EXCESSIVE INVARIANCE CAUSES ADVERSARIAL VULNERABILITY

ABSTRACT

Despite their impressive performance, deep neural networks exhibit striking failures on out-of-distribution inputs. One core idea of adversarial example research is to reveal neural network errors under such distribution shift. We decompose these errors into two complementary sources: sensitivity and invariance. We show deep networks are not only too sensitive to task-irrelevant changes of their input, as is well-known from $\epsilon$-adversarial examples, but are also too invariant to a wide range of task-relevant changes, thus making vast regions in input space vulnerable to adversarial attacks.

We show that such excessive invariance occurs across various tasks and architecture types. We propose the usage of bijective deep networks to enable access to all variations. We introduce metameric sampling as an analytic attack for these networks, requiring no optimization, and show that it uncovers large subspaces of misclassified inputs. Then we apply these networks to MNIST and ImageNet and show that one can manipulate the class-specific content of almost any image without changing the hidden activations. Further, we identify an insufficiency of the cross-entropy loss as a reason for these failures. We extend the standard cross-entropy loss to strengthen the model against such manipulations via an information-theoretic analysis, providing the first approach tailored explicitly to overcome invariance-based vulnerability. We conclude by empirically illustrating its ability to control undesirable class-specific invariance in multiple experiments, showing promise to overcome one major cause for adversarial examples.

1 INTRODUCTION

Adversarial vulnerability is one of the most iconic failure cases of modern machine learning models (Szegedy et al., 2013) and a prime example of their weakness in out-of-distribution generalization. It is particularly striking that under i.i.d. settings deep networks show superhuman performance on many tasks (LeCun et al., 2015), while tiny targeted shifts of the input distribution can cause them to make unintuitive mistakes.
The reasons for these failures and how they may be avoided or at least mitigated is a prime research area (Schmidt et al., 2018; Gilmer et al., 2018b; Bubeck et al., 2018).

So far, the study of adversarial examples has mostly been concerned with the setting of small perturbation, or $\epsilon$-adversaries (Goodfellow et al., 2015; Madry et al., 2017; Raghunathan et al., 2018). Perturbation-based adversarial examples are appealing because they allow to quantitatively measure notions of adversarial robustness (Brendel et al., 2018). However, recent work argued that the perturbation-based approach is unrealistically restrictive and called for the need of generalizing the concept of adversarial examples to the unrestricted case, including any input crafted to be misinterpreted by the learned model (Song et al., 2018; Brown et al., 2018). Yet, settings beyond $\epsilon$-robustness are hard to formalize (Gilmer et al., 2018a).

We argue here for an alternative, complementary viewpoint on the problem of adversarial examples. Instead of focusing on transformations erroneously crossing the decision-boundary of classifiers, we focus on excessive invariance as a major cause for adversarial vulnerability. To this end, we introduce the concept of invariance-based adversarial examples and show that class-specific content of almost any input can be changed arbitrarily without changing activations of the network, as illustrated in figure 1 for ImageNet. This viewpoint opens up new directions to analyze and control crucial aspects underlying vulnerability to unrestricted adversarial examples.

One hypothesis is that adversarial vulnerability is a consequence of narrow learning, yielding classifiers that rely only on a few highly predictive features in their decisions. It has indeed been shown that deep networks strongly rely on spectral statistical regularities (Jo & Bengio, 2017), or stationary statistics (Gatys et al., 2017) to make their decisions, rather than more abstract features like shape and appearance. We hypothesize that one reason for this can be understood from an information-theoretic viewpoint of cross-entropy, which maximizes a bound on the mutual information between labels and representation, giving no incentive to explain all class-dependent aspects of the input. This may be desirable in some cases, but to achieve truly general understanding of a scene or an object, machine learning models have to learn to successfully separate essence from nuisance and subsequently generalize even under shifted input distributions.

Our contributions:

- We identify excessive invariance underlying striking failures in deep networks and formalize the connection to adversarial vulnerability.
- We show these failures can be observed across various tasks and types of deep network architectures, substantiating the general relevance of the problem.
- We propose an invertible network architecture that gives explicit access to its decision tension that provably reduces invariance to semantically meaningful transformations and demonstrates its promise to solve the problem.
- From an information-theoretic viewpoint, we identify the cross-entropy objective as a major reason for the observed failures. Leveraging invertible networks, we propose an extension that provably reduces invariance to semantically meaningful transformations and numerically demonstrate its promise to solve the problem.

## Two Complementary Approaches to Adversarial Examples

In this section, we define pre-images and establish a link to adversarial examples.

**Definition 1 (Pre-images / Invariance).** Let $F : \mathbb{R}^d \to \mathbb{R}^C$ be a neural network, $F = f_L \circ \cdots \circ f_1$ with layers $f_i$ and let $F_i$ denote the network up to layer $i$. Further, let $D : \mathbb{R}^d \to \{1, \ldots, C\}$ be a classifier with $D = \text{arg max}_{k=1, \ldots, C} \text{softmax}(F(x))_k$. Then, for input $x \in \mathbb{R}^d$, we define the following pre-images:

(i) $i$-th Layer pre-image: \( \{x^* \in \mathbb{R}^d \mid F_i(x^*) = F_i(x)\} \)

(ii) Logit pre-image: \( \{x^* \in \mathbb{R}^d \mid F(x^*) = F(x)\} \)

(iii) Argmax pre-image: \( \{x^* \in \mathbb{R}^d \mid D(x^*) = D(x)\} \),

where (i) $\subset$ (ii) $\subset$ (iii) by the compositional nature of $D$.

Moreover, the (sub-)network is invariant to perturbations $\Delta x$ which satisfy $x^* = x + \Delta x$. 

---

Under review as a conference paper at ICLR 2019
Under review as a conference paper at ICLR 2019

Non-trivial pre-images (pre-images containing more elements than input $x$) after the $i$-th layer occur if the chain $f_i \circ \cdots \circ f_1$ is not injective, for instance due to subsampling or non-injective activation functions like ReLU (Behrmann et al., 2018a). This accumulated invariance can become problematic if not controlled properly, as we will show in the following.

We define perturbation-based adversarial examples by introducing the notion of an oracle (e.g., a human decision-maker or the unknown input-output function considered in learning theory):

**Definition 2** (Perturbation-based Adversarial Examples). A **Perturbation-based adversarial example** $x^* \in \mathbb{R}^d$ of $x \in \mathbb{R}^d$ fulfills:

(i) Perturbation of decision: $D(x^*) \neq o(x^*)$, where $D : \mathbb{R}^d \to \{1, \ldots, C\}$ is the classifier and $o : \mathbb{R}^d \to \{1, \ldots, C\}$ is the oracle.

(ii) Created by adversary: $x^* \in \mathbb{R}^d$ is created by an algorithm $A : \mathbb{R}^d \to \mathbb{R}^d$ with $x \mapsto x^*$.

Further, $\epsilon$-bounded adversarial ex. $x^*$ of $x$ fulfill $\|x - x^*\| < \epsilon$, $\|\cdot\|$ a norm on $\mathbb{R}^d$ and $\epsilon > 0$.

Usually, such examples are constructed as $\epsilon$-bounded adversarial examples (Goodfellow et al., 2015). However, as our goal is to characterize general invariances of the network, we do not restrict ourselves to bounded perturbations.

**Definition 3** (Invariance-based Adversarial Examples). Let $G$ denote the $i$-th layer, logits or the classifier (Definition 1) and let $x^* \neq x$ be in the $G$ pre-image of $x$ and $o$ an oracle (Definition 2). Then, an **invariance-based adversarial example** fulfills $o(x) \neq o(x^*)$, while $G(x) = G(x^*)$ (and hence $D(x) = D(x^*)$).

Intuitively, adversarial perturbations cause the output of the classifier to change while the oracle would still consider the new input $x^*$ as being from the original class. Hence in the context of $\epsilon$-bounded perturbations, the classifier is *too sensitive to task-irrelevant changes*. On the other hand, movements in the pre-image leave the classifier invariant. If those movements induce a change in class as judged by the oracle, we call these invariance-based adversarial examples. In this case, however, the classifier is *too insensitive to task-relevant changes*. In conclusion, these two modes are complementary to each other, whereas both constitute failure modes of the learned classifier.

When not restricting to $\epsilon$-perturbations, perturbation-based and invariance-based adversarial examples yield the same input $x^*$ via

$$x^* = x_1 + \Delta x_1, \quad D(x^*) \neq D(x_1), \quad o(x^*) = o(x_1) \tag{3}$$

$$x^* = x_2 + \Delta x_2, \quad D(x^*) = D(x_2), \quad o(x^*) \neq o(x_2) \tag{4}$$

with different reference points $x_1$ and $x_2$, see Figure 2. Hence, the key difference is the change of reference, which allows us to approach these failure modes from different directions. To connect these failure modes with an intuitive understanding of variations in the data, we now introduce the notion of invariance to nuisance and semantic variations, see also (Achille & Soatto, 2018).
For example, such a nuisance perturbation could be a translation or occlusion in image classification. Further in Appendix C we discuss the synthetic example called Adversarial Spheres from [Gilmer et al., 2018b], where nuisance and semantics can be explicitly formalized as rotation and norm scaling.

2.1 Using Bijective Networks to Analyze Excessive Invariance

As invariance-based adversarial examples manifest themselves in changes which do not affect the network $F$, we need a generic approach that gives us access to the discarded nuisance variability. While feature nuisances are intractable to access for general architectures (see comment after Definition[1]), invertible classifiers only remove nuisance variability in their final projection (Jacobsen et al., 2018). For $C < d$, we denote the classifier as $D : \mathbb{R}^d \rightarrow \{1, ..., C\}$. Our contributions in this section are: 1) we introduce an invertible architecture with a simplified readout structure, allowing to exactly visualize manipulations in the hidden-space, 2) we propose a sampling scheme based on this architecture allowing to analyze its decision-making, 3) we reveal striking inversion-based vulnerability in these networks, 4) we show the identified failures do occur in state-of-the-art ResNets as well.

Bijective classifiers with simplified readout. We build deep networks that give access to their decision space by removing the final linear mapping onto the class probes in iRevNet-classifiers and call these networks fiRevNets for fully-invertible. The fiRevNet classifier can be written as $D_\theta = \arg\max_{s=1,...,C}\text{softmax}(F_\theta(x))_s$, where $F_\theta$ represents the bijective network. We denote $z = F_\theta(x)$, $z_s = z_{1,...,C}$ as the logits (semantic variables) and $z_n = z_{C+1,...,d}$ as the nuisance variables ($z_n$ is not seen by classifier). The architecture of the network is very similar to iRevNets Jacobsen et al. (2018) with some additional Glow components like actnorm (Kingma & Dhariwal, 2018), squeezing, dimension splitting and affine block structure (Dinh et al., 2017), see figure 3 for a graphical description. As all components are fairly standard in the bijective network literature, we refer the reader to Appendix B for exact training and architecture details. Due to its simple readout structure, the resulting invertible network allows to qualitatively and quantitatively investigate the task-specific content in nuisance and logit variables. Despite this restriction, we achieve 0% error on the spheres, an error rate of 0.37% on MNIST and performance on par with common baselines on ImageNet, see Table 1.

<table>

Table 1: The table shows error rates on the ILSVRC-2012 validation set of our proposed fully invertible fiRevNet compared to a VGG (Simonyan & Zisserman, 2014) and two ResNet (He et al., 2016) variants, as well as an iRevNet (Jacobsen et al., 2018) with a non-invertible final projection onto the logits. The results show that our proposed fiRevNet performs roughly on par with others.

Analytic attack. To analyze the trained models, we can sample elements from the logit pre-image by computing $x_{\text{pre}} = F^{-1}(z_s, z_n)$. We choose a heuristic based on random combinations of nuisance and logit features from different images, which we term metameric sampling. These samples would be from the true data distribution if the joint would equal the factorial: $P(z_s, z_n) = P(z_s)P(z_n)$. Experimentally we find that logit metamers are revealing adversarial subspaces and are visually close to natural images on ImageNet. Thus, metameric sampling gives us an analytic tool to inspect dependencies between semantic and nuisance variables without the need for expensive and approximate optimization procedures.
Figure 4: Left: Decision-boundaries in 2D subspace spanned by two random data points \(x_1, x_2\). Right: Decision-boundaries in 2D subspace spanned by random datapoint \(x\) and metamer \(x_{\text{met}}\).

**Attack on adversarial spheres.** First, we evaluate our analytic attack on the synthetic spheres dataset and choose \(d = 100\) and \(R_1 = 1, R_2 = 10\). We densely sample points in a 2D subspace, following [Gilmer et al. (2018b)], to visualize two cases: 1) the decision-boundary on a 2D plane spanned by two randomly chosen data points, 2) the decision-boundary spanned by \(x_{\text{met}}\) and reference point \(x\). We visualize these decision-boundaries for the original classifier \(D\) and for a posthoc trained classifier on \(z_n\) (nuisance classifier), see Figure 9. In the metameric sample, or adversarial distribution-shift case, it is possible to move any point from the inner sphere to the outer sphere without changing the output of the classifier. However, this is not possible for the nuisance classifier. Most notably, the visualized failure is not due to a lack of data seen during training but rather due to excessive invariance of \(D\), as the nuisance classifier does not make the same errors.

Figure 5: Each column shows three images belonging together. Top row are source images from which we sample the logits, middle row are logit metamers and bottom row images from which we sample the nuisances. Top row and middle row have the same (approximately for ResNets, exactly for fi-RevNets) logits activations. Thus, it is possible to change the image content completely without changing the 10- and 1000-dimensional logit vectors respectively. This highlights a striking failure of classifiers to capture all task-dependent variability.

**Attack on MNIST and ImageNet.** After validating its potential to uncover adversarial subspaces, we apply metameric sampling to fiRevNets trained on MNIST and Imagenet, see Figure 5. The result is striking, as the nuisance variables \(z_n\) are dominating the visual appearance of the logit metamers, making it possible to attach any semantic content to any logit activation pattern. Note that the entire 1000-dimensional feature vector containing probabilities over all ImageNet classes remains unchanged by any of the transformations we apply. To show our findings are not a particular property of bijective networks, we apply an approximate gradient-based metameric attack that minimizes the mean squared error between a given set of logits from one image to another image (see appendix D for details) on an ImageNet trained ResNet-152 and show that it exhibits the same failure. This highlights the general relevance of our finding and poses the question of the origin of these striking failures, which we will analyze in the following section.

### 3 Overcoming Insufficiency of Cross-Entropy-Based Information-Maximization

In this section we identify why cross-entropy does not necessarily encourage to explain all task-dependent variations of the data and propose a way to fix this. As shown in figure 9, the nuisance classifier uses task-relevant information not captured by the logit classifier \(D_\theta\) (evident by its good performance in the adversarial subspace).
We leverage the simple readout-structure of our invertible network and turn this observation into a formal explanation framework using information theory. Let \( (x, y) \sim D \) with labels \( y \in \{0, 1\}^C \). Then the goal of a classifier can be stated as maximizing the mutual information \((\text{Cover & Thomas, 2006}\)) between semantic features \( z_x \) extracted by network \( F_\theta \) and labels \( y \), denoted by \( I(y; z_x) \).

**Adversarial distribution shift.** As the previously discussed failures required to modify input data from distribution \( D \), we introduce the concept of an adversarial distribution shift \( D_{Adv} \neq D \) to formalize these modifications. This distribution shift could be due to a re-weighting of probability mass while keeping the support; Furthermore, shifts in the support of \( D \) could be possible, like changes in input statistics. Our only assumption for \( D_{Adv} \) is \( I_{D_{Adv}}(z_n; y) \leq I_D(z_n; y) \). Intuitively, the nuisance variables of our network do not become more informative about \( y \). Thus, the distribution shift may reduce the predictiveness of features encoded in \( z_x \), but does not introduce or increase the predictive value of variations captured in \( z_n \).

Bijective networks \( F_\theta \) capture all variations by design which translates to information preservation \( I(y; x) = I(y; F_\theta(x)) \), see \((\text{Kraskov et al., 2004})\). Consider the reformulation

\[
I(y; x) = I(y; F_\theta(x)) = I(y; z_x, z_n) = I(y; z_x) + I(y; z_n|z_x) = I(y; z_n) + I(y; z_s|z_n) \tag{5}
\]

by the chain rule of mutual information \((\text{Cover & Thomas, 2006})\), where \( I(y; z_n|z_s) \) denotes the conditional mutual information. Most strikingly, \( \text{Eq} \) \((5)\) offers three ways forward:

1. Direct increase of \( I(y; z_x) \)
2. Indirect increase of \( I(y; z_s|z_n) \) via decreasing \( I(y; z_n) \)
3. Reducing dependence \( I(z_x; z_n) \) to make maximizing \( I(y; z_x) \) equivalent to minimizing \( I(y; z_n) \), as \( I(y; z_n|z_x) = I(y; z_n) \) under independence \((I(z_x; z_n) = 0)\).

Usually in a classification task, only \( I(y; z_x) \) is increased actively via training a classifier. While this approach is sufficient in most cases, expressed via high accuracies on training and test data, it may fail under \( D_{Adv} \). This highlights why cross-entropy training may not be sufficient to overcome excessive semantic invariance. However, by leveraging the bijection \( F_\theta \) we can 1) minimize the unused information \( I(y; z_n) \) using the intuition of a nuisance classifier, 2) control the dependence structure between \( z_x \) and \( z_n \) via maximum-likelihood under a factorial prior. Hence, we extend cross-entropy minimization by two terms that aim for independence.

**Definition 5 (Independence cross-entropy loss).** Let \( F_\theta : \mathbb{R}^d \rightarrow \mathbb{R}^d \) a bijective network with parameters \( \theta \in \mathbb{R}^{p_\theta} \) and \( F_\theta(x) = \text{softmax}(F_\theta(x)_{1, \ldots, C}) \). Furthermore, let \( D_{\theta_{nC}} : \mathbb{R}^{d-C} \rightarrow [0, 1]^C \) be the nuisance classifier with \( \theta_{nC} \in \mathbb{R}^{p_\theta} \). Then, the independence cross-entropy loss is defined as

\[
\min_{\theta_{nc}} \max_{\theta_{nc}} L_{\text{ICE}}(\theta, \theta_{nc}) = \sum_{i=1}^{C} -y_i \log F_{\theta_i}(x) + \sum_{i=1}^{C} y_i \log D_{\theta_{nc}(F_{\theta_i}(x)))} - \sum_{k=1}^{d-C} \log p_k(F_{\theta_i}(x)_{k}) |\det(J_{\theta_i})|
\]

with \( (x, y) \sim D \). Furthermore, \( \det(J_{\theta_i}) \) denotes the determinant of the Jacobian of \( F_{\theta_i}(x) \) and \( p_k \sim \mathcal{N}(\beta_k, \gamma_k) \) with \( \beta_k, \gamma_k \) learned parameter.

The underlying principles of the nuisance classification loss \( L_{n\text{ICE}} \) can be understood using a variational lower bound on mutual information \((\text{Barber & Agakov, 2003})\). In summary, the minimization is with respect to a lower bound on \( I_P(y; z_n) \), while the maximization aims to tighten the bound. Furthermore, the term \( L_{\text{MLE}_{n}} \) on the nuisance variables together with \( L_{n\text{ICE}} \) is maximum-likelihood under a factorial prior. See \( \text{Lemma} 8 \) and its proof in \( \text{Appendix A} \). By using these results, we now state the main result under the assumed distribution shift and successful minimization (proof in \( \text{Appendix A.1} \)):

**Theorem 6 (Information \( I_{D_{Adv}(y; z_x)} \) maximal after distribution shift).** Let \( D_{Adv} \) denote the adversarial distribution and \( D \) the training distribution. Assume \( I_D(y; z_n) = 0 \) by minimizing \( L_{n\text{ICE}} \) and the distribution shift satisfies \( I_{D_{Adv}}(z_n; y) \leq I_D(z_n; y) \). Then,

\[
I_{D_{Adv}}(y; z_x) = I_D(y; x).
\]

In summary, incorporating the nuisance classifier allows for the discussed indirect increase of \( I_{D_{Adv}}(y; z_x) \) under an adversarial distribution shift, visualized in Figure 6.
Figure 6: Left: Mutual information under distribution $D_{\text{train}}$, Right: Effect of distributional shift to $D_{\text{Adv}}$. Each case under training with cross-entropy (CE) and independence cross-entropy (iCE). Under distribution $D$, the iCE-loss minimizes $I(y; z_n)$ (Lemma 8, Appendix A), but has no effect as the CE-loss already maximizes $I(y; z_s)$. However under the shift to $D_{\text{Adv}}$, the information $I(y; z_n)$ decreases when training only under the CE-loss (orange arrow), while the iCE-loss induces $I(y; z_s) = 0$ and thus leaves $I(y; z_s)$ unchanged (Theorem 6).

Just as in GANs the quality of the result relies on a tight bound provided by the nuisance classifier and MLE convergence. Thus, it is important to analyze the success of the objective after training. We do this by applying our metameric sampling attack, but there are also other ways like evaluating a more powerful nuisance classifier after training.

4 Applying Independence Cross-entropy

In this section, we show that our proposed independence cross-entropy loss is effective in reducing invariance-based vulnerability in practice by comparing it to vanilla cross-entropy training in four aspects: 1) error on train and test set, 2) effect under distribution shift: perturbing nuisances via metameric sampling and 3) evaluate accuracy of a classifier on the nuisance variables to quantify the class-specific information in them, 4) on our newly introduced shiftMNIST, an augmented version of MNIST to benchmark adversarial distribution shifts according to theorem 6.

For all experiments we use the same network architecture and settings, the only difference being that one network the two additional loss terms as explained in Definition 5. In terms of test error of the logit classifier, both losses perform approximately on par, whereas the gap between train and test error vanishes for our proposed loss function, indicating less overfitting. For classification errors see table 2 in appendix B.

Figure 7: Samples $\tilde{x} = F^{-1}(z_s, \tilde{z}_n)$ with logit activations $z_s$ taken from original image and $\tilde{z}_n$ obtained by linear interpolating from the original nuisance $z_n$ (first row) to the nuisance of a target example $z^*_n$ (last row in logits block). The used target example is shown at the bottom. When training with cross-entropy, virtually any image can be turned into any class without changing the logits $z_s$, illustrating strong vulnerability to invariance-based adversaries. Yet, training with independence cross-entropy solves the problem and interpolations between nuisances $z_n$ and $z^*_n$ preserve the semantic content of the image.

Robustness under metameric sampling attack. To analyze if our proposed loss indeed leads to independence between $z_s$ and the labels, we attack it with our metameric sampling procedure. As we are only looking on data samples and not on samples from the model, this attack should reveal if the network learned to trick the objective. In Figure 7 we show interpolations between original images and logit metamers in CE and iCE fRevNets. In particular, we are holding the activations $z_s$ constant, while linearly interpolating nuisances $z_n$ down the column. The CE-trained network allows us to transform any image into any class without changing the logits. However, when training with our proposed iCE, the picture changes fundamentally and interpolations in the pre-image only change the style of a digit, but not its semantic content.
Figure 8: shiftMNIST experiments. (a): Binary shiftMNIST, where the class is additionally encoded with a location-based binary code on the left border of the image (highlighted with red circles). The shifted adversarial test distribution does not have the binary class encoding. (b): Texture shiftMNIST, where the class is additionally encoded in background texture type. The texture-class coupling is randomized in the shifted adversarial test distribution. Right: Results of CE-trained ResNet, fiRevNet and iCE-trained fiRevNet. The CE-based models build excessive invariance with respect to the digit identity on $\mathcal{D}_{\text{train}}$ and fail on $\mathcal{D}_{\text{Adv}}$. Difference denotes the largest improvement between CE-trained and iCE-trained model. The iCE model is more resilient to removing informative features, and reduces the error on $\mathcal{D}_{\text{Adv}}$ up to 38%.

This is strong evidence for our loss having the ability to overcome the issue of excessive task-related invariance and encourages the model to explain and separate all task-related variability of the input from the nuisances of the task. A classifier trained on the nuisance variables of the cross-entropy trained model performs almost as well as the logit classifier. Yet, a classifier on the nuisances of the independence cross-entropy trained model is performing poorly (Table 2 in appendix B), indicating little class-specific information in the nuisances, as intended by our objective function. Note also that this inability of the nuisance classifier to decode class-specific information is not due to it being hard to read out from $z_n$, this would be visible in the metameric sampling procedure, which is not the case.

**shiftMNIST: Benchmarking adversarial distribution shift.** To further test the efficacy of our proposed independence cross-entropy, we introduce a simple, but challenging new dataset termed shiftMNIST to test classifiers under adversarial distribution shifts $\mathcal{D}_{\text{Adv}}$. The dataset is based on vanilla MNIST, augmented by introducing additional, highly predictive features at train time that are randomized or removed at test time. This allows us to reduce mutual information between category and the newly introduced feature in a targeted and controllable manner. (a) Binary shiftMNIST is vanilla MNIST augmented by coding the category for each digit into a single binary pixel scheme. The location of the binary pixel reveals the category of each image unambiguously, while only minimally altering the image’s appearance. At test time, the binary code is not present and the network can not rely on it anymore. (b) Textured shiftMNIST introduces textured backgrounds for each digit category which are patches sampled from the describable texture dataset (Cimpoi et al., 2014). At train time the same type of texture is underlayed each digit of the same category, while texture types across categories differ. At test time, the relationship is broken and texture backgrounds are paired with digits randomly, again minimizing the mutual information between background and label in a targeted manner. See figure 8 for examples.

It turns out that this task is indeed very hard for standard classifiers and their tendency to become excessively invariant to semantically meaningful features, as predicted by our theoretical analysis. When trained with cross-entropy, ResNets and fi-RevNets make zero errors on the train set, while having error rates of up to 87% on the shifted test set. This is striking, given that e.g. in binary shiftMNIST, only one single pixel is removed under $\mathcal{D}_{\text{Adv}}$, leaving the whole image almost unchanged. When applying our independence cross-entropy, the picture changes again. The errors made by the network improve by up to almost 38% on binary shiftMNIST and around 28% on textured shiftMNIST. This highlights the effectiveness of our proposed loss function and its ability to minimize catastrophic failure under severe distribution shifts exploiting excessive invariance.

5 RELATED WORK

Adversarial examples. Adversarial examples often include $\epsilon$-norm restrictions [Szegedy et al., 2013], while [Gilmer et al., 2018a] argue for a broader definition to fully capture the implications for security. Some works [Song et al., 2018; Fawzi et al., 2018] consider unrestricted adversarial examples, which are closely related to invariance-based adversarial vulnerability. The difference to human perception revealed by adversarial examples fundamentally questions which statistics deep networks use to base their decisions [Jo & Bengio, 2017; Tsipras et al., 2018].

Relationship between standard and bijective networks. We leverage recent advances in reversible [Gomez et al., 2017] and bijective networks [Jacobsen et al., 2018; Ardizzone et al., 2018; Kingma & Dhariwal, 2018] for our analysis. It has been shown that ResNets and iRevNets behave similarly on various levels of their representation on challenging tasks [Jacobsen et al., 2018] and that iRevNets as well as Glow-type networks are related to ResNets by the choice of dimension splitting applied in their residual blocks [Grathwohl et al., 2018]. Perhaps unsurprisingly, given so many similarities, ResNets have been shown to be provably bijective under mild conditions themselves [Behrmann et al., 2018b]. Further, excessive invariance of the type we discuss here has been shown to occur in non residual-type architectures as well [Gilmer et al., 2018b; Behrmann et al., 2018a]. For instance, it has been observed that up to 60% of semantically meaningful input dimensions on the adversarial spheres problem are learned to be ignored, while retaining excellent performance [Gilmer et al., 2018b]. In summary, there is ample evidence that RevNet-type networks are closely related to ResNets, the de-facto state of the art deep learning architecture, while providing a principled framework to study widely observed issues related to excessive invariance in deep learning in general and adversarial robustness in particular.

Information-theory. The information-theoretic view has gained recent interest in machine learning due to the information bottleneck [Tishby & Zaslavsky, 2015; Shwartz-Ziv & Tishby, 2017; Alemi et al., 2017] and usage in generative modelling [Chen et al., 2016; Hjelm et al., 2018]. As a consequence, the estimation of mutual information [Barber & Agakov, 2003; Alemi et al., 2018; Achille & Soatto, 2018; Belghazi et al., 2018] has attracted growing attention. The concept of group-wise independence between latent variables goes back to classical independent subspace analysis [Hyvärinen & Hoyer, 2000] and received attention in learning unbiased representations, e.g. see the Fair Variational Autoencoder [Louizos et al., 2015]. Furthermore, extended cross-entropy losses via entropy terms [Pereyra et al., 2017] or minimizing predictability of variables [Schmidhuber, 1991] has been introduced for other applications. Our proposed loss also shows similarity to the GAN loss [Goodfellow et al., 2014]. However, in our case there is no notion of real or fake samples, but exploring similarities in the optimization are a promising avenue for future work.

6 CONCLUSION

Failures of deep networks under distribution shift and their difficulty in out-of-distribution generalization are prime examples of the limitations in current machine learning models. The field of adversarial example research aims to close this gap from a robustness point of view. While a lot of work has studied $\epsilon$-adversarial examples, recent trends extend the efforts towards the unrestricted case. However, adversarial examples with no restriction are hard to formalize beyond testing error. Based on our reverse view we: 1) show that a major cause for adversarial vulnerability is excessive invariance to semantically meaningful variations, 2) show that this issue persists across tasks and architectures; and 3) make the control of invariance tractable via fully-invertible networks.

In summary, we demonstrated how a bijective network architecture enables us to identify large adversarial subspaces, due to excessive invariance on multiple datasets like the adversarial spheres, MNIST and ImageNet. We formalized the distribution shifts causing such undesirable behavior via information theory and find one of its major reasons in the insufficiency of the vanilla cross-entropy loss to learn semantic representations that capture all task-dependent variations in the input. We extend the loss function by components that explicitly encourage a split between semantically meaningful and nuisance features and show that this split can remove unwanted invariances, as empirically evaluated on a set of targeted invariance-based distribution shift experiments.

A INFORMATION THEORY

Computing mutual information is often intractable as it requires the joint probability \( p(x, y) \), see (Cover & Thomas, 2006) for an extensive treatment of information theory. However, following variational lower bound can be used for approximation, see (Barber & Agakov, 2003).

**Lemma 7** (Variational lower bound on mutual information). Let \( X, Y \) be random variables with conditional density \( p(y|x) \). Further, let \( q_\theta(y|x) \) be a variational density depending on parameter \( \theta \). Then, the lower bound

\[
I(Y; X) = h(Y) - h(Y|X) = h(Y) + \mathbb{E}_X \mathbb{E}_{Y|X} \log q_\theta(y|x) + \mathbb{E}_X \mathbb{E}_{y|X} \log q_\theta(y|x)
\]

\[
\geq h(Y) + \mathbb{E}_X \mathbb{E}_{Y|X} \log q_\theta(y|x)
\]

holds with equality if \( p(y|x) = q_\theta(y|x) \).

While above lower bound removes the need for the computation of \( p(y|x) \), estimating the expectation \( \mathbb{E}_{Y|X} \) still requires sampling from it. Using this bound, we can now state the effect of the nuisance classification loss.

**Lemma 8** (Effect loss terms). Define semantics as \( z_s = \theta(s)_{1,\ldots,C} \) and nuisances as \( z_n = \theta_n(x)_{C+1,\ldots,d} \), where \( (x, y) \sim D \). Then, the nuisance classification loss yields

(i) **Minimization of** \( I(z_s; z_n) : \theta^* = \arg \min_\theta \mathcal{L}_{sCE}(\theta) + \mathcal{L}_{MLE, n}(\theta) \) minimizes \( I(z_s; z_n) \).

(ii) **Minimization of lower bound on** \( I_D(y; z_n) \): \( \theta^* = \arg \min_\theta \mathcal{L}_{sCE}(\theta, \theta^*_{nc}) \) minimizes \( I_{\theta_n^*(y; z_n)} \), where \( \theta^*_{nc} \) minimizes \( I_{\theta_n^*(y; z_n)} \).

(iii) **Maximization to tighten bound on** \( I_D(y; z_n) \): Under a perfect model of the conditional density, \( D_{\theta_n^*(y; z_n)} = p(y|z_n) \), it holds \( I_{\theta_n^*(y; z_n)} = I_D(y; z_n) \).

**Proof.** We begin by proving claim (i), which handles the dependence \( I(z_s, z_n) \). Let \( \hat{z}_s = \text{softmax}(z_s) \). Then minimizing the loss terms \( \mathcal{L}_{sCE} \) and \( \mathcal{L}_{MLE, n} \) is a maximum likelihood estimation under the factorial prior

\[
p(\hat{z}_s, z_n) = p(\hat{z}_s)p(z_n)
\]

\[
= \text{Cat}((\hat{z}_s)_1, \ldots, (\hat{z}_s)_C) \prod_{k=1}^{d-C} p_k(z_n)_k,
\]

where...
where $Cat$ is a categorical distribution. As $softmax$ is shift-invariant, $softmax(x + c) = softmax(x)$, above factorial prior for $z_s$ and $z_n$ yields independence between logits $z_s$ and $z_n$ up to a constant $c$. Finally, note, the $\log$ term and summation in $\mathcal{L}_{MLE_n}$ and $\mathcal{L}_{CE}$ is re-formulation for computational ease but does not change its minimizer as the logarithm is monotone.

For claim (ii) and (iii), we need to draw the connection to the variational lower bound on mutual information from Lemma 7. Let the nuisance classifier $D_{\theta_{nc}}(z_n)$ model the variational posterior $q_{\theta_{nc}}(y|z_n)$. Then we have the lower bound

$$I(y; z_n) \geq h(y) + \mathbb{E}_{z_n} \mathbb{E}_{y|z_n} \log D_{\theta_{nc}}(z_n) =: I_{\theta_{nc}}(y; z_n).$$

(8)

From Lemma 7 follows, that if $D_{\theta_{nc}}(z_n) = p(y|z_n)$, it holds $I(y; z_n) = I_{\theta_{nc}}(y; z_n)$. Hence, the nuisance classifier needs to model the conditional density perfectly.

Estimating this bound via Monte Carlo simulation requires sampling from the conditional density $p(y|z_n)$. Following (Alemi et al., 2017), we have the Markov property $y \leftrightarrow x \leftrightarrow z_n$ as labels $y$ interact with inputs $x$ and representation $z_n$ interacts with inputs $x$. Hence,

$$p(y|z_n)p(z_n) = p(y, z_n)$$

$$= \int_X p(x, y, z_n) dx$$

$$= \int_X p(z_n|x, y)p(y|x)p(x) dx$$

$$= \int_X p(z_n|x)p(y|x)p(x) dx$$

$$= \mathbb{E}_x[p(z_n|x)p(y|x)].$$

Including above and assuming $F_{\theta}(x) = z_n$ to be a deterministic function, we have

$$\mathbb{E}_{z_n} \mathbb{E}_{y|z_n} \log D_{\theta_{nc}}(z_n) = \mathbb{E}_x \mathbb{E}_{y|x} \mathbb{E}_{z_n|x} \log D_{\theta_{nc}}(z_n) = \mathbb{E}_x \mathbb{E}_{y|x} \log D_{\theta_{nc}}(z_n).$$

\[ \square \]

### A.1 PROOF OF THEOREM 6

From the assumptions follows $I_{\mathcal{D}_{Adv}}(y; z_n) = 0$. Furthermore

$$I_{\mathcal{D}_{Adv}}(y; z_s|z_n) = I_{\mathcal{D}_{Adv}}(z_s; y|z_n) = I_{\mathcal{D}_{Adv}}(z_s; y),$$

where the first equality follows from the symmetry of mutual information and the last from the properties of conditional mutual information under independence $I_{\mathcal{D}_{Adv}}(y; z_n) = 0$. By the chain rule of mutual information (Cover & Thomas, 2006) and information preservation under homeomorphisms (Kraskov et al., 2004), we have

$$I_{\mathcal{D}_{Adv}}(x; y) = I_{\mathcal{D}_{Adv}}(y; z_n) + I_{\mathcal{D}_{Adv}}(y; z_s|z_n)$$

$$= I_{\mathcal{D}_{Adv}}(z_s; y).$$

### A.2 MUTUAL INFORMATION BOUNDED

**Remark 9.** Since our goal is to maximize the mutual information $I(y; z_s)$ while minimizing $I(y; z_n)$, we need to ensure that this objective is well defined as mutual information can be unbounded from above for continuous random variables. However, due to the data processing inequality (Cover & Thomas, 2006) we have $I(y; z_n) = I(y; F_\theta(x)) \leq I(y; x)$. Hence, we have a fixed upper bound given by our data $(x, y)$. Compared to (Belghazi et al., 2018) there is thus no need for gradient clipping or a switch to the bounded Jensen-Shannon divergence as in (Hjelm et al., 2018) is not necessary.
A.3 Additional Batch of Metameric Samples

Figure 9: Here we show a large batch of randomly sampled metamers from our ImageNet-trained fiRevNet-48. The quality is generally similar, sometimes colored artifacts appear.

B Training and Architectural Details

All experiments were based on a fiRevNet model with different hyperparameters for each dataset. For the spheres experiment we used Pytorch (Paszke et al., 2017) and for MNIST, as well as ImageNet Tensorflow (Abadi et al., 2016).

B.1 Spheres Experiments

The network is a fully connected fiRevNet. It has 4 RevNet-type ReLU bottleneck blocks with additive couplings and uses no batchnorm. We train it via cross-entropy and use the Adam optimizer (Kingma & Ba, 2014) with a learning rate of 0.0001 and otherwise default Pytorch settings. The nuisance classifier is a 3 layer ReLU network with 1000 hidden units per layer.

We choose the spheres to be 100-dimensional, with $R_1 = 1$ and $R_2 = 10$, train on 500k samples for 10 epochs and then validate on another 100k holdout set. We achieve 100% train and validation accuracy for logit and nuisance classifier.
Table 2: Results comparing cross-entropy training (CE) with independence cross-entropy training (iCE) from Definition 5 and two architectures from the literature. The accuracy of the logit classifiers is on par for the CE and iCE networks, but the train error is higher for CE compared to test error, indicating less overfitting for iCE. Further, a classifier independently trained on the nuisance variables is able to reach even smaller error than on the logits for CE, but just 27.70% error for iCE, indicating that we have successfully removed most of the information of the label from the nuisance variables and fixed the problem of excessive invariance to semantically meaningful variability with no cost in test error.

B.2 MNIST experiments

We use a convolutional fiRevNet with additional actnorm and invertible 1x1 convolutions between each layer as introduced in \cite{kingma2018}. The network has 3 stages, after which half of the variables are factored out and an invertible downsampling, or squeezing (Dinh et al. 2017; Jacobsen et al. 2018) is applied. The network has 16 RevNet blocks with batch norm per stage and 128 filters per layer. We also dequantize the inputs as is typically done in flow-based generative models.

The network is trained via Adamax (Kingma & Ba, 2014) with a base learning rate of 0.001 for 100 epochs and we multiply the it with a factor of 0.2 every 30 epochs and use a batch size of 64 and l2 weight decay of 1e-4. For training we compare vanilla cross-entropy training with our proposed independence cross-entropy loss. To have a more balanced loss signal, we normalize $L_{nCE}$ by the number of input dimensions it receives for the maximization step. The nuisance classifier is a fully connected 3 layer ReLU network with 512 units. As data-augmentation we use random shifts of 3 pixels. For classification errors of the different architectures we compare, see table 2.

B.3 ImageNet experiments

We use a convolutional fiRevNet with 4 stages, 4 RevNet blocks per stage and invertible downsampling after each stage, as well as two invertible downsamplings on the input of the network. The first three stages consist of additive and the last of affine coupling layers. After the final layer we apply an orthogonal 2D DCT type-II to all feature maps and read out the classes in the low-pass components of the transformation. This effectively gives us an invertible global average pooling and makes our network even more similar to ResNets, that always apply global average pooling on their final feature maps. We train the network with momentum SGD for 128 epochs, a batch size of 480 (distributed to 6 GPUs), a base learning rate of 0.1, which is reduced by a factor of 0.1 every 32 epochs. We apply momentum of 0.9 and l2 weight decay of 1e-4. As we have relatively large feature maps in the final layer on ImageNet, we apply a DCT on them and read out the logits from the low-pass components, effectively giving us an invertible global average pooling and making our network more similar to ResNets in design.

C Semantic and Nuisance Variation on Adversarial Spheres

Example 10 (Semantic and nuisance on Adversarial Spheres (Gilmer et al., 2018b)). Consider classifying inputs $x$ from two classes given by radii $R_1$ or $R_2$. Further, let $(r, \phi)$ denote the spherical coordinates of $x$. Then, any perturbation $\Delta x$, $x^* = x + \Delta x$ with $r^* \neq r$ is semantic. On the other hand, if $r^* = r$ the perturbation is a nuisance with respect to the task of discriminating two spheres.

In this example, the max-margin classifier $D(x) = \text{sign} \left( \|x\| - \frac{R_1+R_2}{2} \right)$ is invariant to any nuisance perturbation, while being only sensitive to semantic perturbations. In summary, the transform to spherical coordinates allows to linearize semantic and nuisance perturbations. Using this notion, invariance-based adversarial examples can be attributed to perturbations of $x^* = x + \Delta x$ with following two properties.
1. Perturbed sample $x^\ast$ stays in the pre-image $\{x^\ast \in \mathbb{R}^d \mid D(x^\ast) = D(x)\}$ of the classifier.
2. Perturbation $\Delta x$ is semantic, as $o(x) \neq o(x + \Delta x)$.

Thus, the failure of the classifier $D$ can be thought of a mis-alignment between its invariance (expressed through the pre-image) and the semantics of the data and task (expressed by the oracle).

**Example 11 (Mis-aligned classifier on Adversarial Spheres).** Consider the classifier

$$D(x) = \text{sign}(\|x_1,\ldots,d-1\| - \frac{R_1 + R_2}{2}),$$

(9)

which computes the norm of $x$ from its first $d-1$ cartesian-coordinates. Then, $D$ is invariant to a semantic perturbation with $\Delta r = R_2 - R_1$ if only changes in the last coordinate $x_d$ are made.

We empirically evaluate the classifier in equation 9 on the spheres problem (10M/2M samples setting (Gilmer et al., 2018b)) and validate that it can reach perfect classification accuracy. However, by construction, perturbing the invariant dimension $x_d^\ast = x_d + \Delta x_d$ allows us to move all samples from the inner sphere to the outer sphere. Thus, the accuracy of the classifier drops to chance level when evaluating its performance under such a distributional shift.

To conclude, this underlines how classifiers with optimal performance on finite samples can exhibit non-intuitive failure modes due to excessive invariance with respect to semantic variations.

## D Approximate Gradient-based Metameric Samples

We use a standard Imagenet pre-trained Resnet-154 as provided by the torchvision package (Paszke et al., 2017) and choose a logit percept $y = f(x)$ that can be based on any seed image. Then we optimize various images $\tilde{x}$ to be metameric to $x$ by simply minimizing a mean squared error loss of the form:

$$\mathcal{L}_{\text{MSE}}(F(x), F(\tilde{x})) = \frac{1}{K} \sum_{k=1}^{K} (F(x)_k - F(\tilde{x})_k)^2$$

(10)

in the 1000-dimensional semantic logit space via stochastic gradient descent. We optimize with Adam in Pytorch default settings and a learning rate of 0.01 for 3000 iterations. The optimization thus takes the form of an adversarial attack targeting all logit entries and with no norm restriction on the input distance. Note that our metameric sampling attack in bijective networks is the analytic reverse equivalent of this attack. It leads to the exact solution at the cost of one inverse pass instead of an approximate solution here at the cost of thousands of gradient steps.
