Abstract
The optimal track certainly is the most attracted and probably the most prestigious event in the International Planning Competition (IPC). In this position paper we stress that symbolic search and pattern databases were the dominating planning approaches in the latestIPC in 2018, and in continuation to the precursor IPC in 2014 should be considered as the current state-of-the-art. Five of the Top 6 planners in the 2018 competition, namely Complementary (1 and 2), Planning-PDBs, Symbolic-Bidirectional, and Scorpion are all based on these technologies. These planners use the same technology across all domains and plan in one state space. The winner of IPC 2018 with an ≈ 1% lead in problems being solved, however, is a so-called portfolio planner, consisting of a selection of 17 different planners, one of which is chosen in a classifier that was trained on a manually selected set of benchmark instances. In about half of its successful runs, it called the winner of the previous IPC.

Introduction
Being inspired by the ultimate goal of general problem solving, in the field of action planning, there is a common understanding that planning competitions ran on a set of unknown and partly new set of benchmark problems, advance planning technology the most.

Starting in 1998, over the years considerable progress has been made in the development of new planners, due to competitors being brave enough to face a coding contest with an unknown benchmark set and with the obligation to offer their source code. Over the years, they have been confronted with an increasing set of challenges, both in the planning domain description language (PDDL) expressiveness, in problem metrics, in their inherent complexity, and in scaling problem sizes. While several tracks were spawned, the probably most attractive one is the deterministic part of the IPC, and its track on cost-optimal planning.

The outcome of the optimal track in the most recent 2018 International Planning is revisited in Table 1. The corresponding output on IPC 2014 has been provided and discussed by (Edelkamp, Kissmann, and Torralba 2015).

While most planners present one sole planning technology, the winning planner Delfi (Sievers et al. 2019) is a Portfolio, a mixture of different technologies. Given a problem task, it selects a planner based on a classifier, being trained on a manually chosen set of known planning benchmark instances. In its set of planners, 16 were contained as part of the Fast Downward planning framework, including at least one (Canonical PDB) that used pattern databases. The most effective approach chosen by this classifier, however, was the symbolic search planning system, which won the precursor 2014 IPC competition. In the only domain, where Delfi scored overall best (see results for Petri Net Alignment), it called this planner.

From the individual planner algorithmic side, in portfolios there is often little that is novel, the contribution of these planners is often found in the machine learning algorithm, which is trained on a set of known planning problems and that eventually selects the planner configuration to call. In terms of the potential of different planning approaches available to Delfi, the IPC outcome with a lead of only two more being solved (≈ 1% of 200 benchmark problems) is quite small, showing that cost-optimal planning is tough, even for portfolios. A change in one domain would have resulted a different outcome.

While portfolio planning is in alignment with the rules of the competition, one underlying issue to be discussed in this paper is that the teams of other participating planners opted against using portfolio technology for one sole planning approach to avoid blurring the scientific outcome in favour of a clearer picture on what technology is currently leading. They prefer working on new technologies and refused going in for a mixture of existing planners.

Given the outcome of the competition and the different type of contributions available in portfolio and non-portfolio planners, people interested in planning especially outside to the core community have to be warned not to derive wrong scientific conclusions by simply looking at the outcome. Competition results always have to be dealt with care.

The stress of this paper, therefore, is to argue that that the two technologies of BDD-based symbolic search planning (Edelkamp and Helmert 2001) and planning pattern databases (Edelkamp 2001) first joint up by (Edelkamp 2005) dominated the competition, and have demonstrated state-of-the-art in 2018. This position paper a) provides a clearer picture on what is the currently leading technology according to IPC 2018 and b) discusses on whether or not a portfolios help to push or blur the outcome of a competition.

1Planners are described in the IPC 2018 competition booklet.
Symbolic Search and Pattern Databases

The IPC 2018 planner Symbolic-Bidirectional (SymBiDir), suggested as a baseline planning technology, includes no lower bound at all, it relies on so-called blind search, i.e., a search with no heuristic search guidance. As actions carry cost, instead of a breadth-first exploration this induces a cost-first traversal of the state-space graph.

In symbolic planning, the core difference to explicit-state space planning is the use of binary decision diagrams (BDDs) to represent state sets in the search compactly (Bryant 1986). As actions can also be represented in form of BDDs encoding the transition relation, it is possible to progress and regress in this succinct functional state set representation to perform forward and backward exploration in an operation called relational product (Clarke et al. 1996). An A*-type algorithm has been proposed by (Edelkamp and Reffel 1998).

Memory savings in turn often leads to savings in CPU time. The gain of a symbolic representation in IPC 2018 is amplified, when comparing the performance gap of SymBiDir with ExplicitBlind search. Indicated by the name, the two blind search baseline planners are not executing the exact same exploration, mainly due to the fact that coding regression search is not at all immediate for the usual partial goal state representation given; so that the latter conducts a forward state-space traversal only.

To the contrary, SymBiDir executes bidirectional cost-based search, much in the sense of bidirectional application of Dijkstra’s single-source shortest path algorithms (Dijkstra 1959), taking care of the fact that the optimal solution might not be established on the first meeting of both search frontiers. As the BDDs represent state sets, recursive solution construction is needed for extracting optimal plans. Aspects like a partitioned computation of successors (called the image), variable ordering based, as well as the inclusion invariant constraints to rule out illegal and dead-end states turn out to be crucial factors to improve the exploration efficiency (Torralba et al. 2017).

The performance results of SymBiDir revealed, that in only two of the ten domains (Snake, Spider) it was not doing well, otherwise this suggested baseline planner would have won the competition! This indicates the power of symbolic state space representation, and suggests that the vast amount of refined heuristics for planning does not necessarily lead to a thorough leading technology.

According to the result of the 2018 competition, planning pattern databases (PDBs) (Edelkamp 2001) are one of the few exceptions. The combination of PDBs and symbolic search in the planners Complementary (1/2) and Planning-PDB are significantly outperforming Symbolic Bidirectional Search. The former two are inspired by results of (Franco et al. 2017), while the latter improves on bin packing algorithms for the pattern selection problem. Besides a major rewrite, one new feature is that the forward search is explicit-state, while the backward traversal is symbolic.

Recall that planning pattern databases are serving as heuristics and that they are based on a complete backward exploration in some state-space abstraction. Often a larger number of (hopefully) diverse and complementary patterns are generated and the corresponding databases sought to be combined in an admissible manner to preserve being a lower bound. Perimeter pattern databases turned out to be good candidates in this PDB zoo (Felner and Ofek 2007). While Scorpion is an explicit-state PDB planner (performing slightly worse to SymBiDir in IPC 2018), it showed distinguished performance, and further results illustrate that it is performing much better across all IPC benchmarks, i.e., ones including the ones from previous competitions (Seipp and Helmert 2018; 2019). When normalizing the success alongside the domains (some have 150 instances), Scorpion
compares well with the top-tier symbolic planning systems: 0.621 (Complementary 2), 0.601 (Scorpion), 0.594 (Planning PDBs), 0.576 (Complementary 1), 0.555 (SymBiDir). Using Delfi in this comparison hardly applies, as for this case the training set overlaps the test set.

**Portfolio Planning**

Portfolios erected on existing plan technology, are a recurring pattern in many competitions, and range from restarting strategies, over learning classifiers, to scheduling time slices to existing planners.

Once having fixed the metric and submission instructions, the IPC 2018 organizers felt that they had to follow them. If a planner wins by the metric they decided on before, the competition and the organizers didn’t crown it the winner, the teams would rightfully complain.

The coverage metric of problems solved seems not to be the issue, so one thing the organizers could have done, would have been to change the rules for submissions. They explained that they had an internal discussion about portfolios early on in the course of running the competition, but decided that the line between a planner with multiple components and a portfolio was too blurry to accurately define. That is why they decided to not have a special rule against portfolios. As one reason given, the LAMA system (Richter and Westphal 2010), one previous IPC winner, might have to be considered a portfolio, because it runs different planners one after the other.

In terms of the organizers of the competition is difficult to set rules that identify portfolios to give them a special treatment, because either they’d be too restrictive and most planners of the competition would be considered portfolios, or they would be too ambiguous, generating complaints about what planners are considered to be portfolios.

One way to limit the impact of portfolios in the competition is what Mauro and others have suggested for the 2019 IPC², where planners are evaluated based on how well they do on individual instances/domains, rather than on getting a good average score. However, this suggestion comes with some issues as well. In particular, the score of a planner completely depends on which other planners are submitted to the competition. Henceforth, if someone submits a version of your planner that works only slightly better, he could get 0 points. One has to wait for the results to see how the approach materializes. Unfortunately, the organizers of this competition are only running the agile track, without insisting on cost-optimal plans. In complexity terms, optimization is known to be of crucial importance. For example, solving many planning benchmarks (such as Blocksworld, Logistics, Sliding Tile Puzzle) are polynomial, if —as the case in *satisficing* planning— only plan existence is considered, while optimization is hard (Helmert 2008).

The emerging set of portfolio may be seen as a side effect of the requirement of releasing source code, as it becomes easier to bundle the planners into one code base, but access to the source code is not a strict necessity for these type of planners. For some people, the core issue and concern of portfolio planning is that other researchers use their code, and not so much that the participating planner is a portfolio. So the organizers thought about having had a rule against using code from another research groups. That would have excluded most planners based on Fast Downward planner framework, though, and since they were the majority of the submissions, this would not have been a good idea as well.

The solution Fahiem Bacchus suggested (in personal conversation with the author) based on his own experience with portfolios in the SAT competitions, is having stated a license that prohibits the use of the code in other tools, would be an option, but then the authors of the planners would have to do so before the competition. In case of planners based on Fast Downward, this, however, is also problematic because such a clause would be hardly compatible with the license of the framework.

While intuitively rather obvious, it is far from simple to distinguish portfolio from non-portfolio planner in a formal definition. One may try to start with the following criteria.

A planner portfolio selects, invokes, and possibly terminates different existing planners, based on a trained or hard-coded decision procedure.

These definition may not be a perfect discriminator, as one might be able to transform a portfolio into a non-portfolio without changing the performance by much: just moving the decision procedure further down the line.

It does also not cover a planner that uses the maximum of ten heuristics in an A* search. Some people would like to treat this as a portfolio, because there is no contribution except for the selection of the ten heuristics. At the end, the question remains on when a planner is a novel contribution.

Another suggested definition for identifying portfolio planning is the following.

A non-portfolio planner is a single core planning technology, which invokes a plan search in one state space.

But what is with traversing state-space abstractions, which are needed to compute heuristic estimates? Clearly, defining portfolios turns out to be intrinsically difficult. There are planners that are clearly portfolios, there are planners that are clearly not, and there is a larger gray area in between.

According to a definition, FF (Hoffmann and Nebel 2001) should not be judged as a portfolio planner. It searches one state space with one heuristic. But FF switches from enforced hill-climbing to best-first search, based on some progress measure. This alone should not classify it as a portfolio approach.

LAMA runs a greedy search based on $h^{FF}$ and a landmark heuristic (three techniques developed by different authors) and then several weighted $A^*$ searches (a different planner and an algorithm also developed by other authors). LAMA may or may not be seen as a portfolio. If it runs three independent searches in parallel, than this may be interpreted as a portfolio, but the interconnection of the search is more subtle. LAMA had additional algorithmic contributions on how to move back and forth the states in the different priority queues. If LAMA continues searching the same

search space, this is a sign of a non-portfolio. At least it does not start different existing planner.

It is, however, abundantly clear that Delfi is a portfolio planner (not even the authors questions that). It even prints its task-dependent calls to the planner binaries. Delfi actually uses 2 executables, SymBA* and 16 parameters of selecting planners in the Fast Downward framework. It has a decision procedure trained on a set of manual selected planning tasks. Note that in this setting, we do not count the learning as running but programming time. The belated aspect of other people that contribute new planning ideas to the IPC is that more than 99.9% of the actual running time is exclusively spend on existing technology.

By public access to the planners at IPC 2018, one can look at the source code of the contributed planner to validate, on whether or not a planner is in fact a portfolio.

Fast Downward’s code base has grown too big, there are pros and cons to that. On the pro side the planner suite is good for benchmarking. For the symbolic search engines in IPC 2018, it was better to use it to combine explicit with symbolic search than sticking to an independent technology in Gamer. In fact, there are myriads of parameters that make Fast Downward behave totally different. Fast Downward is no longer one planner, it is a framework. On the cons side, results on mixing different calls it may blur the messages you take home.

There were at least two different portfolio planners in IPC 2018: Delfi1 and Delfi2, where Delfi1 was so much better, so that in the following we concentrate on this one, and used Delfi for its shortcut notation. There is published work of the planner authors in the IPC booklet that explain the architecture and the machine learning approach of using deep neural nets in more detail, so that we concentrate on the main aspects. The main idea is to train a classifier on the performance curves of known planning benchmark problems, provided as input images. We had some problems to reproduce the results on our machine, but could look at the competition results. The planners being invoked by Delfi in the IPC 2018 are shown in Table 2.

The story on portfolios will go on. Essentially, even when pushing the field with new and brilliant ideas, one hardly can win the race against a portfolio, if there is no ban. Portfolios have already started integrating the systems from 2018.

What is worse, with winning of the IPC in the pocket, portfolio planners help to acquire project money and to publish on high-ranked journals conferences, where non-portfolio planners have a hard time arguing that they are carrying the actual contribution in planning technology, as a second place is not considered state-of-the-art.

About credits. For a scientific paper it is rather clear that one has to become a co-author, if one contributes substantially to the outcome. With portfolios this is slightly different. In the extreme case, the one contributes and the other ones take the credits for the work.

Of course we wouldn’t ask Hart, Nilsson and Raphael to be co-authors of every forward-search planning paper using A* but we would still cite their work (Hart, Nilsson, and Raphael 1972). Probably the same is true for portfolio planners: they should give credit, where it is due (and the planner abstracts do this).

They also have their own contribution. The contribution in a portfolio planner is the combination of techniques, e.g., how much better is this combination than just running all $n$ components for a $n$-th of the time.

In this respect the competition booklet helps a lot as it links the IPC planners to the people, but it is rarely counted a publication. This is what one may ask for a portfolio, be explicit on which planner call achieves which individual performance, and not to bury this information in a lot of other stuff, e.g., on how advanced the neural network training is.

Often we insist on a proper publication before the release of the code, but this does not work for competitions like IPC 2018. The problem is essential, as with the competition the coders provide all source to the public, so we should take more care on who contributes what.

If an outside contribution is dominating the own one consider asking the authors. Sometimes you cite and acknowledge, sometimes you feel this is authorship. For the IPC, we see people taking code, shake it a bit to improve the results slightly, and go on publishing.

Whether or not portfolio planners being trained on sample plans are domain-independent, is also a controversy, especially given that training plan samples selected by hand. Extremist think they are not, but other people may think differently. Surely portfolio planners belong to the learning track. Of course, organizers were quite happy to have that many competitors, and for us it was a tremendous success to see how good our planners performs, even when facing portfolios. We enjoyed to see how hard it is to get some good result in cost-optimal by machine learning.

**Conclusion**

The international planning competition 2018 pushed the field in action planning, set up and executed a well-designed externally controlled experiment, aimed at insights about the true performance of planners, falsified and strengthened hypotheses on essential components, compared different technologies on a common rule set, same architecture, and an agreed input formalism. It awarded scientific prizes and provided opportunities for upcoming publications. The evaluation is much better than what one experienced in conference and journal papers. The results are often surprising, when
Compared to wisdom only taken from looking at existing publications. Of course, every competition is limited in what it can prove, but its scientific impact should not to be underestimated.

In a competition is always good to refer to a wider set of planners, but fundamental differences should be highlighted and could have been put into the awarding considerations. It is fine to have portfolios inside the competition, but they should at least be tagged as such, given a portfolio is a different type of planner and, otherwise, wrong conclusions are drawn from the event. Otherwise, the competition is doomed to swallow its own core contributors. The risk is that these efforts will die out.

Considering on how many different planning heuristics have been suggested in the past, given that places 2 to 6 are symbolic search and planning pattern database planners only, and that the winner of IPC 2018 called a symbolic search planner half of its time is a striking fact. We are not aware of any technology that performs better especially on the 2018 IPC benchmark set. Given fluctuations in the results many planners are playing in the same ballpark.

Recent improvements and simplifications indicate that one can lift the results of symbolic pattern database planning towards winning the IPC 2018 competition post mortem.

Acknowledgement Programming is a serious job, but comes with a lot of fun. The IPC 2018 is a programming contest that allowed all competitors to impress with stunning and outstanding performance results on yet unseen complex, and diverse problem domains. We thank the competitors for the variety of new planning approaches given, advancing the state-of-the-art in many respects. The organizers of the IPC 2018 did a great job, both with the choice and design of the benchmark domains and for running the competition with that much care. Eventually, they had to decide on the winner according to the rules set.
