Applying Intrinsic Debiasing on Downstream Tasks: Challenges and Considerations for Machine Translation

Anonymous ACL submission

Abstract

Most works on gender bias focus on intrinsic bias - removing traces of information about a protected group from the model's internal representation. However, these works are of-005 ten disconnected from the impact of such debiasing on downstream applications, which is the main motivation for debiasing in the first place. In this work, we systematically test how 009 methods for intrinsic debiasing affect neural machine translation models, by measuring the extrinsic bias of such systems under different design choices. We highlight three challenges 012 and mismatches between the debiasing techniques and their end-goal usage, including the choice of embeddings to debias, the mismatch between words and sub-word tokens debiasing, and the effect on different target languages. We 017 find that these considerations have a significant impact on downstream performance and the success of debiasing.

1 Introduction

021

022

033

034

Natural language processing models were shown to over-rely and over-represent gender stereotypes.¹
 These can typically be found in their internal representation or predictions. For example, consider the following sentence:

Inferring that *her* refers to the nurse rather than the doctor may indicate that the model is biased. A useful distinction of model's biases was proposed by (Goldfarb-Tarrant et al., 2021a; Cao et al., 2022a): *Intrinsic bias* typically manifests in the geometry of the model's embeddings. For example, finding that stereotypically female occupations

The doctor and the nurse

Figure 1: A schematic view of a neural machine translation system, highlighting different possibilities for applying intrinsic debiasing techniques. We examine three considerations: (1) where to apply the debiasing; (2) which tokens to apply the debiasing to (e.g. only gender-indicative words or the entire vocabulary); and (3) the effect of different target languages.

(e.g. "nurse", "receiptionist") are grouped together in the embedding space, while stereotypically male occupations (e.g. "doctor", "CEO") are closer to each other (Gonen and Goldberg, 2019). *Extrinsic bias* on the other hand is measured in downstream tasks. For instance, in machine translation (MT), which is the focus of this work, a biased model may translate Example (1) to Spanish using a masculine inflection for the word "doctor", even though a human translator is likely to use a feminine inflection (Stanovsky et al., 2019). Intrinsic and extrinsic bias do not necessarily correlate (Cao et al., 2022b; Goldfarb-Tarrant et al., 2021b), and biases might reoccur when applying debiased models on other tasks (Orgad et al., 2022).

In this work, we identify a gap in the literature between intrinsic bias mitigation and its influence on downstream tasks. Namely, while *extrinsic bias* may affect human users in a variety of applications, debiasing techniques often focus only on *intrinsic* 035

¹Throughout this work we refer to morphological gender, and specifically to masculine and feminine pronouns as captured in earlier work. We note that future important work can extend our work beyond these pronouns to e.g., neo-pronouns (Lauscher et al., 2022).

measures, aiming to obfuscate gender from pretrained embeddings (Bolukbasi et al., 2016; Elazar 056 and Goldberg, 2018; Ravfogel et al., 2020). These 057 approaches leave many questions unanswered that arise when deploying them within a complex downstream model for specific tasks. As shown in Figure 1, we systemically explore three fundamen-061 tal challenges when integrating intrinsic debiasing techniques within a complex open-source neural MT architectures. We find that different design 064 choices lead to a wide difference in extrinsic bias as well as task performance. First, we explore different approaches to cope with discrepancies between 067 different tokenization strategies. While intrinsic debiasing is largely performed over complete words from a fixed dictionary, modern MT requires mapping those onto sub-word elements determined via a data-dependant tokenizer. We find that debiasing only complete words outperforms a more naive 073 debiasing of all sub-word tokens. Second, there are several word embedding tables which could be debiased within an MT system. Therefore, a preliminary architectural question is which of them to debias. We explore various combinations, finding the optimal configuration depends on the intrinsic debiasing technique. We explore the effects of debiasing a translation model over three target languages (Hebrew, German, and Russian). While all three encode morphological noun gender, they differ in script, typology, and morphology. We find that an important factor for debiasing efficiency is the number of words represented as single tokens, a property determined both by the language's morphological properties as well as its sampled distribution in the tokenizer training data. Taken together, our results suggest that extrinsic debiasing 090 involves many interdependent challenges which cannot be inferred from an intrinsic outlook. We hope our work will promote more research on combining intrinsic debiasing method to downstream tasks to produce extrinsically fairer MT models.

2 Background

100

101

102

103

104

There is an abundance of debiasing methods in the field (Wang et al., 2021; Schick et al., 2021; Shen et al., 2021; Dev and Phillips, 2019; Dev et al., 2021; Kaneko and Bollegala, 2021; Shao et al., 2023). Most of them focus on intrinsic debiasing. We focus on three prominent methods, outlined below. Importantly, all of these methods learn a transformation that can be applied to arbitrary vectors, once the model has finished training, and all were tested mostly intrinsically.

Intrinsic debiasing methods. We experiment with three methods: (1) Hard-Debiasing (Bolukbasi et al., 2016) removes a gender subspace via a Principal Component Analysis (PCA) of predetermined word pairs which are considered as indicative of gender; (2) INLP (Ravfogel et al., 2020) learns the direction of the gender subspace rather than using a predefined list of words; and (3) LEACE (Belrose et al., 2023) which prevents all linear classifiers from detecting a guarded concept. A key difference between the methods is that Hard-Debiasing is non-linear and non-exhaustive, leaving stereotypical information after its' application (Gonen and Goldberg, 2019). In contrast, INLP and LEACE are linear and exhaustive; after applying INLP, stereotypical information can't be extracted with a specific linear classifier, and after applying LEACE, it can't be extracted with any linear classifiers.

The effect of debiasing on NMT. Most related to our work, Escudé Font and Costa-jussà (2019) explored the impact of debiasing methods on an English-to-Spanish MT task. However, they tested the MT models only on a simple synthetic data, while here we focus on complex data reflecting real biases, and explore various design choices.

3 Integrating Intrinsic Debiasing in MT

We examine debiasing methods within the popular encoder-decoder approach to MT, as shown in Figure 1. Next we describe the different research questions addressed in our setup.

Which *embedding* to debias? An encoderdecoder model has multiple embedding tables that can be intrinsically debiased: (1) the input matrix of the encoder; (2) the input matrix of the decoder; and (3) the output of the decoder, usually before the softmax layer.² We employ different intrinsic debiasing techniques to each of these tables and evaluate their effect on downstream performance.

Which *words* to debias? Tokenization poses a challenge for extrinsic debiasing as it may introduce discrepancies between the intrinsically debiased elements (complete words) and the MT input

²In a complex system, such as the transformer encoderdecoder architecture, the representations after each transformer layer and within each layer can be debiased as well. We leave the investigation of such debiasing to future work.

Language	Dataset Name	Dataset Size
Russian	newstest2019	1997
German	newstest2012	3003
Hebrew	TED dev	1000

Table 1: Datasets used for evaluating BLEU for each language. Dataset Size describes the number of sentences in the dataset. Russian and German datasets are described in Choshen and Abend (2021)'s paper. The Hebrew dataset is based on Opus TED talks dataset (Reimers and Gurevych, 2020).

model (sub-word tokens) (Iluz et al., 2023) We ex-150 151 periment with three different configurations: (1) all-tokens: debiases embeddings of all tokens in 152 the model's vocabulary; (2) n-token-profession: debiases all embeddings of words that appear in a 154 predefined set of professions, even if they are split 155 across multiple tokens, and (3) 1-token-profession: 156 debiases only the embeddings of a predefined set 157 of professions that align with the vocabulary of the 158 debiasing technique, e.g., "nurse" is debiased only 159 if it appears as a single token. 160

How does debiasing affect different *languages*?

We experiment with three target languages which encode morphological gender for nouns, representing different typological features: (1) Hebrew, a Semitic language with abjad script, (2) Russian, a Slavic language with a Cyrillic script, and (3) German, a Germanic language with Latin alphabet.

4.1 Experimental Setup

MT model. We make use of OPUS-MT (Tiedemann and Thottingal, 2020),³ a transformer-based MT model built of 6 self-attention layers and 8 attention heads in the encoder and the decoder. The model was trained on Opus,⁴ an open-source webtext dataset, which uses SentencePiece tokenization (Kudo and Richardson, 2018).

Metrics and datasets. For extrinsic debiasing measurement, we employ the automatic accuracy metric from Stanovsky et al. (2019), assessing the percentage of instances where the target entity retains its original gender from the English sentence, using morphological markers in the target language. We focus on the performance on the *anti-stereotypical* set of 1584 sentences from

Target Language	German	Hebrew	Russian
no-debiasing	57.7	45.6	41.0
n-token-profession 1-token-profession	60.9 61.9	48.3 48.4	41.0 41.2

Table 2: Accuracy on different target languages when varying the tokens debiasing strategy. Presenting results for applying (1) the baseline (no-debiasing), (2) *n-token-profession*, debiasing tokens corresponding to professions that are tokenized into one or more tokens, and (3) *1-token-profession*, debiasing only professions that are tokenized into a single token. For brevity, each cell presents the the best performing choice of embedding table and debiasing method.

Embedding Table	Baseline	Hard-Debiasing	INLP	LEACE
Encoder Input	48.1	49.6	43.2	43.4
Decoder Input	48.1	48.0	50.0	53.8
Decoder Output	48.1	48.0	50.7	53.8

Table 3: Opus MT's gender prediction accuracy with intrinsic debiasing methods applied on different embedding tables. Each cell is averaged across our target languages (*de*, *he*, *ru*). Bold numbers represent best per debiasing method. The accuracy is measured by Stanovsky et al. (2019)'s method on their WinoMT dataset

WinoMT (Stanovsky et al., 2019). These consist of anti-stereotypical gender role assignments, such as the female doctor in Example 1. In addition, we approximate the translation quality before and after debiasing using BLEU (Papineni et al., 2002) on several parallel corpora described in Table 1, and manually evaluate the translations to corroborate our findings. Finally, all results are statistically significant with p-value < 0.05, see Appendix C for details.

4.2 Results

Debiasing *1-token-profession* **professions outperforms other approaches.** Table 2 shows the gender translation accuracy when applying debiasing methods on different tokens. ⁵ For the three tested languages, debiasing only professions that are tokenized into single tokens improved the gender prediction the most. This hints that the sub-word tokens that compose a profession word do not hold the same gender information as the whole word.

³https://github.com/Helsinki-NLP/Opus-MT

⁴https://opus.nlpl.eu

⁵Excluding results for debiasing all tokens, as it led to garbled translations where automatic debiasing measures are irrelevant.

The optimal embedding table to debias depends on the debiasing method. Table 3 shows the im-206 provement in gender prediction averaged across languages when applied on different embedding tables. Hard-Debiasing improves gender prediction only when debiasing the encoder's inputs, while 210 INLP and LEACE improves gender prediction ac-211 curacy the most when applied to the decoder output. 212 This may be explained by INLP's and LEACE's 213 linearity, which therefore works best at the end of 214 the decoder, after all nonlinear layers, while Hard-Debiasing employs a non-linear PCA component.⁶ 216

Results vary between languages. Debiasing has 217 a positive impact on the accuracy of gender trans-218 lation in both German and Hebrew, with German 219 improving by 3.7 points and Hebrew by 2.8 points. In contrast, Russian did not see as much improve-221 ment (Table 2). The difference may be due to Russian's relatively rich morphology (e.g., it has 7 cases compared to 4 in German (Dryer and Haspelmath, 2013)), resulting in much fewer single-token professions (59% in Russian compared to 65% in Hebrew, and 83% in German). 227

LEACE and Hard-Debiasing do not significantly harm BLEU scores. Figure 2 shows the relationship between the difference in the gender prediction and the difference in BLEU. Hard-Debiasing and 231 LEACE both have a small negative effect to the BLEU scores, while in comparison, INLP presents a trade-off between the improvement in gender prediction and the translation quality according to BLEU scores. This shows that INLP removes information which is important for the translation model, 237 while LEACE (which was proved to be the minimal 238 transformation needed to remove gender information) and Hard-Debiasing indeed preserve more of the information. In terms of the gender predic-241 tion accuracy, the best setting of Hard-Debiasing 242 is when applied to the encoder, while INLP and 243 LEACE improve the gender prediction the most when applied to the decoder outputs. LEACE per-245 forms better than INLP when applied on the de-246 coder as it was designed to prevent all linear clas-247 sifiers from detecting the guarded concept, while 248 INLP learns to obfuscate only one linear classifier. 249

> Human evaluation shows that gender prediction is indeed improved with Hard-Debiasing. We manually annotate a portion of the translation to

252

Figure 2: The relation between gender prediction accuracy difference (orange) and the BLEU difference (blue) between the original model (without any intervention) and the debiased model. The left part presents the results with Hard-Debiasing, INLP in the middle, and LEACE on the right. For each method, we present the results per each location (Encoder, Decoder-input, and Decoder-output), as well as each language).

assess how well the automatic gender prediction metrics estimate real bias. We annotate the configuration of Hard-Debiasing which changes the translations the most compared to other methods: applying Hard-Debiasing to the encoder's input with the *1-token-profession* paradigm. Out of the 1584 sentences in the dataset, 184 (11%) changed after the debiasing. 32% out of all the sentences that changed after the debiasing improved the profession's gender prediction. These numbers are somewhat higher the automatic metrics suggest (26% improvement on the same setup). See Appendix A for additional details. 253

5 Conclusions and Future Work

We systematically explore different challenges and design choices when integrating intrinsic debiasing methods within complex machine translation systems. We find that it is better to debias only words representative of gender and correspond to single tokens, that it is important to couple the debiasing method with the specific embedding table (e.g., encoder versus decoder), and that different target languages lead to vastly different results. Future work can evaluate additional debiasing methods on additional tasks, that may require other considerations when applying such methods.

⁶We tested debiasing all 8 combinations of the three embedding tables, but this did not change our findings.

279 Limitations

Our work explores the integration of debiasing within a complex machine translation system. As 281 such, the space of possible combinations to explore 282 is very large, including the embedding table to debias, the choice of target languages, their corresponding test corpora, the debiasing method to explore and their hyperparameter settings, and more. We systematically explore a subset of these options, which may hinder the generalizability of our specific results, e.g., which tokenization scheme works best. We encourage future work to re-examine our findings in other settings and possibly refine 291 or amend them, while our main takeaway is the broader set of considerations which should be taken 293 into account when debiasing complex, real-world 294 systems. Additionally, our work focuses on gender bias, but certain debiasing techniques are broad and 296 can be used for other protected attributes, thus we 297 aspire that our work will pave the way for exploring other attributes in future works.

A Human Evaluation

The evaluation proposed by Stanovsky et al. (2019) is automatic and thus bound to introduce some noise. To mitigate this concern, we perform a human evaluation which complements the automatic metric and provides a more thorough analysis of the results. The evaluation was applied to translations into Hebrew which were debiased according to the *1-token-profession* words (see Section 3), when specifically applied on encoder's input. We only analyze the sentences that changed in any way compared to the original (non debiased) translations. There were 184 out of 1584 sentences which changed (11%). 32% of the changed sentences improved the gender prediction (i.e the gender of a profession was incorrect in the original translation

and correct in the debiased translation), 3% of the 497 changed sentences were detracted (i.e the gender of 498 a profession was correct in the original translation 499 and incorrect in the debiased translation), and in the rest 65% the change did not affect the gender of the profession. In 23% out of the 65% of unaf-502 fected sentences, the gender of the other profession 503 in the sentence was changed, for example in the sentence "The salesperson talked to the auditor because she was worried about the audit" the gender of salesperson did not change in the debiased trans-507 lations, but the gender of the auditor was changed 508 from male to female form. Note that this is not a 509 mistake since the gender of auditor is unknown in 510 the source sentence. This shows that the debias-511 ing method affects a larger amount of professions 512 which are not counted in the improvement of the 513 model. 514

542 543 To define the gender direction in the target language for both debias methods, we needed the translations of the 10 representative gender word pairs for each language. To get those pairs, we asked a native speaker of each of these languages to translate them into their language. In the case of a pair that is irrelevant to the target language (like Mary and John which are common male and female names in English but not in other languages), we asked them to adapt the pair to represent gender pairs in their language. The set of professions that we debias was also translated into the target languages by three native speakers in each language. The professions annotations were taken from Iluz et al. (2023). The translations of the 10 pairs were collected for four languages, German, Hebrew, Russian, and Spanish. 7

C Statistical Significance

In order to determine the statistical significance of our findings, we employed McNemar's test, as recommended by Dror et al. (2018). McNemar's test is designed for models with binary labels, therefore it is suitable to test the gender bias scores where each sentence is classified as correct if the gender is accurately identified in the translation and incorrect otherwise. The null hypothesis for this test states that the marginal probability for each outcome is equal between the two algorithms being compared, indicating that the models are identical. 544 In our case, the two models being compared are the 545 original translation model and the debiased version. 546 When concatenating results per debias method, we 547 get that the results of Hard Debias are significant 548 with p-value of 3.01E-07, and the results of INLP 549 are significant with p-value of 9.65E-06. When 550 comparing the results per embedding table to de-551 bias, we get that debiasing the encoder inputs is 552 significant with p-value of 5.42E-10, debiasing the 553 decoder inputs is significant with p-value of 0.016 554 and debiasing the decoder outputs is significant 555 with p-value of 0.014. finally when concatenating 556 all the results, we get that comparing the outputs 557 of a debiased model to a the original model, the 558 results are significant with p-value of 0.01. 559

⁷link for the 10 pairs datasets will be released upon publication.
