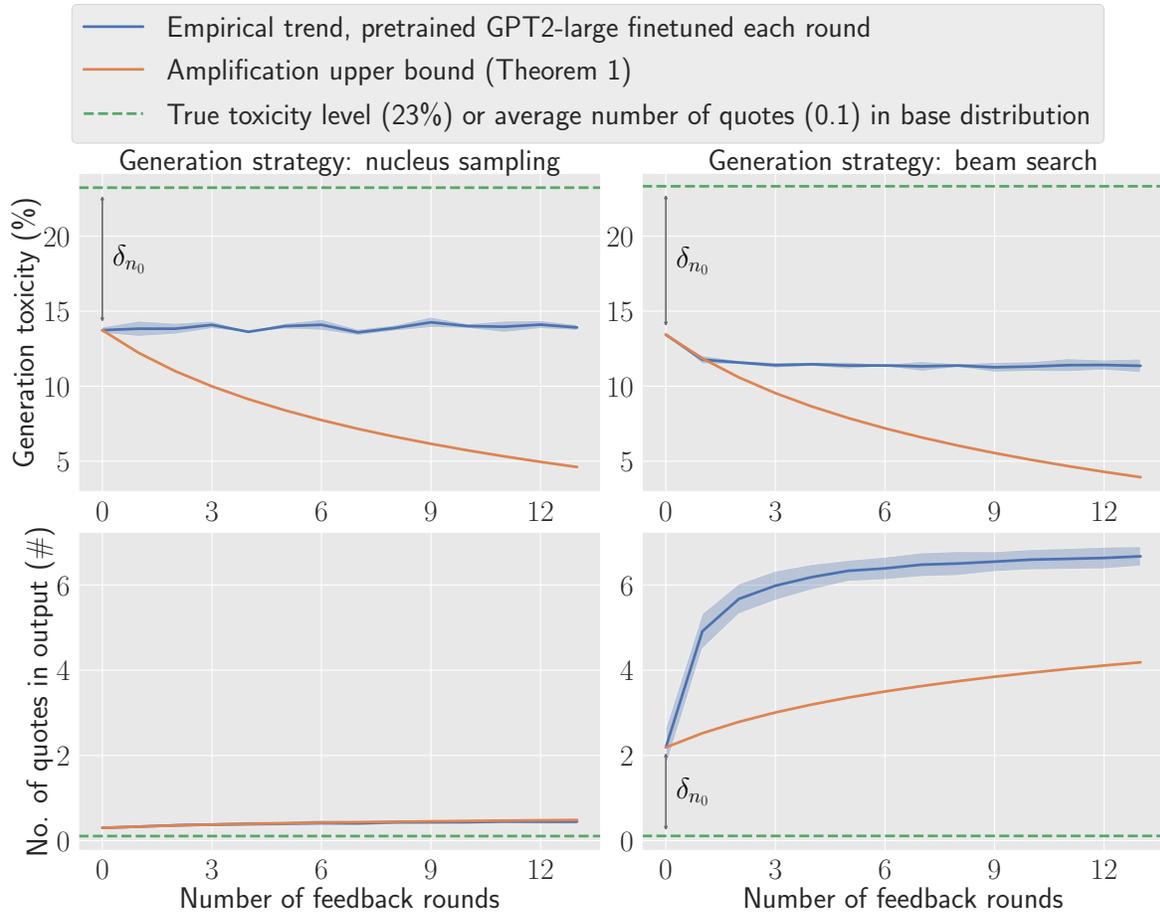

Figure 24: Toxicity and repetition amplification on Real Toxicity Prompts. The language model used is GPT2-large. All other experimental settings are the same as in Figure 5.
