

Balancing GreenAI: Efficiency and Impact of LLMs in Climate-Vulnerable Communities

Anonymous ACL submission

Abstract

Large language models (LLMs) are revolutionizing natural language processing (NLP), but their creation comes at a significant environmental cost. This research investigates the carbon emissions produced by pre-training BERT-based language models and situates these findings within the broader context of global carbon emissions. Climate change disproportionately affects low- and middle-income countries (LMICs), so we weigh LLMs’ impact within the context of these disadvantaged communities. We explore methodologies for estimating the carbon footprint of model training. We contemplate trade-offs between model efficiency and potential bias, considering how such side effects could exacerbate existing inequalities, particularly in LMICs. Furthermore, this research emphasizes the necessity of transparency and accountability in NLP. LLMs should be developed with clear purposes and a focus on both efficiency and mitigating potential harms, particularly in climate-vulnerable communities.

1 Introduction

LLMs are gaining prominence in both NLP research and everyday use. However, creating these models comes with significant computational costs. Industry rivals continuously invest in developing LLMs, which incurs financial expenses and contributes to environmental degradation through carbon emissions. This environmental impact is often overlooked.

Global climate change is a crisis, and carbon emissions actively contribute to it. Consequently, when developing LLMs, researchers should think of both accuracy and efficiency, as the energy required to train models can be traced to greenhouse gas emissions.

This research aims to estimate the carbon emissions produced by pretraining widely used LLMs, and to ground these findings in the broader con-

Figure 1: Global surface temperatures in January 2024 compared to the 1991-2020 average. Most areas exhibited warmer-than-average temperatures (depicted in red), with scattered colder-than-average regions (depicted in blue)¹.

text of carbon emissions. We will determine how much the LLMs emit and provide insights into current industry practices and LLM applications to recommend action in the wake of climate change.

Alongside all other carbon-intensive industries, LLM development contributes to global climate change. We focus on how such climate consequences disproportionately harm historically disadvantaged communities worldwide. NLP’s climate impact is felt globally, but its benefits do not follow suit.

2 Related Work

2.1 Green AI

The method for calculating model pretraining carbon emissions is derived from Strubell et al. (2019), where the authors reported the training carbon impacts of four LLMs: T2T, BERT, ELMo, and GPT-2. We train a different set of models. We follow the same methodology of querying for machine power usage, averaging such results, and computing carbon dioxide and monetary estimates. However, we diverge in the qualitative aspects of this research and seek greater context to such carbon

¹Source:<https://www.climate.gov/news-features/understanding-climate/global-climate-summary-january-2024>

065 emission estimates, considering global systems for
066 valuating emissions and the ultimate goals of train-
067 ing LLMs. We emphasize interdisciplinary eval-
068 uation on whether LLMs’ carbon footprints are
069 appropriately offset by their impact, specifically in
070 healthcare applications in the communities most
071 impacted by climate change.

072 [Schwartz et al. \(2019\)](#) discuss Green AI in the
073 exponential growth of computational requirements
074 for deep learning research and the resulting environ-
075 mental and financial costs. The authors advocate
076 for integrating efficiency, alongside accuracy and
077 other relevant metrics as an evaluation criteria for
078 research.

079 [Kaack et al. \(2022\)](#) discuss the Information
080 and Communication Sector (ICT)’s environmen-
081 tal impact and emphasize the need for AI research
082 to align with climate change mitigation efforts
083 through transparent, comprehensive reporting on
084 compute costs and emissions. They address con-
085 cerns that efficiency gains in machine learning may
086 lead to rebound effects, where reduced emissions
087 per-run could be countered by increased consump-
088 tion, undermining environmental benefits.

089 2.2 Emissions & Climate Change

090 Climate change has driven concerns about the im-
091 pact of data centers and their ever-growing com-
092 pute demands. A single data center can consume
093 as much electricity, and emit subsequent carbon,
094 as 50,000 homes ([Monserrate, 2022](#)). [Siddik et al. \(2021\)](#)
095 calculate the carbon and water footprints of
096 data centers in the U.S, referencing how U.S. data
097 centers use 1.8% of national electricity and account
098 for about 25% of global data centers.

099 In 2021, electricity and heat generation made
100 up almost 44% of global carbon dioxide emissions
101 from fuel combustion, and coal accounted for 73%
102 of such emissions ([IEA, 2023](#)). Fossil fuels, such
103 as coal, oil, and natural gas, are carbon-based, non-
104 renewable energy sources that release carbon into
105 the atmosphere upon combustion ([Eurostat](#)).

106 The Paris Agreement, established in 2015, seeks
107 to limit global warming to 1.5°C above pre-
108 industrial levels to mitigate severe climate impacts
109 ([Nations](#)). Climate change results in rising sea lev-
110 els, intensified storms and droughts, and dwindling
111 sea ice. These effects cascade through ecosystems
112 and human activities, impacting health, agricul-
113 ture, and infrastructure ([NASA, 2024](#)). To reach
114 the Paris Agreement’s goal, global emissions must

115 decrease by 45% by 2030 and reach net-zero by
116 2050 ([Nations](#)). Carbon emissions must be reduced
117 because they contribute to the greenhouse effect,
118 which traps heat in the atmosphere and warms the
119 planet ([NRDC, 2023](#)).

120 2.3 Racial Justice & Climate Change

121 Climate change affects the entire globe, but some
122 regions are impacted more. Developing countries,
123 or LMIC, often face the greatest climate-related
124 risks and are the least equipped to manage such
125 events.

126 For instance, Haiti, which lacks the infrastruc-
127 ture for adequate disaster preparedness, has faced
128 great devastation from earthquakes and hurricanes,
129 where the 2010 earthquake cost \$8 billion– more
130 than the country’s GDP. The population is heavily
131 reliant on agriculture, but as sea levels rise, saltwa-
132 ter may permeate farmland and fresh water, leaving
133 a large portion of the country without a livelihood
134 ([Law, 2019](#)).

135 Additionally, rising sea levels threaten Kiribati’s
136 existence, as the country’s islands are only six feet
137 above sea level. Rising sea levels may contaminate
138 fresh water supplies and soil, and ocean acidifica-
139 tion and rising ocean temperatures harm Kiribati’s
140 vital fishing industry ([Law, 2019](#)).

141 In the face of climate change, equitable climate
142 resilience is necessary. Environmental destruction
143 disproportionately harms certain racial, ethnic, and
144 national groups. Historical abuse and colonialism
145 have left these communities most vulnerable to and
146 least equipped to handle such events ([Achiume,
147 2022](#)).

148 To consider human health specifically, [Berberian et al. \(2022\)](#)
149 report that U.S. communities
150 of color, including Black, LatinX, Native Amer-
151 ican, Pacific Islander, and Asian communities, face
152 higher risks of climate-related health impacts than
153 Whites. These disparities manifest in increased
154 mortality, respiratory and cardiovascular diseases,
155 mental health issues, and heat-related illnesses. Cli-
156 mate change exacerbates existing social and eco-
157 nomic inequalities, compounding racial health dis-
158 parities in marginalized communities.

159 2.4 AI & Healthcare in LMIC

160 [Ciecierski-Holmes et al. \(2022\)](#) write how artifi-
161 cial intelligence, including LLMs, has the capacity
162 to improve health systems by supporting and stan-
163 dardizing clinical judgments and applying health-
164 care processes with an objective, data-oriented ap-

proach. This power would be particularly beneficial in LMIC, where medical care is often limited, by improving the efficiency of existing labor and reducing training needed when expanding the workforce (Weissglass, 2022). However, the effective deployment of AI in LMICs faces significant challenges. Ciecierski-Holmes et al. (2022) reference how training data from LMIC is limited and may not be accessible, current, or expansive enough. Further, in low-resource settings, AI tools are only effective if they can be used or integrated into the existing infrastructure. Yet, these low-resource settings may not have the means to support such tools; for instance, some have no or unstable internet access. AI’s promise in LMIC healthcare hinges on addressing data gaps, infrastructure hurdles, and integration challenges.

2.5 Bias in Model Compression

Ramesh et al. (2023) investigate how model compression techniques such as pruning, quantization, and distillation affect bias in language models. It explores intrinsic and extrinsic measures of fairness evaluation in language models and identifies the impact of compression techniques on fairness.

Gonçalves and Strubell (2023) study the propagation of social biases and tradeoffs between bias reduction and efficiency in LLMs, highlighting the challenges of addressing biases in pretrained models due to the computational expense of retraining.

3 Data

We use a subset of the AllenAI C4 English dataset. The AllenAI C4 dataset is a cleaned version of Common Crawl’s web crawl corpus and is commonly used for training NLP models due to its fast coverage and quality. The C4 English dataset is 305 GB and 364,868,892 entries, consisting of an entry’s URL, text, and timestamp (for AI, 2024).

Due to memory constraints, we use a small subset of the dataset. As we will discuss later, the experiment focuses on the act of training, not the training outcomes themselves, as we limit pretraining time to 8 hours. The subset was preprocessed to use only the text with each sentence formatted to the models’ criteria.

4 Models

Devlin et al. (2019)’s Bidirectional Encoder Representations from Transformers (BERT) leverages a

deep multi-layered Transformer encoder with self-attention to analyze all words in a sentence bidirectionally, capturing richer context compared to unidirectional models. Pre-training with masked language modeling further strengthens BERT’s ability to understand word relationships and meaning. The original authors trained BERT-base on 16 TPU chips for 4 days. In 2019, AWS reportedly trained BERT-base in 62 minutes on 2,048 32GB V100 GPUs (Bindal et al., 2019).

Sanh et al. (2020)’s DistilBERT inherits the core architecture of BERT but achieves a smaller size and faster inference by employing knowledge distillation. This technique trains a smaller "student" model (DistilBERT) to mimic the outputs of a larger, pre-trained "teacher" model (BERT). DistilBERT achieves this through a combination of a reduced number of layers and a specialized loss function that incorporates knowledge distillation alongside traditional language modeling objectives. The authors trained DistilBERT for 90 hours on 8 16GB V100 GPUs.

Lan et al. (2020)’s ALBERT builds upon BERT’s architecture, maintaining strong performance, but reduces parameters and training time via two key modifications. First, ALBERT employs a factorized parameterization technique, which breaks down the self-attention mechanism into smaller, more manageable components. Second, ALBERT uses a cross-layer parameter sharing, where the weights of specific layers are shared across the entire encoder. AWS reportedly trained ALBERT-base in 20 hours on 64 32GB V100 GPUs, or in 39 hours on 64 16GB V100 GPUs (Nielsen et al., 2020).

5 Method

We assess the models’ environmental impacts by quantifying their total carbon and financial costs from training. Our process and calculations are adapted from Strubell et al. (2019).

We pre-train the previously referenced models, BERT-base, DistilBERT, and ALBERT, using “out-of-box,” default settings for a set period. Each model was trained for 8 hours on 1 32GB V100 GPU. While training, we repeatedly query for GPU power draw in watts using nvidia-smi. nvidia-smi reports the last measured power-draw for the entire board, which includes the GPU chip, memory modules, power delivery circuitry, cooling solution, connectors, and supporting components, and

Model	Hardware	n_{gpu}	t (hours)	p_{gpu}	$P_{totalpower}$	C_{CO_2} (lbs)	C_{fin}
BERT-base	32GB V100 GPU	2048	1.03333	0.268854	898.968	770.416	6722.67
DistilBERT	16GB V100 GPU	8	90	0.154449	175.701	150.576	2349.6
ALBERT	16GB V100 GPU	64	39	0.198559	783.054	671.077	8145.28
ALBERT	32GB V100 GPU	64	20	0.198559	401.566	344.142	4066.13

Table 1: Estimated carbon and financial costs of complete training for three models. Listed hardware, t , and n_{gpu} are derived from instances of complete training. p_{gpu} is calculated from experiments run on 1 32GBV100 GPU.

is accurate within +/- 5 watts².

After training, we estimate the total power draw, in kilowatt-hours (kWh), of training each model P to completion using our experimental average power draws and the training specifications reported in instances of complete training. The experimental average GPU power-draw in kilowatts (kW), p_g , is derived from the data points collected using nvidia-smi during training. We multiply this value by the global PUE coefficient e and the hours t and number of GPUs n_{gpu} reported in instances of complete training. The PUE coefficient measures data center efficiency, where 1.0 is the ideal, indicating that all energy consumed by the data center is used to power computing devices. Energy used for non-computing components, such as lighting and cooling, increases PUE above 1.0. The 2023 global average PUE is 1.58 (Bizo, 2023).

$$P = e \times p_g \times n_{gpu} \times t$$

After calculating the total power P consumed in training each model, we can convert it to pounds of carbon dioxide C_{CO_2} . For each kWh of electricity generated in the U.S., an average of 0.857 pounds of CO₂ is released at the power plant (Center for Sustainable Systems, University of Michigan, 2023). So, we calculate C_{CO_2} as follows.

$$C_{CO_2} = P \times 0.857$$

Then, we can estimate the financial cost of training each model using cloud computing resources, $C_{financial}$. We approximate the average hourly compute cost C_{cloud} of one 16GB or 32GB V100 GPU across three major cloud providers: AWS, Google Cloud Platform, and Microsoft Azure³. Then, depending on the hardware reported in complete trainings, we calculate the financial cost using

²Source: <https://developer.download.nvidia.com/compute/DCGM/docs/nvidia-smi-367.38.pdf>

³Average C_{cloud} for one 32GB V100 GPU is 3.18, and average C_{cloud} for one 16GB V100 GPU is 3.06. Source: <https://www.paperspace.com/gpu-cloud-comparison>

the referenced GPU’s hourly rates and the quantity of GPUs employed n_{gpu} .

$$C_{financial} = n_{gpu} \times t \times c_{cloud}$$

6 Results

Table 1 lists the estimated carbon and financial costs of training the models referenced in 4. Our experimental average power draw, p_g , is derived from a 32GB V100 GPU, while some instances of complete training, which contain n_{gpu} and t , were trained on 16GB V100 GPU. We observed that BERT-base is the most carbon-intensive model, and DistilBERT is the least.

7 Discussion around contextualizing CO₂ emissions

7.1 Carbon Valuation

Existing cap-and-trade systems worldwide attribute a monetary value to an “allowance” of one metric tonne of carbon dioxide emissions or the equivalent of other greenhouse gases. This market-driven approach curtails pollution by establishing an annual ceiling, or “cap,” on the greenhouse gas emissions within a given region. Participating entities are allotted specific carbon allowances, within which they must confine their emissions. They can trade surplus allowances via auctions, akin to a carbon open market. The system’s cap diminishes annually, directing companies to reduce their carbon footprints and invest in cleaner technologies (Commission).

The European Union’s Emissions Trading System (ETS), the Regional Greenhouse Gas Initiative (RGGI), and California’s Cap-and-Trade Program are three implemented Cap-and-Trade programs. The ETS applies to electricity and heat, energy-intensive (oil refineries, etc.), aviation, and maritime transport industries in the European Union (Commission). In 2024, one allowance is traded

at an average of €89.60 (approximately \$95.48) (Chen, 2023). Less robust, the RGGI applies to fossil-fuel-fired power generators in the northeastern U.S.⁴(RGGI, 2024a). In March 2024, one allowance cleared for an average of \$16 (RGGI, 2024b). Additionally, California’s Cap-and-Trade Program encompasses 80% of the state’s emissions (CA.gov, 2024). In February 2024, one allowance was auctioned at an average of \$41.76.

With these systematic valuations of carbon emissions, we can examine LLMs’ carbon footprints’ costs. In our experiment (see section 6, we estimate the financial cost of training the models on cloud resources, but we do not consider the financial cost of the emissions produced. Using the ETS allowance value, emissions from training the most expensive model, BERT-base, would cost $C_{co2} * 95.48 = 33.37$. Under RGGI, BERT-base emissions would cost $C_{co2} * 16.00 = 5.59$. Under California’s Cap-and-Trade Program, BERT-base emissions would cost $C_{co2} * 41.76 = 14.59$

So, if LLM developers participated in such Cap-and-Trade systems, they would have to pay a respective \$33.37, \$5.59, or \$14.59 to account for their carbon emissions. Imposing Cap-and-Trade rates could act as a deterrent to inefficient training or finetuning for LLMs. However, one tonne of carbon dioxide is not consistently valued high enough to provoke a significant change in action. If we were to train BERT-base in Massachusetts, using our experimental averages, it would cost \$6723 using cloud resources, and the proposed additional emissions fee of \$5.59 would be merely 0.083% of the estimated compute cost.

Incorporating a standardized system for assigning prices to tonnes of greenhouse gas emissions could spur more energy-efficient LLMs, but this solution is dependent on how such systems set the price. Too low of an evaluation would have a negligible impact on LLM development.

7.2 Impact of LLMs in LMIC

As previously mentioned in Section 2, climate change is a global crisis, and it disproportionately affects historically disadvantaged groups. To consider only one aspect, Berberian et al. (2022) describes how communities of color in the U.S. face a greater risk of climate-related health impacts than Whites. To expand internationally, inequalities in the distribution of basic resources expose the eco-

⁴CT, ME, MD, MA, NH, NJ, NY, PA, RI, VT

nomically disadvantaged to disability, disease, and premature death at a higher rate than the wealthy (Weissglass, 2022). So, there is a need for greater access to healthcare, and LLMs could be beneficial tools in labor and resource-lacking environments. However, implementing such tools faces fundamental challenges including access to training data and infrastructure in LMIC.

In the wake of climate change, there is an even greater need for healthcare in LMIC. LLMs are a promising solution, but we first must consider potential side effects.

LLMs are powerful tools, and they require a lot of power to build them. Our research experiment aims to assess just how much energy is required in training and to calculate the subsequent carbon emissions. These greenhouse gas emissions contribute to climate change, which in turn harms LMIC. To justify the carbon-cost of training, the LLMs produced must be usable and beneficial to their users.

Thus, compressed, more efficient models are preferred when developers aim to limit emissions. However, such compression techniques may introduce bias in LLMs (Ramesh et al., 2023). By chasing efficient models, we risk deploying biased tools in disadvantaged communities that have already been systematically subjected to and damaged by societal prejudices and biases. To this, we pose but do not answer the question: is poor help better than no help?

To limit contributions to climate change, LLMs must be built with energy, and therefore carbon, efficiency in mind. However, we warn against tunnel vision in pursuing this metric, as an efficient model will have no use in a setting that cannot support basic technology, and a biased yet efficient model may have a greater capacity for harm than good.

8 Conclusion

In our experiment, we propose a method for calculating the carbon impact of training BERT-based LLMs.

Recently, there have been greater efforts for transparency and reporting on the carbon impacts of LLMs and other computer science applications in the industry. Researchers more frequently report their pretraining carbon emissions (Meta, 2024; Luccioni et al., 2022). Further, major cloud providers include an account’s carbon emissions insights (AWS, 2024; Microsoft, 2024; Cloud, 2024).

Model	Hardware	n_{gpu}	t (hours)	p_{gpu}	$P_{totalpower}$	C_{CO_2} (lbs)	C_{fin}
BERT-base	32GB V100 GPU	1	8	0.268854	3.39832	2.91236	25.4133
DistilBERT	16GB V100 GPU	1	8	0.154449	1.95223	1.67307	26.1067
ALBERT	16GB V100 GPU	1	8	0.198559	2.50979	2.15089	26.1067
ALBERT	32GB V100 GPU	1	8	0.198559	2.50979	2.15089	25.4133

Table 2: Estimated carbon and financial costs of experimental training for three models. Our experiments were run for 8 hours on 1 32GB V100 GPU. Costs were calculated as described in Section 5.

433 However, industry leaders like OpenAI still do not
434 report their carbon emissions and overall lack trans-
435 parency in their models (de Bolle, 2024).

436 While the community is moving in the right di-
437 rection, the lack of transparency in company emis-
438 sions leads to a lack of accountability. We em-
439 phasize the need for regulations to mandate emis-
440 sions reporting and, ideally, limit it. As industry
441 researchers compete to build the best LLMs, mod-
442 els are growing in size, and their energy use follows
443 (Sundberg, 2023).

444 The National Institute of Standards and Technol-
445 ogy’s AI Risk Management Framework outlines
446 how the environmental impact of AI model train-
447 ing and management should be assessed and docu-
448 mented (NIST, 2024). Most radically, we suggest
449 not only strict enforcement of the NIST Frame-
450 work, but to enact regulations on researchers’ total
451 carbon emissions, including any emissions com-
452 panies claim to have offset. While this aim for
453 transparency regulation and emissions constraints
454 may be extreme, the sentiment is a core value.

455 Climate change is a global crisis that dispro-
456 portionately affects disadvantaged groups, both within
457 the U.S. and internationally. We assess LLMs’ cli-
458 mate impact with the understanding that not all
459 people are affected equally. This problem is com-
460 plex and highly interdisciplinary; merely building
461 "green" models will not help LMICs that lack basic
462 resources. To truly benefit disadvantaged commu-
463 nities, LLMs must be developed with carbon effi-
464 ciency, fairness, and context in mind, avoiding the
465 pitfalls of deploying biased models. LLMs are pow-
466 erful tools, but many communities are not equipped
467 to use them, rendering these tools powerless.

468 In tandem with promoting efficiency, trans-
469 parency, and accountability, we emphasize the ne-
470 cessity of reflection and careful evaluation in devel-
471 oping LLMs. Developing and finetuning LLMs to
472 serve unclear purposes will contribute to climate

473 change, while the model may sit unused. LLMs are
474 powerful tools with a great capacity for good, but
475 aimless, expensive development should not become
476 commonplace.

9 Ethics Statement 477

478 We acknowledge that our experiments are not ex-
479 empt from carbon emissions. So, we report the
480 carbon and financial costs of our 8-hour experimen-
481 tal trainings (Table 2) to promote transparency and
482 accountability.

10 Limitations 483

484 We were constrained by GPU memory and uptime
485 while obtaining our experimental average power
486 draws. The original models were trained on far
487 larger datasets, which may impact energy usage.
488 Further, we were unable to record the CPU and
489 dynamic random access memory (DRAM) statis-
490 tics, which contribute to overall power usage, so
491 our estimated power consumption is incomplete.

11 Future Work 492

493 Research could be expanded to consider additional
494 power metrics, models, and hardware. Our experi-
495 ment calculates carbon cost based solely on GPU
496 power draw, but including CPU and DRAM statis-
497 tics would provide a more comprehensive energy
498 analysis. This experiment focuses only on BERT-
499 based models, but we could include newer LLMs
500 with different architectures. Additionally, we could
501 explore differences in hardware, such as TPUs and
502 A100 GPUs. Finally, we aim to consider the carbon
503 footprint of downstream training.
