¹SLB

001 Abstract

002 Accurate forecasting of wind power is essential for
003 grid stability and integration of renewable energy.
004 This work presents a hybrid framework for the pre-
005 diction of short-term wind power in four Norwegian
006 bidding zones. Models are trained at the wind park
007 level and aggregated to zone-level forecasts. We
008 combine physics-informed feature engineering with
009 Liquid Time-Constant Networks (LTC), XGBoost,
010 and a Calibrated LSTM (C-LSTM) module. LTC
011 captures nonlinear temporal dynamics, XGBoost
012 handles structured inputs, and C-LSTM adaptively
013 corrects wind speed forecasts during inference. The
014 model achieves a Mean Absolute Error of 10.9 MW
015 and a RMSE of 10.92 MW, corresponding to less
016 than 9% error relative to average zone-level produc-
017 tion (~130 MW), demonstrating robust performance
018 under various wind conditions.

019 1 Introduction

020 Forecasting wind power generation is a critical task
021 in balancing supply and demand in renewable en-
022 ergy systems. In this project, our objective is to
023 predict the wind power output up to 48 hours in
024 advance for four Norwegian bidding zones. The pro-
025 posed solution integrates physics-informed feature
026 engineering with a hybrid learning framework that
027 combines XGBoost and Liquid Time-Constant Net-
028 works (LTC). XGBoost captures structured patterns
029 from raw meteorological input, while LTC models
030 the nonlinear temporal dynamics inherent in wind
031 behavior [1–3].

032 A key challenge in wind forecasting is the uncer-
033 tainty in predicted wind speeds, which can degrade
034 the reliability of the model. To mitigate this, we in-
035 corporate a Calibrated LSTM (C-LSTM) module [4]
036 that dynamically adjusts wind speed predictions dur-
037 ing inference. This calibration mechanism improves
038 short-term accuracy by correcting systematic biases
039 in the input features.

2 Methodology 040

2.1 Dataset 041

To enhance spatial resolution and forecast accuracy, 042
we adopt a bottom-up modeling strategy. Instead 043
of training a single model per bidding zone, we 044
train individual models for each wind park using 045
publicly available meteorological and production 046
data. The Zone-level forecasts are then computed 047
by aggregating the predictions from all wind parks 048
within the respective zone. 049

2.2 Feature Engineering 050

To create a robust and stable model, the following 051
features were added to the data set: 052

- **Time-based features:** Monthly indicators are 053
extracted to reflect seasonal variations in wind 054
speed, such as higher wind activity in winter 055
and lower in summer. These features help the 056
model account for cyclical patterns in wind 057
behavior [5]. 058
- **Lag features:** Historical wind power values 059
at 1-, 2-, and 3-hour intervals are included to 060
model temporal dependencies. These lagged 061
inputs are derived from factual historical data 062
and improve the model’s ability to learn auto 063
regressive patterns [6]. 064

2.3 Model Development 065

2.3.1 Calibrated LSTM (C-LSTM) 066

To improve short-term wind power forecasting, we 067
implement a Calibrated LSTM (C-LSTM) model 068
inspired by Wang et al. [4], which introduces an adap- 069
tive mechanism to correct wind speed forecasts. The 070
model builds on the standard LSTM architecture 071
and learns a dynamic blending coefficient $\alpha \in [0, 1]$ 072
that fuses forecasted wind speed with a proxy for 073
recent observations. This calibration mechanism 074
addresses systematic biases in numerical weather 075
predictions by leveraging the temporal autocorrela- 076
tion of wind speed. 077

During training, the model receives both fore- 078
casted and observed wind speed sequences to learn 079
how to generate α . At inference time, when only 080

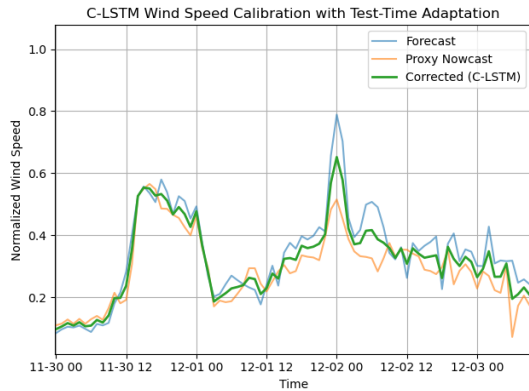

Figure 1. (C-LSTM) Wind Speed Calibration Example

081 forecast data is available, the model estimates α
 082 based on forecast-only inputs. The corrected wind
 083 speed is computed as:

$$084 \quad v_{\text{corrected}} = \alpha \cdot v_{\text{forecasted}} + (1 - \alpha) \cdot v_{\text{proxy}} \quad (1)$$

085 Here, v_{proxy} represents a learned approximation
 086 of recent wind speed observations, derived from pat-
 087 terns in the forecast data itself. This proxy acts
 088 as a stand-in for real-time measurements, enabling
 089 the model to adjust predictions even when actual
 090 nowcast data is unavailable.

091 2.3.2 Hybrid LTC + XGBoost Framework

092 To capture both temporal dynamics and struc-
 093 tured feature interactions, we implement a hybrid
 094 model that combines Liquid Time-Constant Net-
 095 works (LTC) with XGBoost, enhanced by a rich set
 096 of raw meteorological features. LTC is designed to
 097 model time-varying signals with continuous dynam-
 098 ics, making it well-suited for tracking wind fluctua-
 099 tions. Its output—typically the final hidden state or
 100 pooled sequence embedding—is passed to XGBoost,
 101 which excels at learning from structured inputs and
 102 selecting the most relevant features.

103 In addition to the LTC embeddings, we include
 104 raw features such as:

- 105 • Nowcasted wind speed and direction
- 106 • Temperature, pressure, and humidity
- 107 • Time-based encodings (hour, day of week, sea-
 108 son)
- 109 • Lagged power output and rolling statistics

110 This fusion allows XGBoost to learn from both
 111 high-level temporal representations and granular
 112 physical signals, improving short-term forecast ac-
 113 curacy.

114 Krevnevičiūtė et al. [7] proposed a hybrid LTC +
 115 XGBoost model for wind power forecasting, where

both models were trained independently and their
 outputs combined. While the ensemble approach
 demonstrated strong performance, our method di-
 verges by using LTC as a temporal feature extractor
 whose output is fused with raw meteorological inputs
 and fed into XGBoost. This stacked architecture
 allows XGBoost to learn from both high-level tem-
 poral representations and structured raw features,
 potentially improving short-term forecast accuracy.

3 Results

The hybrid model was trained at the wind park level
 and aggregated to produce bidding zone forecasts.
 Across all four Norwegian zones, it consistently out-
 performed baseline configurations. On average, it
 achieved a Mean Absolute Error of 10.9 MW and
 a Root Mean Square Error of 10.92 MW. Given
 that typical zone-level wind production averages
 around 130 MW, this corresponds to less than 9%
 error—demonstrating strong short-term forecast ac-
 curacy and robustness across diverse wind condi-
 tions.
