## Abstract

In Large Language Model (LLM) development, Reinforcement Learning from Human Feedback (RLHF) is crucial for aligning models with human values and preferences. RLHF traditionally relies on the Kullback-Leibler (KL) divergence between the current policy and a frozen initial policy as a reference, which is added as a penalty in policy optimization algorithms like Proximal Policy Optimization (PPO). While this constraint prevents models from deviating too far from the initial checkpoint, it limits exploration of the reward landscape, reducing the model's ability to discover higher-quality solutions. As a result, policy optimization is often trapped in a narrow region of the parameter space, leading to suboptimal alignment and performance. This paper presents **SALSA** (Soup-based Alignment Learning for Stronger Adaptation), a novel approach designed to overcome these limitations by creating a more flexible and better located reference model through weight-space averaging of two independent supervised fine-tuned (SFT) models. This model soup allows for larger deviation in KL divergence and exploring a promising region of the solution space without sacrificing stability. By leveraging this more robust reference model, SALSA fosters better exploration, achieving higher rewards and improving model robustness, out-of-distribution generalization, and performance. We validate the effectiveness of SALSA through extensive experiments on popular open models (Llama2-7B, Mistral-7B, and Gemma-2B) across various benchmarks (MT-Bench, Arena-Hard, UltraFeedback), where it consistently surpasses PPO by fostering deeper exploration and achieving superior alignment in LLMs.

1 INTRODUCTION

Large language models (LLMs) have revolutionized natural language processing (NLP) by demonstrating remarkable capabilities in understanding and generating human language. These models, powered by vast amounts of data and advanced neural architectures, have set new benchmarks in various NLP tasks, from machine translation to conversational agents. Despite these advancements, aligning LLMs with human values and preferences remains a significant challenge. Misalignment can lead to undesirable behaviors, including generating biased or inappropriate content, which undermines the reliability and safety of these models (Kenton et al., 2021; Bender et al., 2021; Bommasani et al., 2021; Gehman et al., 2020).

Reinforcement Learning from Human Feedback (RLHF) has become a promising technique 044 for aligning large language models (LLMs) with human preferences. By fine-tuning LLMs 045 based on human feedback, RLHF guides models towards more human-aligned behaviors, 046 improving truthfulness, helpfulness, and harmlessness while maintaining the generation of high-probability, correct answers (Christiano et al., 2017). Reward-based RLHF methods 048 utilize a reward model to determine the reward for a given (prompt, response) pair. The 049 policy model is then optimized by maximizing the average reward through reinforcement learning algorithms like Proximal Policy Optimization (PPO) (Schulman et al., 2017). A 051 crucial aspect of RLHF is the use of a reference model to compute the Kullback-Leibler (KL) divergence penalty, which prevents the fine-tuning process from deviating too far from the 052 original model (Ziegler et al., 2019). This approach ensures that the policy remains close to the initial model, reducing the risk of generating nonsensical responses.

While effective, reliance on a single reference model can be limiting. The KL penalty term constrains the policy model to stay close to the initial supervised fine-tuning (SFT) model, restricting its ability to fully explore the solution space for higher-reward models. This constraint can lead to suboptimal alignment and a lack of robustness in the training process, increasing the risk of generating nonsensical outputs. Ensuring that the reference model is already positioned in a robust space can mitigate this issue, allowing for more confident exploration without compromising output quality.

061 To address this limitation, we propose SALSA. It integrates a "model soup" as the reference 062 model within the RLHF framework. A model soup is constructed by performing weight-063 space averaging of multiple independently supervised fine-tuned models that demonstrate 064 comparable performance. This method leverages the principle that fine-tuned models from the same pre-trained initialization often reside in a shared low-error basin in the 065 loss landscape, enabling effective weight interpolation without compromising accuracy. As 066 evidenced by Wortsman et al. (2022), this approach results in significant improvements in 067 both in-distribution and out-of-distribution generalization. The key advantage of model 068 soup lies in its ability to harness the complementary strengths of diverse models, reducing 069 variance and improving robustness, while maintaining computational efficiency. This makes 070 the "model soup" reference model a superior choice for improving the stability and reliability 071 of the RLHF training process compared to relying on a single reference model. 072

In this paper, we demonstrate the effectiveness of SALSA through comprehensive experiments. We apply SALSA to Llama2-7B, Mistral-7B, and Gemma-2B and benchmark the results against standard evaluation datasets, including MT-Bench, Arena-Hard, and UltraFeedback—the latter being used for RLHF training in our experiments. Our findings reveal that weight space averaging is a straightforward yet effective approach for aligning LLMs with human preferences, and enhancing their performance on real-world-like datasets.

- 079 In particular our contributions are following:
  - We demonstrate that the reward in the region near the model soup is inherently superior to that of the original SFT model. The improvement in reward is a newly observed phenomenon and is complementary to the improvement in accuracy of model soups. We further show having model soups as reference point of RLHF results in higher reward outcomes. (Section 4.2).
    - Drawing from these observations, we propose SALSA, a novel approach for implementing RLHF that utilizes the model soup as the reference model.
    - We perform a comprehensive evaluation across diverse benchmarks and models, demonstrating that SALSA consistently outperforms PPO (Section 4.3).

The remainder of this paper is organized as follows: Section 2 reviews related work on RLHF and model averaging techniques. Section 3 details our methodology for creating and integrating the model soup in the RLHF process. Sections 4.1 through 4.4 present the experimental results and analysis of model averaging for better alignment.

2.1 Model Soup

Model soups build on the findings of (Neyshabur et al., 2020), which showed that independently fine-tuned models often lie within the same loss basin, allowing their weights to be successfully combined through interpolation. (Wortsman et al., 2022) extended this, demonstrating that averaging fine-tuned model weights can improve performance compared to using a single model. Unlike traditional ensembling, model soups require no extra memory or inference time, while still enhancing robustness. This method has shown consistent performance gains across NLP and image classification tasks (Wortsman et al., 2022; Izmailov et al., 2018).

121

122 123

124

Figure 1: Comparison of SALSA and PPO. The main difference between SALSA and PPO is in the reference model within KL divergence of loss. SALSA consistently outperforms PPO across different models and tasks.

Large language models (LLMs) have achieved significant success across tasks, thanks to
fine-tuning methods like Supervised Fine-Tuning (SFT) and Reinforcement Learning from
Human Feedback (RLHF) (Ouyang et al., 2022; Touvron et al., 2023a; Bai et al., 2022; Anil
et al., 2023). RLHF has been crucial for aligning models with human preferences, enabling
outputs that are more helpful and aligned with societal values (Ziegler et al., 2019; Stiennon
et al., 2020; Achiam et al., 2023).

RLHF methods are divided into reward-based and reward-free approaches. Reward-based 132 methods rely on training a reward model to guide policy optimization, typically with Proximal 133 Policy Optimization (PPO) (Schulman et al., 2017; Gao et al., 2023). PPO is widely used for 134 its balance of stability and exploration (Ouyang et al., 2022). Studies have also examined the 135 importance of hyperparameter tuning and reward model quality to avoid overoptimization 136 (Casper et al., 2023; Zheng et al., 2023a). Reward-free methods, such as Direct Preference 137 Optimization (DPO), bypass the reward model by directly optimizing human preference data 138 (Rafailov et al., 2023; Liu et al., 2023; Yuan et al., 2023). While DPO simplifies training and 139 performs well on tasks like instruction following (Touvron et al., 2023a), it struggles with 140 out-of-distribution data, and its generalization capabilities are limited (Yuan et al., 2024; Xu 141 et al., 2024).

- 142 In this paper, we focus on Proximal Policy Optimization (PPO) for its demonstrated 143 robustness in managing large models and diverse tasks. Studies such as (Xu et al., 2024) 144 highlight the limitations of Direct Preference Optimization (DPO), which tends to find 145 biased solutions when confronted with out-of-distribution responses and is highly sensitive to 146 distribution shifts. In contrast, PPO effectively mitigates these challenges through the use 147 of reward models and KL divergence regularization (Ouyang et al., 2022; Schulman et al., 2017). This enables PPO to consistently outperform DPO in tasks like dialogue and code 148 generation, proving its reliability across alignment challenges (Xu et al., 2024). 149
- 150 Recent RLHF research has introduced novel approaches to improve upon traditional methods, 151 particularly in addressing the limitations of using reference models. SimPO (Meng et al., 152 2024) eliminates the need for a reference model by optimizing the average log probability of sequences with a reward-free approach. This reduces computational costs and improves 153 memory efficiency over traditional DPO, achieving better performance across benchmarks like 154 AlpacaEval and Arena-Hard. SimPO underscores the limitations of static reference models in 155 DPO and advocates for scalable, reference-free approaches. Conversely, (Gorbatovski et al., 156 2024) introduces a dynamic reference model that evolves throughout training using Trust 157 Region methods. This dynamic approach allows the reference model to adapt alongside the 158 policy, preventing constraints imposed by outdated checkpoints and enabling more effective 159 generalization and alignment with human preferences. 160
- 161 The aforementioned papers have identified that the reference model may limit the optimization process in DPO, and they propose innovative solutions to address this issue. Similarly, we

aim to solve this problem within the PPO framework. We adopt a model soup approach,
 which averages the weights of fine-tuned models. This method allows the optimization
 process in PPO to explore a broader solution space, offering greater flexibility and enhancing
 alignment performance.

In this section we present our method, SALSA (Soup-based Alignment Learning for Stronger Adaptation). We begin with a brief overview of Proximal Policy Optimization (PPO), and model soup, followed by a detailed description of our approach.

173 3.1 RLHF

In our main experiments, we focus on reward-based RLHF, in particular Proximal Policy
Optimization (PPO). The conventional framework for reward-based RLHF consists of several
key stages as follows.

Supervised Fine-Tuning (SFT). The initial stage of alignment involves supervised fine-tuning, where a pre-trained language model is refined using a high-quality instruction dataset.

**Reward Model.** Reward-based RLHF involves training a reward model, which is typically initialized from the SFT model. In this process, the logit layer of the SFT model is replaced by a new linear layer. This linear layer takes the embedding of the last token and outputs a scalar reward. Higher rewards indicate better samples. For a given prompt x and a pair of responses  $y_w$  (chosen) and  $y_l$  (rejected), the loss function is optimized as:

$$\mathcal{L}(R_{\theta}) = -\log \sigma(R_{\theta}(x, y_w) - R_{\theta}(x, y_l)), \tag{1}$$

where  $R_{\theta}(\cdot, \cdot)$  is the reward model,  $\theta$  denotes its parameters,  $\sigma$  indicates the sigmoid function.

189 Policy Training. The last phase of RLHF is dedicated to training the policy model, which 190 is initialized from a reference model, typically the SFT model. Based on a recent study (Xu 191 et al., 2024), PPO performs better in distribution shifts and results in superior alignment with human preferences across challenging tasks like code generation and dialogue systems. 192 Therefore, we selected PPO as the training algorithm. The goal is to optimize the policy 193 model to maximize the reward for a given prompt x and its generated response y, while 194 also minimizing the KL divergence between the policy model and the reference model. The 195 overall loss function for this stage is given by: 196

$$\mathcal{L}_{\mathcal{PPO}}(\pi_{\theta}) = -R(x, y) + \beta \mathrm{KL} \left(\pi_{\theta}(y \mid x) \mid \boldsymbol{\pi}_{\mathrm{ref}}(y \mid x)\right)$$
(2)

where  $\pi_{\theta}$  is the policy model,  $\pi_{ref}$  is the reference model, and R(.,.) is the trained reward model.

201 3.2 MODEL SOUP

202 The concept of a model soup, introduced in Wortsman et al. (2022), aims to enhance model 203 performance by averaging the weights of multiple pre-trained networks. This technique 204 combines the parameters of independently trained models to produce a more robust outcome, leveraging the strengths of each. There are three primary strategies for constructing a model 205 soup: uniform, greedy, and learned. In our approach, we employ its most basic strategy, *i.e.*, 206 the uniform method, where the parameters of separate SFTs are averaged. Investigating 207 other mixing strategies for RLHF and comparing them is left as future work. Formally, we 208 construct our soup model using two SFT models:  $\pi_{ref}$ , which serves as the initialization of 209 the policy model in the PPO framework, and  $\pi_{other}$ , an additional SFT model trained on 210 the same data with a different random seed. Their weights denoted as  $\theta$  is averaged using a 211 coefficient  $\alpha$ : 212

$$\theta_{soup} = (1 - \alpha)\theta_{ref} + \alpha\theta_{other} \tag{3}$$

214 In our experimental setup, as shown in Figure 4a, setting  $\alpha$  to 0.5 produces the best results. 215 This will be further discussed in the next section, where we also explain our proposed method, SALSA.

# 216 3.3 SALSA

The KL term in equation 2 ensures that the model remains closely aligned with the reference model. This term is essential because optimizing solely for the reward can result in the generation of nonsensical outputs. However, it also imposes a constraint by preventing the model from deviating significantly from the initial reference model. To address this limitation, we propose replacing the KL term in 2, with the following loss function:

$$\mathcal{L}_{SALSA}(\pi_{\theta}) = -R(x, y) + \beta \mathrm{KL}\left(\pi_{\theta}(y \mid x) \parallel \pi_{\mathrm{soup}}(y \mid x)\right)$$
(4)

225 As mentioned in Equation 3,  $\pi_{soup}$  refers to a model soup, which is the result of averaging 226 two independently trained supervised fine-tuned models (SFTs), including the reference 227 model. Since the policy model  $\pi_{\theta}$  is initialized from the reference model  $\pi_{ref}$ , substituting 228 the KL term in equation 2 with the KL term in 4 which is the model soup of  $\pi_{ref}$  and  $\pi_{other}$ allows the policy model to search around averaged model, thereby enabling exploration of 230 a broader and more promising parameter space. The primary distinction between the loss 231 terms in equations 2 and 4 is that the soup model is used in place of the reference model. 232 This substitution keeps our approach straightforward to implement while proving highly effective. Our experiments demonstrate improved performance, resulting in higher win rates 233 over PPO across three models and three datasets. These consistent results indicate SALSA's 234 effectiveness in various settings. 235

236 237

238

223 224

# 4 Experiments

239 4.1 EXPERIMENTAL SETUPS240

In this section, we outline our experimental setup. We use three models: Llama2-7B (Touvron 241 et al., 2023b), Mistral-7B (Jiang et al., 2023), and Gemma-2B (Team et al., 2024). For 242 Supervised Fine-Tuning (SFT), we employ the UltraChat-200k dataset (Ding et al., 2023). 243 The UltraFeedback dataset (Cui et al., 2023) is utilized for both training the reward model 244 and optimizing preferences. All experiments across the three stages (SFT, reward model, 245 RLHF) are conducted using the TRL library by HuggingFace (von Werra et al., 2020). For 246 both PPO and SALSA, we use the KL coefficient  $\beta$  that achieves the highest win rate. 247 Further details on the hyperparameter settings are available in Appendix A. 248

Evaluation Benchmarks. We evaluate the effectiveness of our method using three wellestablished instruction-following benchmarks: MT-Bench (Zheng et al., 2024), Arena-Hard v0.1 (Li et al., 2024), and UltraFeedback (Cui et al., 2023) test dataset. MT-Bench comprises 80 questions across 8 categories, while Arena-Hard is an enhanced version of MT-Bench, featuring 500 well-defined technical problem-solving questions.

In our evaluation process, we used the datasets described in the previous section to generate samples. Pairwise comparisons were then conducted using GPT-4-Turbo as the judge model, following the "LLM-as-a-judge" methodology. The prompt used for our judge model is provided in Figure 7 in the Appendix. For evaluation, we utilized the FastChat repository (Zheng et al., 2023b). For the MT-Bench questions, which involve two rounds, we generated and evaluated outputs for each round.

260261 4.2 REWARD ANALYSIS

262 We hypothesize that  $\pi_{soup}$  resides in a region of the parameter space associated with generally 263 higher rewards, suggesting that models explored in this vicinity could generate responses 264 with increased reward values, in addition to the improved loss observed in the original model 265 soup paper Wortsman et al. (2022). To test this hypothesis, we conducted an analysis 266 along the interpolation line between two SFT models,  $\pi_{ref}$  and  $\pi_{other}$ , for Gemma-7B and 267 Llama2-7B, examining how the mean reward changes for the MT-Bench dataset. These rewards were calculated on raw models prior to RLHF process. As illustrated in Figure 2a 268 and 2b, we observe that the mean reward on the dataset increases as we move towards the 269 midpoint between these two models, and subsequently decreases beyond this point. This

281

282

284

297

298 299 300

Figure 2: (a) The reward of model averaging for Gemma-7B peaks in  $\alpha = 0.5$ . (b) The same phenomenon is seen for Llama2-7b (c) The heatmap of rewards of Llama2-7B around 3 SFT model in a Barycentric space. Inside the triangle which is closer to average of 3 models has significantly higher reward than outside triangle. This shows model soups are in a more promising region for searching.

Figure 3: Comparison of reward distributions between SALSA and PPO for the Llama2-7B model. SALSA gets higher reward in average across both datasets.

pattern indicates that  $\pi_{soup}$  - which represents the average of the SFTs - resides in a region of the parameter space associated with higher rewards further supporting our hypothesis.

303 Next, based on our observations of improved rewards from model soup combining two SFT 304 models, we extended our experiments to explore reward behavior within the space defined by three SFT models. These models were trained on UltraChat-200k using a pretrained 305 Llama2-7B, each initialized with different random seeds. Specifically, we evaluated rewards 306 on a plane defined by these three models, both inside and outside this space. Figure 2c 307 presents the results of these experiments. The vertices of the dotted-line triangle represent 308 the three SFT models. As shown, moving towards the midpoint between any two SFT 309 models consistently leads to increased rewards. A similar trend is observed as we approach 310 the center of the triangle. Additionally, the rewards for points outside the triangle decreases. 311 Since PPO tends to find solutions near the vertices of the triangle (due to its reliance on the 312 initial SFT model), the corresponding rewards in these regions are lower, as shown in the 313 figure. This suggests that PPO may struggle to guide the model towards areas associated 314 with higher rewards, which are located more centrally between the SFT models

315 Third, we hypothesize that SALSA's ability to explore a better parameter space, enables the 316 model to discover regions with higher rewards while maintaining the generation of sensible 317 responses. This expanded exploration ultimately results in SALSA's superior performance 318 over PPO. To validate this hypothesis, we compared the reward distributions for responses 319 generated by SALSA and PPO across the MT-Bench and Arena-Hard datasets. Figure 3 320 illustrates the reward distributions for both methods. The plot reveals that the reward 321 distribution for SALSA is shifted towards higher values compared to PPO. This rightward shift is consistent across both datasets, indicating that SALSA consistently generates responses 322 associated with higher rewards. Furthermore, the mean reward for SALSA is higher than 323 that of PPO in both datasets, further supporting our hypothesis.

Dataset	Model	SALSA vs PPO	SALSA vs SFT
MT Bonch	Llama2-7B	52.50	52.50
MII-Dentin	Mistral-7B	51.89	55.94
	Gemma-2B	57.19	56.88
	Llama2-7B	54.01	54.70
Arena-Hard	Mistral-7B	54.40	55.70
	$\operatorname{Gemma-2B}$	53.7	53.8
	Llama2-7B	50.75	52.23
UltraFeedback	Mistral-7B	52.40	51.93
	Gemma-2B	50.68	54.32

Table 1: Comparison of Adjusted Win Rates across Models and Datasets

Furthermore our findings indicate that employing a model soup as the reference model
permits greater deviation in KL divergence. This increased flexibility allows the policy to
investigate a more extensive area within the solution space. More info in this regard can be
found in Appendix A.4.

#### 342 343

344

324

330

### 4.3 Main Results

Figure 1 visualizes the win rate comparison between SALSA and PPO, where SALSA achieves 345 346 notable win rates of 54.01% for the Llama2-7B model and 54.40% for the Mistral-7B model on the challenging Arena-Hard dataset. Table 1 provides a comparative analysis of SALSA 347 against the original PPO and SFT models for Llama2-7B, Mistral-7B, and Gemma-2B. The 348 results indicate that SALSA consistently outperforms both PPO and SFT, demonstrating its 349 effectiveness. Based on the detailed results in tables 2, 3, and 4 in the Appendix results, PPO 350 and SFT often perform similarly on MT-Bench and Arena-Hard, likely because UltraFeedback 351 and UltraChat, which are utilized for SFT, Reward Modeling, and RLHF, are considered 352 out-of-distribution for these benchmarks. As a result, a basic version of PPO does not 353 significantly outperform SFT. However, SALSA's robustness to out-of-distribution data 354 (derived from weight averaging and model soup techniques) delivers improvements of up to 355 57% and 54% on these datasets. These results underscore SALSA's effectiveness in enhancing 356 out-of-distribution robustness in RLHF training while maintaining competitive performance for in-distribution, and emphasize SALSA's superior exploration capabilities and improved 357 reward optimization, resulting in better task alignment and overall performance. Additional 358 detailed results are available in tables 2, 3, and 4 in the Appendix. Also a qualitative 359 comparison of responses generated by SALSA and PPO is presented in Figure 8 in Appendix. 360

361

363

## 362 4.4 Ablation Study

We explored using alternative reference points along the line between  $\pi_{\rm ref}$  and  $\pi_{\rm other}$  by 364 varying the  $\alpha$  value in Equation 3. For each  $\alpha$ , we adjusted the KL divergence to achieve the 365 optimal win rate over PPO. This systematic adjustment allowed us to observe how the win 366 rate varies with  $\alpha$ , as shown in Figure 4a which reveals a clear trend: the adjusted win rate 367 increases as  $\alpha$  approaches 0.5, peaking at this midpoint before declining at higher values. 368 Notably, using  $\pi_{other}$  alone does not enhance performance, yielding an adjusted win rate of 369 only 43.07% over PPO. This outcome arises because, although the model explores a wide 370 range between  $\pi_{ref}$  and  $\pi_{other}$ , it ultimately converges on a lower-reward region near  $\pi_{other}$ . 371 These findings support our hypotheses on reward dynamics (Section 4.2) and the effects of 372 KL divergence (Section A.4).

To explore alternatives to SALSA, we experimented with a different loss function,  $\mathcal{L}_{MKL}$ , shown in equation 5, which regularizes the policy by averaging the KL divergences between the policy  $\pi_{\theta}$  and two SFT models,  $\pi_{ref}$  and  $\pi_{other}$ .

$$\mathcal{L}_{\mathcal{MKL}}(\pi_{\theta}) = -R(x, y) + \frac{\beta}{2} \left[ \mathrm{KL}\left(\pi_{\theta}, \boldsymbol{\pi}_{\mathrm{ref}}\right) + \mathrm{KL}\left(\pi_{\theta}, \pi_{\mathrm{other}}\right) \right]$$
(5)

Figure 4: (a) Win rates of SALSA vs. PPO (Mistral-7B) on Arena-Hard for various  $\alpha$  values. (b) Win rates of SALSA and Multiple KLs over SFT (Mistral-7B) on MT-Bench and Arena-Hard.

While SALSA employs model soup (an ensemble average of two models) as a reference point, this alternative approach calculates individual divergences from each model separately. Our empirical results, as demonstrated in Figure 9d and Table 5, indicate that this method does not outperform PPO. These findings highlight the significance of the averaging methodology between SFT models: using the averaged model as a single reference point for KL divergence proves more effective than computing the average of two separate KL divergences with distinct reference points.

Finally, we conducted an ablation study to assess the impact of using soups with more than two SFT models. As illustrated in Figure 2c, the reward is higher at the midpoints between SFTs compared to the vertices. Moreover, the reward near the center of the triangle is at its peak, higher than other regions. This suggests that incorporating more SFTs into the soup is likely to enhance SALSA's performance. Figure 5 supports this hypothesis, showing that the win rate increases as the number of SFTs in the soup model grows. Although increasing the number of SFTs for constructing the soup yields better performance, we limit the number to two due to computational constraints. Investigating soups of more than three elements and finding the optimal one is left as future work. 

Figure 5: Effect of the number of models in the soup on win rate. SALSA-n represents n references in the soup, with SALSA-1 being equivalent to PPO. Llama2-7B is used for the above experiments.

# 432 5 CONCLUSION

This paper presents SALSA, a novel method for improving alignment in large language models by leveraging a model soup as a reference in the RLHF framework. By utilizing weight-space averaging of fine-tuned models as the reference, SALSA facilitates more effective exploration during policy optimization, leading to stronger performance in in-distribution and more resilience in out-of-distribution regimes. We showed that model soup resides in a higher reward region even before the PPO process, enabling SALSA to search for higher potential model. Furthermore we showed using model soup as a reference model allows for larger deviation in KL enabling search in a larger region. Experimental results across multiple benchmarks consistently show that SALSA outperforms PPO, yielding higher win rates, increased average rewards, and improved alignment with human preferences. We further extended our work to show averaging over more SFT models results even in higher win rates and robustness. 

There are many avenues to extend this work: applying model soups to other forms of
learning from human feedback like DPO is a very interesting future work. Systematically
exploring other forms of ensembling different models as reference, and model averaging with
a non-uniform or adaptive weights is another valuable line of work. Finding out remedies for
KL-Hacks when using SALSA is another direction for theoretical and emperical research.

#### HYPER-PARAMETER SETTING А

#### A.1 SUPERVISED FINE-TUNING SETUP

We use a learning rate of 2.5e - 5, warmup ratio of 0.03, and batch size of 8 for Llama2-7B and Mistral-7B, and 16 for Gemma-2B. For each of these models, we train two supervised finetuned models with different random seeds. Flash attention is applied to conserve resources, and the maximum sequence length is set to 2048 tokens for all models.

A.2 REWARD MODEL TRAINING

The reward model training uses a learning rate of 2e-5, with a batch size of 8. We apply a weight decay of 0.001 and use the AdamW optimizer. The learning rate schedule follows a linear decay policy.

A.3 RLHF SETUP

665 For the RLHF stage, we use different learning rates: 2e - 6 for Llama2-7B and Mistral-7B, 666 and 1e - 7 for the Gemma-2B model. The batch size is set to 8, with 2 epochs of training. We set the initial KL divergence coefficient to 0.2 for the PPO experiments and 0.01 for the 668 SALSA experiments.

A.4 KL DIVERGENCE

The model soup resides on the line between two SFT models. As previous work by Wortsman 673 et al. (2022) has shown, each point along the line between two fine-tuned models can 674 improve the accuracy compared to the individual fine-tuned models. With this intuition, we 675 hypothesize that there is a broader search space around the model soup that can still be 676 beneficial for RLHF. Essentially, instead of searching for a model that does not diverge from 677 a single SFT model, we can find models that do not diverge from the line between two SFT 678 models. This allows for higher KL-divergence from the model soup. To verify this hypothesis, 679 we tried using a small KL-divergence coefficient of  $\beta = 0.01$  for PPO as well (in comparison 680 to  $\beta = 0.2$  in the optimal setting). Figure 6 illustrates that while PPO converged to a state 681 producing gibberish output, SALSA, using the same  $\beta$  value, achieved its optimal win rate.

682 Furthermore, high KL coefficients cannot be applied when using SALSA because the response 683 length tends to converge to zero. Specifically, if the response length y for a given prompt x is 684 zero, the KL divergence between the trained policy and the frozen policy (whether reference 685 or soup model) also becomes zero. As a result, the policy can gravitates toward regions 686 where the response length is zero, a phenomenon we refer to as the KL-Hack. Investigating 687 this issue is an interesting future research direction.

Table 2: Comparison of SALSA, PPO, and SFT across Various Datasets for Llama2-7B
 Model

# D WIN RATES

This section provides a comprehensive breakdown of win rates across all our experiments. We have included the details of win rates for all the experiments for llama2-7b in table 2, for gemma-2b in table 4 and for Mistral-7b in table 3. For each dataset we have compared the win rates of SALSA over PPO, SALSA over SFT and PPO over SFT. We have included win rates and adjusted win rates. SALSA consistently outperforms PPO and SFT.

E Multiple KL

Table 5 gives additional info of win MKL win rate over PPO. We compared MKL win rate over PPO over MT-Bench and Arena-Hard and in both cases MKL doesn't outperform PPO. This means simply trying to use multiple models is not gonna be effective and doing weight averaging in SALSA is crucial for effectiveness.

# F KL TRAINING CURVES

In this section we have included the KL and rewards for ultra feedback dataset. In figure 9
the KL curves and rewards of PPO and SALSA look similar, KL starts to get some distance
from the original point in SALSA similar to PPO. Reward on samples seen during training
for both methods increases similarly. The final model of SALSA has higher reward over the
whole dataset as it can bee seen in Fiugre 3.

Table 3: Comparison of SALSA, PPO, and SFT across Various Datasets for Mistral-7B model

Dataset	Comparison	Win	$\mathbf{Loss}$	$\mathbf{Tie}$	Win Rate	Adj. Win Rate

UltraFeedback	SALSA	465	388	1146	23.26	51.93
	$\mathbf{SFT}$	388	465	1146	19.41	48.07
	PPO	455	450	1095	22.75	50.65
	$\mathbf{SFT}$	450	455	1095	20.89	49.35

Table 4: Comparison of SALSA, PPO, and SFT across Various Datasets for Gemma-2B model

Dataset	Comparison	Win	$\mathbf{Loss}$	$\mathbf{Tie}$	Win Rate	Adj. Win Rate
		Gemm	a-2B M	Iodel		
	SALSA	37	14	109	23.13	57.19
	PPO	14	37	109	8.75	42.81
MT-Bench	SALSA	40	18	102	25.0	56.88
	SFT	18	40	102	11.25	43.12
	PPO	14	8	138	8.75	51.88
	SFT	8	14	138	5.0	48.12
	SALSA	154	117	229	30.8	53.7
	PPO	117	154	229	23.4	46.3
Arena-Hard	SALSA	154	116	230	30.8	53.8
	SFT	116	154	230	23.2	46.2
	PPO	24	19	451	4.86	50.51
	SFT	19	24	451	3.84	49.49
	SALSA	174	147	1660	8.78	50.68
	PPO	147	174	1660	7.42	49.32
UltraFeedback	SALSA	300	129	1548	15.17	54.32
	$\mathbf{SFT}$	129	300	1548	6.53	45.68
	PPO	276	129	1580	13.90	53.70
	SFT	129	276	1580	6.50	46.30

Table 5: Comparison of MKL and PPO across MT-Bench and Arena-Hard for Mistral-7B.

Dataset	Comparison	Win	Loss	Tie	Win Rate	Adj. Win Rate
MT-Bench	MKL PPO	$\begin{array}{c} 69 \\ 85 \end{array}$	$\frac{85}{69}$	$\begin{array}{c} 340\\ 340\end{array}$	$13.97 \\ 17.21$	48.38 <b>51.62</b>
Arena-Hard	MKL PPO	$20 \\ 29$	29 20	111 111	$12.50 \\ 18.13$	47.19 <b>52.81</b>
