

A Simple Unsupervised Data Depth-based Method to Detect Adversarial Images

Anonymous authors

Paper under double-blind review

Abstract

Deep neural networks suffer from critical vulnerabilities regarding robustness, which limits their exploitation in many real-world applications. In particular, a serious concern is their inability to defend against adversarial attacks. Although the research community has developed a large amount of effective attacks, the detection problem has received little attention. Existing detection methods either rely on additional training or on specific heuristics at the risk of overfitting. Moreover, they have mainly focused on ResNet architectures while transformers, which are state-of-the-art for vision tasks, have not been properly investigated. In this paper, we overcome these limitations by introducing **APPROVED**, a simple unsupervised detection method for transformer architectures. It leverages the information available in the logit layer and computes a similarity score with respect to the training distribution. This is accomplished using a *data depth* that is: (i) computationally efficient; and (ii) non-differentiable, making it harder for gradient-based adversaries to craft malicious samples. Our extensive experiments show that **APPROVED** consistently outperforms previous detectors on CIFAR10, CIFAR100 and Tiny ImageNet.

1 Introduction

Recent years have seen a rapid development of Deep Neural Networks (DNNs), which have led to a significant improvement over previous state-of-the-art methods (SOTA) in numerous decision-making tasks. However, together with this growth, concerns have been raised about the potential failures of deep learning systems, which limit their large-scale adoption (Alves et al., 2018; Johnson, 2018; Subbaswamy & Saria, 2020). In Computer Vision, a particular source of concern is the existence of *adversarial attacks* (Szegedy et al., 2014), which are samples created by adding to the original (clean) image a well-designed additive perturbation, imperceptible to human eyes, with the goal of fooling a given classifier. The vulnerability of DNNs to such kinds of attacks limits their deployment in safety-critical systems as in aviation safety management (Ali et al., 2020), health monitoring systems (Leibig et al., 2017; Meinke & Hein, 2020) or in autonomous driving (Bojarski et al., 2016; Guo et al., 2017). Therefore, it is crucial to deploy a proper strategy to defend against adversarial attacks (Amodei et al., 2016).

In this context, the task of distinguishing adversarial samples from clean ones is becoming increasingly challenging as developing new attacks is getting more attention from the community (Gao et al., 2021; Wang et al., 2021a; Naseer et al., 2021; Duan et al., 2020; Zhao et al., 2020; Lin et al., 2019; Deng & Karam, 2020a;b; Wu et al., 2020b; Croce & Hein, 2020; Jia et al., 2020; Dong et al., 2019). Inspired by the concept of *rejection channels* (Chow, 1957), which was proposed over 60 years ago for the character recognition problem, one way to address adversarial attacks is to construct a detector-based rejection strategy. Its objective is to discriminate malicious samples from clean ones, which implies discarding samples detected as adversarial. Research in this area focuses on both *supervised* and *unsupervised* approaches (Aldahdooh et al., 2021c). The supervised approaches rely on features extracted from adversarial examples generated according to one or more attacks (Kherchouche et al., 2020; Feinman et al., 2017; Ma et al., 2018); the unsupervised ones, instead, do not rely on prior knowledge of attacks and, in general, only learn from clean data at the time of training (Xu et al., 2018; Raghuram, 2021).

In this work, we focus on the unsupervised scenario, which is often a reasonable approach to real-world use-cases. We model the adversarial detection problem as an *anomaly detection* framework (Breunig et al., 2000; Schölkopf et al., 2001; Liu et al., 2008; Staerman et al., 2019; 2020; Chandola et al., 2009), where the aim is to identify abnormal observations without seeing them during training. Statistical tools called *data depths* are natural similarity score in this context. Data depths have a simple geometric interpretation as they provide center-outward ordering of points with respect to a probability distribution (Tukey, 1975; Zuo & Serfling, 2000). Geometrically speaking, the data depths measure how deep a sample is in a given distribution. Although data depths have received attention from the statistical community, they remain overlooked by the machine learning community.

Contributions. Our contributions can be summarized as follows:

1. **Building on novel tools: data depths.** Our first contribution is to introduce **APPROVED**, A simPle unsuPeRvised method for adVersarial image Detection. Given an input, **APPROVED** considers its embedding in the last layer of the pre-trained classifier and computes the depth of the sample w.r.t the training probability distribution. The deeper it is, the less likely it is to be adversarial. Contrarily to existing methods that involve additional networks training (Raghuram, 2021) or heavily rely on opaque feature engineering Xu et al. (2018), **APPROVED** is computationally efficient and has a simple geometrical interpretation. Moreover, data depths non-differentiability making it harder for to gradient-based attackers to target **APPROVED**.

2. **A truly upgraded experimental setting.** Motivated by practical considerations which are different from previous works (Kherchouche et al., 2020; Xu et al., 2018; Meng & Chen, 2017; Ma et al., 2018; Feinman et al., 2017; Raghuram, 2021) focusing on ResNets He et al. (2016), we choose to benchmark **APPROVED** on vision transformers models (Dosovitskiy et al., 2021; Tolstikhin et al., 2021; Steiner et al., 2021; Chen et al., 2021; Zhai et al., 2022). Indeed, such networks achieve state-of-the-art results on several visual tasks, including object detection He et al. (2021), image classification Wang et al. (2021b) and generation (Parmar et al., 2018), largely outperforming ResNets. Moreover, Vision Transformers are becoming increasingly important as they can be scaled up while retaining the benefits of scale Dehghani et al. (2023). Interestingly enough, we empirically observe that transformers behave differently from ResNets, which justifies the need to develop detection techniques such as **APPROVED**, that leverage the specific features of transformers’ architectures. Moreover, to avoid overfitting on a specific attack, we test our detection method on a wide range of attack mechanisms.

3. **Ensuring reproducibility.** We provide the open-source code of our method, attacks, and baseline to ensure reproducibility and reduce future research computation and coding overhead.

Organization of the paper. The paper is organized as follows. In Sec. 2, we review detection methods along with attack mechanisms. In Sec. 3, we introduce our detector **APPROVED** and focus on the description of the data depth on which it relies. In Sec. 4, we study the performance of adversarial attacks on vision transformers and give insights on models’ behavior under threat. In Sec. 5, we evaluate **APPROVED** through numerical experiments and concluding remarks are relegated to Sec. 6.

2 Background and Related Work

Notations. Let us consider the classical supervised learning problem where $x \in \mathcal{X} \subseteq \mathbb{R}^d$ denotes the input sample in the space \mathcal{X} , and $y \in \mathcal{Y} = \{1, \dots, C\}$ denotes its associated label. The unknown data distribution is denoted by p_{XY} . The training dataset $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^n$ is defined as $n \geq 1$ independent identically distributed (i.i.d.) realizations of p_{XY} . Consider $\mathcal{D}_c = \{(x_i, y_i) \in \mathcal{D} : y_i = c\}$, the training data for a given class $c \in \mathcal{Y}$. We define the empirical training distribution for the class c at layer ℓ as $p_c^\ell = \frac{1}{|\mathcal{D}_c|} \sum_{x \in \mathcal{D}_c} \delta_{f_\theta^\ell(x)}$ where δ_u is the dirac mass at point u .

Let $f_\theta^\ell : \mathcal{X} \rightarrow \mathbb{R}^{d_\ell}$ with $\ell \in \{1, \dots, L\}$, denote the output of the ℓ -th layer of the DNN, where d_ℓ is the dimension of the latent space induced by the ℓ -th layer. The class prediction is obtained from the L -th layer

softmax output as follows:

$$f_{\theta}^L(x) \triangleq \arg \max_{c \in \mathcal{Y}} q_{\theta}(c|x) \text{ with } q_{\theta}(\cdot|x) = \text{softmax}(f_{\theta}^{L-1}(x)).$$

2.1 Review of attack mechanisms

The existence of adversarial examples and their capability to lure a deep neural network have been first introduced in Szegedy et al. (2014). The authors define the adversarial generation problem as:

$$x' = \arg \min_{x' \in \mathbb{R}^d : \|x' - x\|_p < \varepsilon} \|x' - x\|_p \text{ s.t. } f_{\theta}^L(x') \neq y, \quad (1)$$

where y is the true label associated to a natural sample $x \in \mathcal{X}$ being modified, $\|\cdot\|_p$ is the L_p -norm operator, and ε is the maximal allowed perturbation.

Multiple techniques have since been crafted to solve this problem. They can be divided into two main groups of attack mechanisms depending on the knowledge they have of the DNN model: whitebox and blackbox attacks. The former has full access to the model, its weights, and gradients, while the latter can only rely on queries.

Carlini & Wagner's (CW) (Carlini & Wagner, 2017) attack is among the strongest whitebox attacks developed yet. It attempts to solve the adversarial problem in Eq. (1) by regularizing the minimization of the perturbation norm by a surrogate of the misclassification constraint. *DeepFool (DF)* (Moosavi-Dezfooli et al., 2016) is an iterative method that solves a locally linearized version of the adversarial problem and takes a step in that direction.

The authors of Goodfellow et al. (2014) relax the problem as follows:

$$x' = \arg \max_{x' \in \mathbb{R}^d : \|x' - x\|_p < \varepsilon} \mathcal{L}(x, x'; \theta), \quad (2)$$

where $\mathcal{L}(x, x'; \theta)$ is the objective of the attacker, which is a surrogate of the misclassification constraint, and propose the *Fast Gradient Sign Method (FGSM)* that approximates the solution of the relaxed problem in Eq. (2) by taking one step in the direction of the sign of the gradient of the attacker's objective w.r.t. the input. *Basic Iterative Method (BIM)* (Kurakin et al., 2018) and *Projected Gradient Descent (PGD)* (Madry et al., 2018) are two iterative extensions of the FGSM algorithm. Their main difference relies on the initialization of the attack algorithm, i.e., while BIM initializes the adversarial examples to the original samples PGD adds a random uniform noise on it. Although created for L_{∞} -norm constraints, these three methods can be extended to any L_p -norm constraint.

To overcome the absence of knowledge about the model to attack, *Hop Skip Jump (HOP)* (Chen et al., 2020) tries to estimate the model's gradient through queries. *Square Attack (SA)* (Andriushchenko et al., 2020) is based on random searches for a perturbation. If the perturbation doesn't increase the attacker's objective, it is discarded. Finally, *Spatial Transformation Attack (STA)* (Engstrom et al., 2019) rotates and translates the original samples to fool the model.

2.2 Review of detection methods

Defending methods against adversarial attacks have been widely studied for classical CNNs (Madry et al., 2018; Zhang et al., 2019; Alayrac et al., 2019; Wang et al., 2019; Hendrycks et al., 2019; Rice et al., 2020; Atzmon et al., 2019; Huang et al., 2020; Carmon et al., 2019; Wu et al., 2020a). Whereas a few works have focused on studying the robustness of vision transformers to adversarial samples (Aldahdooh et al., 2021a; Benz et al., 2021; Mahmood et al., 2021). Meanwhile, to protect adversarial attacks from disrupting DNNs' functioning, it is possible to craft detectors to ensure that the sample can be trusted.

Building a detector falls down to finding a scoring function $s : \mathbb{R}^d \rightarrow \mathbb{R}$ and a threshold $\gamma \in \mathbb{R}$ to build a binary rule $g : \mathbb{R}^d \rightarrow \{0, 1\}$. For a given test sample $x \in \mathbb{R}^d$,

$$g(x) = \mathbb{I}\{s(x) > \gamma\} = \begin{cases} 1 & \text{if } s(x) > \gamma, \\ 0 & \text{if } s(x) \leq \gamma. \end{cases} \quad (3)$$

If s is an anomaly score, $g(x) = 0$ implies that x is considered as ‘natural’, i.e., sampled from p_{XY} , and $g(x) = 1$ implies that x is considered as ‘adversarial’, i.e., perturbed, and if s is a similarity score, the opposite decision is made.

A detection method can act on the model to be protected by modifying its training procedure using tools such as reverse cross-entropy (Pang et al., 2018) or the rejection option (Sotgiu et al., 2020; Aldahdooh et al., 2021b). In that case, both detector and model are trained jointly. Those methods are usually vulnerable to changes in attack mechanisms, and thus, they need global re-training if a modification of the detector is introduced. On the other hand, it is also possible to craft detectors on top of a fixed trained model. Those methods can be divided into two main categories: supervised methods, where the detector knows the attack that will be perpetrated, and unsupervised methods, where the detector can only rely on clean samples, which is not desired in practice.

Generally, supervised methods use simple machine learning algorithms (e.g., SVM or a logistic regressor) to distinguish between natural and adversarial examples. The effectiveness of such methods heavily relies on natural and adversarial feature extraction. They can be extracted directly from the network’s layers (Lu et al., 2017; Carrara et al., 2018; Metzen et al., 2017), or using statistical tools (e.g., maximum mean discrepancy (Grosse et al., 2017), PCA (Li & Li, 2017), kernel density estimation (Feinman et al., 2017), local intrinsic dimensionality (Ma et al., 2018), model uncertainty (Feinman et al., 2017) or natural scene statistics (Kherchouche et al., 2020)). Supervised methods, which heavily depend on the knowledge about the perpetrated attack, tend to overfit to that attack mechanism and usually generalize poorly.

Unsupervised methods do not assume any knowledge of the attacker. Indeed, new attack mechanisms are crafted every year, and it is realistic to assume knowledge about the attacker. To overcome that absence of prior knowledge about the attacker, unsupervised methods can only rely on natural samples. The features extraction rely on different techniques, such feature squeezing (Xu et al., 2018), adaptive noise, Liang et al. (2021), using denoising autoencoders (Meng & Chen, 2017), network invariant (Ma et al., 2019) or training an auxiliary model (Sotgiu et al., 2020; Aldahdooh et al., 2021b; Zheng & Hong, 2018). Raghuram (2021) uses dimension reduction, kNN and layer aggregation to distinguish between natural and adversarial samples. In this paper, we only focus on unsupervised methods that cannot act on the model to be protected.

3 Our Proposed Detector

3.1 Background on data depth

The notion of data depth goes back to John Tukey in 1975, who introduced the halfspace depth (Tukey, 1975). Data depth functions are useful nonparametric statistics allowing to rank elements of a multivariate space \mathbb{R}^d w.r.t. a probability distribution (or a dataset). Given a random variable Z which follows the distribution p_Z , a data depth can be defined as:

$$\begin{aligned} D : \mathbb{R}^d \times \mathcal{P}(\mathbb{R}^d) &\longrightarrow [0, 1], \\ (z, p_Z) &\longmapsto D(z, p_Z). \end{aligned} \tag{4}$$

The higher the value of the depth function, the deeper the element is in the reference distribution. Various data depths have been introduced over the year (see Chapter 2 of Staerman (2022) for a survey), including halfspace depth (Tukey, 1975), the simplicial depth (Liu, 1990), the projection depth (Liu, 1992) or the zonoid depth (Koshevoy & Mosler, 1997). Despite their applications in statistics and machine learning (e.g., regression (Rousseeuw & Hubert, 1999; Hallin et al., 2010), classification (Mozharovskiy et al., 2015), automatic text evaluation (Staerman et al., 2021b) or anomaly detection (Serfling, 2006; Rousseeuw & Hubert, 2018; Staerman et al., 2020; 2022)) the use of data depth with representation models, and more generally to deep learning, remains overlooked by the community. The halfspace depth is the first and the most studied depth in the literature probably due to its appealing properties (Donoho & Gasko, 1992; Zuo & Serfling, 2000) as well as its connections with univariate quantiles. However, it suffers from computational burden in practice (Rousseeuw & Struyf, 1998; Dyckerhoff & Mozharovskiy, 2016). Indeed, it requires solving an optimization problem over the unit hypersphere of a non-differentiable quantity. To remedy this drawback, Ramsay et al. (2019) introduced the Integrated Rank-Weighted (IRW) depth (see also Chen et al.

(2015); Staerman et al. (2021a)), which involves an expectation as an alternative to the infimum over the unit hypersphere of the halfspace depth, making it easier to compute. The IRW depth is scale and translation invariant and has been successfully applied to anomaly detection (Chen et al., 2015; Staerman et al., 2021a) making it a good candidate for our purposes. Formally, the IRW depth is defined as:

$$D_{\text{IRW}}(z, p_Z) = \int_{\mathbb{S}^{d-1}} \min \{F_u(\langle u, z \rangle), 1 - F_u(\langle u, z \rangle)\} du, \quad (5)$$

where the unit hypersphere is denoted as \mathbb{S}^{d-1} and $F_u(t) = \mathbb{P}(\langle u, Z \rangle \leq t)$. A Monte-Carlo scheme is used to approximate the expectation by an empirical means. Given a training dataset $\mathcal{S}_n = \{z_1, \dots, z_n\}$ following p_Z , denotes $u_k \in \mathbb{S}^{d-1}$, the empirical version of the IRW depth, which can be computed in $\mathcal{O}(n_{\text{proj}}nd)$ and is then linear in all of its parameters, is defined as:

$$\tilde{D}_{\text{IRW}}^{\text{MC}}(z, \mathcal{S}_n) = \frac{1}{n_{\text{proj}}} \sum_{k=1}^{n_{\text{proj}}} \min \left\{ \frac{1}{n} \sum_{i=1}^n \mathbb{I}_{\{\langle u_k, z_i - z \rangle \leq 0\}}, \frac{1}{n} \sum_{i=1}^n \mathbb{I}_{\{\langle u_k, z_i - z \rangle > 0\}} \right\}, \quad (6)$$

3.2 APPROVED: Our depth-based detector

Intuition. Our detector tries to answer this simple question: can we find a metric that will be able to distinguish between natural and arbitrary adversarial samples? At the logit layer, we want to compare the new input to the training samples of its predicted class to measure whether the new sample is behaving as expected. Data depths, particularly the IRW depth, are serious candidates as they measure the ‘distance’ between a given new input to the training probability distribution.

APPROVED in a nutshell. To detect whether a given model f_θ can trust a new input x , APPROVED will perform three steps:

1. **Logits computation.** For an new input x , APPROVED first require to extract the logits (i.e., $f_\theta^{L-1}(x)$) from the pretrained classifier.
2. **Similarity score computation.** APPROVED relies on the IRW depth score $D_{\text{IRW}}(f_\theta^{L-1}(x), p_{\hat{y}}^{L-1})$, between $p_{\hat{y}}^{L-1}$, the training distribution of the predicted class $\hat{y} = f_\theta^L(x)$ at the logit layer, and $f_\theta^{L-1}(x)$, using Algo.1 in Appendix B to evaluate equation 6.
3. **Thresholding.** For a given threshold γ , the test input sample x is detected as clean if $D_{\text{IRW}}(f_\theta^{L-1}(x), p_{\hat{y}}^{L-1}) > \gamma$, otherwise, it is considered as adversarial. A classical way to select γ it by selecting an amount of training samples the detector can wrongfully detect.

3.3 Comparison with existing detectors

We benchmark our approach with two unsupervised detection methods: FS and JTLA. We chose these baselines because they are unsupervised and do not modify the model to protect. We could consider NIC Ma & Liu (2019) but extracting features at each layer is computationally expensive.

The Feature Squeezing method (FS; Xu et al. (2018)). It computes the feature squeezing of the input, extracts its prediction, and compares it to the original prediction. The further away they are, the more likely the input is adversarial. In practice, four versions of the input are needed: the original input, a low-precision version, a median-filtered version, and a denoising-filtered version. One inference on the model is required for each of the four inputs. Later, the maximal L_1 difference between the original prediction and each of the other three is picked. FS is, therefore, parameter-free and does not require training. However, the necessary time to extract the essential features and the memory needed to store all the input modifications and their prediction are quite high.

Joint statistical Testing across DNN Layers for Anomalies (JTLA; (Raghuram, 2021)). This method is composed of four different steps. The first one consists in computing a test statistics for each layer of the model. The goal here is to determine how abnormal the sample is compared to a normal distribution

(i.e., the training distribution). To do so, for each layers, a k-Nearest Neighbors (kNN) is trained on the training sample, then a multinomial likelihood ratio test (RLT) is computed on each class count of the kNN the output of the new sample to test. The second step consists in normalizing the previously obtained RLT values for each layer. Later, an aggregation step is performed to combined the score for each class and each layer to output a single score. Finally, a decision is taking according to a specific threshold. While is method is parameter free, it does require to train a kNN for each layer of the model, which significantly increases the necessary memory and time.

APPROVED, similarly to FS and contrary to JTTLA, does not require training time and is parameter-free. Contrary to FS, it only requires one inference on the model to extract the logits of the input. It is, therefore, *less computationally and time-consuming*. The summary of computational time and resources needed to deploy each detection method is provided in Appendix C. Finally, since data depths are non-differentiable, it is not straightforward for gradient-based attacks that have full access to the detection method to attack APPROVED.

Table 1: ViT-B accuracy for each dataset

Model	Dataset	Acc (%)
ViT-B	CIFAR10	98.7
	CIFAR100	92.4
	Tiny ImageNet	86.4

Table 2: ViT-L accuracy for each dataset

Model	Dataset	Acc (%)
ViT-L	CIFAR10	98.9
	CIFAR100	92.4
	Tiny ImageNet	85.7

4 Adversarial Attacks on Vision Transformers (ViT)

In the following, we provide insights on the behavior of vision transformers under the threat of adversarial attacks, along with a comparison to the classically used ResNets models.

4.1 Set-Up

Datasets and classifiers. We conducted our study on pretrained two differenret Vision Transformers: a ViT-B and a ViT-L. We rely on three widely used vision datasets: CIFAR10 (Krizhevsky, 2009), CIFAR100 and Tiny ImageNet (Tiny) (Jiao et al., 2019). Training details can be found in Appendix A.

Performance measures. We use two different metrics to compare the different detection methods:

AUROC \uparrow : Area Under the Receiver Operating Characteristic curve (Davis & Goadrich, 2006). It represents the relation between True Positive Rates (TPR), i.e., the percentage of perturbed samples detected as adversarial, and False Positive Rates (FPR), i.e., the percentage of clean samples detected as adversarial. The higher the AUROC \uparrow is, the better the detector’s performances are.

FPR $\downarrow_{90\%}$: False Positive Rate at 90% True Positive Rate. It represents the number of natural samples detected as adversarial when 90% of the attacked samples are detected. Lower is better.

Remark. We discard the perturbed samples that do not fool the underlying classifier. Indeed, detecting a sample that does not perturb the classifier’s functioning as natural or adversarial is a valid answer.

Attacks. For the experiments, we will evaluate the different detection methods on the attacks presented in Sec. 2.1. Under L_1 -norm constraint, we craft attacks following PGD¹ scheme. For the L_2 -norm constraint, we consider PGD², DF and HOP. Under L_∞ -norm constraint, we study PGD $^\infty$, BIM and FGSM attacks, CW $^\infty$ and SA. Finally, we create STA attacks, which are not subject to a norm constraint. The values of the maximal allowed perturbation are discussed in the next section.

4.2 Adversarial attack calibration

Given that the variety of attacks comes from choosing the L_p -norm constraint and the maximal allowed L_p -norm perturbation ε , it is crucial to select them carefully. Adversarial attacks and defense mechanisms have been widely studied for classical convolutional networks, particularly for ResNets, with an input size of (32*32*3) (Goodfellow et al., 2014; Moosavi-Dezfooli et al., 2016; Zhang et al., 2019; Madry et al., 2018; Xu et al., 2018; Meng & Chen, 2017). Hence, choosing the maximally allowed perturbation ε for ViT, using inputs of size (224*224*3) comes naturally from comparing the success attack rates between attacks on

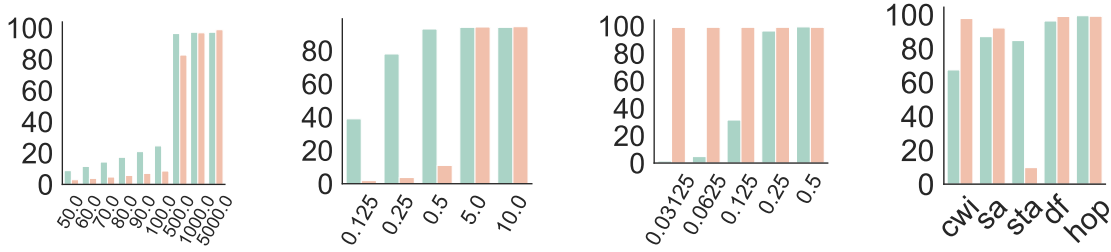

Figure 1: Percentage of successful attacks depending on the L_p -norm constraint, the maximal perturbation ϵ and the attack algorithm on ResNet18 (green) and ViT (orange).

ResNets and ViTs.

In Fig. 1, we present the success rates for attacks on Resnet18 (resp. on ViT-B) in blue (resp. in orange), for different attack mechanisms, different L_p -norms and different maximal perturbation ϵ (the results for FGSM and BIM are relegated to Appendix D). Attacks behave differently on ResNets and on ViTs: on L_∞ -norm constraints, at equal ϵ , the attacks are more potent on the ViT than on ResNet18. Indeed, the input of a ViT has more pixels than the input of a ResNet ($32 \times 32 \times 3$ for ResNet and $224 \times 224 \times 3$ for ViT). Limiting the perturbation by an L_∞ -norm constraint, i.e., controlling the maximal perturbation pixel-wise without controlling the number of modified pixels, will create samples further away from the original sample if it has more pixels. On the contrary, under L_1 and L_2 -norm constraints, the opposite behavior is observable: at fixed ϵ , the attack are more potent on ResNets than on ViTs. This can be explained by the fact that limiting L_1 or L_2 -norm perturbations controls the average perturbations on the whole input sample. The modifications are therefore smaller pixel-wise if the image is bigger. While on ResNets, the classical values of ϵ are lower than 40 on L_1 -norm constraints and 2 on L_2 -norm-constraints, we had to increase the maximum ϵ studied for those L_p -norm constraint to have successful enough attacks. Finally, Spatial Transformation Attacks (STA) disturb ResNets’ functioning more easily than ViTs’.

Summary. To sum up, in the remaining of the paper, under L_1 -norm constraint, we craft PGD¹ attacks with maximum norm constraint $\epsilon \in \{50, 60, 70, 80, 90, 100, 500, 1000, 5000\}$. For the L_2 -norm, we consider PGD² with $\epsilon \in \{0.125, 0.25, 0.5, 5, 10\}$, DF with no ϵ , and HOP attacks with 3 restarts and $\epsilon = 0.1$. Under L_∞ -norm constraint, we consider PGD[∞], BIM and FGSM attacks with $\epsilon \in \{0.03125, 0.0625, 0.125, 0.25, 0.5\}$, CW[∞] with $\epsilon = 0.3125$ and SA with $\epsilon = 0.125$. Finally, STA attacks, which are not subject to a norm constraint, can rotate the input up to 60° , and translate it up to 10 pixels.

4.3 Locating the relevant information

In the previous section, we saw that the attacks behave differently w.r.t. the classifier on which they are perpetrated. We now continue this investigation by looking at the differences between the two models from the depth scores’ perspective. In this framework, we define the layer to have relevant information when the difference between the depth score on the naturals and the depth score on the adversarial is significant. Indeed, the higher the difference, the more evident the shift between the distributions of the natural and the adversarial induced by the depth score will be, and hence the easier it will be to find a threshold that distinguishes natural from adversarial samples. We start by computing layer per layer the differences between the IRW depth on the natural samples ($D_{\text{IRW}}(f_\theta^\ell(x); p_y^\ell)$) and on the adversarial samples ($D_{\text{IRW}}(f_\theta^\ell(x'); p_{y'}^\ell)$) both for ViT and for ResNet18. In Fig. 2, we plot the mean and standard deviation for each layer and each network. The diamond points represent the outliers. Fig. 2 shows that the information about whether a sample is natural or adversarial, based on the study of the IRW depth, is significantly spread across the ResNet18 model: in each layer, the values range between 0 and 0.06. On the contrary, on ViT, this information is concentrated in the logit layer, where the values range between 0.05 and 0.2 while the values range from 0 to 0.05 for the other layers. To summarize, while relevant information to distinguish between natural and adversary samples is diffused in the ResNet18 model, which has small and similar values for all the layers, the most valuable information is instead concentrated at the logit layer for the ViT network,

Figure 2: Difference between natural and adversarial IRW depth values as a function of the layer on ViT-B (top) and on ResNet18 (bottom), averaged over the attacks.

Table 3: Results on ViT-B averaged over the different attacks for each considered L_p -Norm constraints for APPROVED, FS and JTTLA, along with the Averaged results over the norms tested. The results are presented as `mean \pm standard_deviation`. The best results are presented in **bold**.

which experiences larger values only for that particular layer. It seems, therefore, relevant to build a detector *specific* for vision transformers based *only* on the output of the logit layer.

5 Experiments

5.1 Results

Performances of APPROVED compared to other unsupervised detection methods. In Tab. 9, Tab. 10, Tab. 11, Tab. 12, Tab. 13, and Tab. 14 relegated to Appendix F, we report the detailed results for each considered detection method under the threat of each attack mechanism, L_p -norm constraint and maximum perturbation ε . In Tab. 3 and Tab. 4, we report the averaged AUROC \uparrow and FPR $\downarrow_{90\%}$ on each of the considered L_p -norm, along with the global average for each detector, on CIFAR10, CIFAR100, and Tiny ImageNet on the ViT-B and ViT-L respectively. Overall, APPROVED shows better results than the SOTA detection methods. On CIFAR10, APPROVED creates an increase of AUROC \uparrow of 18.9% (resp. 14.9%) and a decrease of FPR $\downarrow_{90\%}$ of 30.7% (resp. 37.3%) compared to the best performing state-of-the-art detector, i.e., FS (resp. JTTLA) on ViT-B (resp. ViT-L). On CIFAR100, the improvements are 16.9% (resp. 12.9%) and 24.8% (resp. 28.2), respectively, while they are 16.9% (resp. 10.2%) and 32.3% (resp. 18.2%) on Tiny ImageNet. In addition, all methods have similar dispersions. Moreover, under specific L_p -norm constraints, our method consistently outperforms SOTA methods, especially under the L_∞ -norm constraint where APPROVED outperforms FS (resp. JTTLA) by 22.3% (resp. 15.1%) in terms of AUROC \uparrow and 40.0% (resp. 48.7%) in terms of FPR $\downarrow_{90\%}$ on CIFAR10 when applied to ViT-B models. On ViT-L, APPROVED increases AUROC \uparrow values by 19.4% (resp. 10.2%) and decreases FPR $\downarrow_{90\%}$ values by 34.8 % (resp. 28.6%) compared to FS (resp. JTTLA) on CIFAR10. Finally, by looking at the detailed results presented in Appendix F, we can deduce that FS and APPROVED have opposite behaviors: when the performances of FS decrease, APPROVED’s performances tend

Table 5: Results on ViT-B averaged over the different types of attack mechanism for APPROVED, FS, and MagNet, along with the averaged results over the norms. The results are presented as $\text{mean} \pm \text{standard_deviation}$. The best results are presented in **bold**. Dashed values (–) corresponds to attacks that take more than 48 hours to run on V100 GPUs.

to improve. For example, under the L_∞ -norm constraint, APPROVED has more trouble detecting attacks with small perturbations, while FS has more difficulty detecting attacks with large perturbations. Indeed, since APPROVED measures the depth of a sample within a distribution, it will be able to recognize the strongest attacks well.

Performances per attack. In Tab. 5 and Tab. 6 we give the overall idea of the results on all three datasets per attack mechanism by showing them in terms of *mean* and *standard deviation* (std) on the AUROC \uparrow and on the FPR $\downarrow_{90\%}$, on each considered model. APPROVED turns out to consistently outperform the state-of-the-art detectors for all datasets. In particular, we notice that the FGSM attacks that are the easiest to generate are the ones that present the highest diversity among the results in the methods examined. Indeed, by looking at Tab. 5, we can find larger values of the standard deviation in correspondence to that attack. Moreover, APPROVED is capable of recognizing attacks that are more difficult for the competitors (e.g., BIM for JTLA or FGSM for FS). We also observe that for APPROVED the most challenging task is to distinguish natural and adversarial samples when they are crafted with DeepFool and the Carlini&Wagner attack. However, it is the best choice even in this case as it reaches better performances than the other detectors.

5.2 Adaptive Attacks

In this experiment, we evaluate APPROVED against adaptive attacks, which has knowledge about the defense (Athalye et al., 2018; Tramer et al., 2020; Carlini & Wagner, 2017). Two scenarios can be considered with adaptive attacks: whitebox and blackbox. Whitebox attacks (e.g. BPDA (Athalye et al., 2018)) are not straightforward to adapt in our case since finding a differentiable surrogate of IRW remains a very challenging

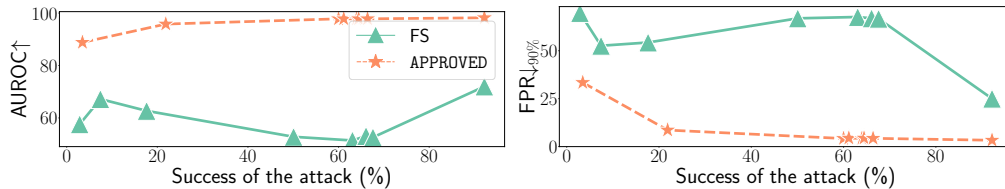

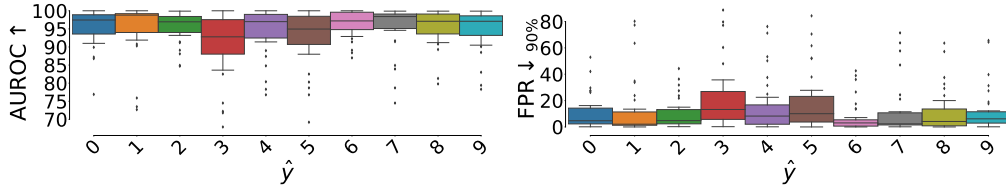

Figure 3: Detector Performances under blackbox Adaptive Attack.

Figure 4: APPROVED’s AUROC \uparrow and FPR $\downarrow_{90\%}$ per class, averaged over CIFAR10.

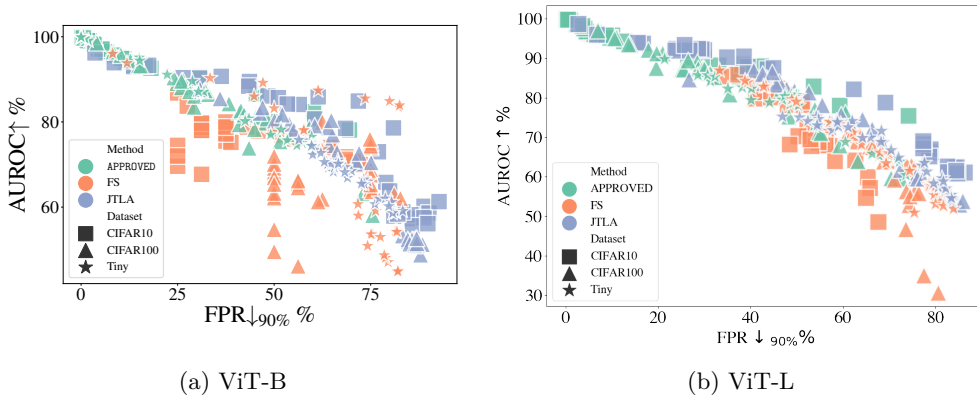

open research question in the statistical community, which has never been tackled. As a matter of fact, the only attempts to approximate a non-differentiable depth was performed not on the IRW depth but on the Tuckey depth in Dyckerhoff et al. (2021), with very poor results as pointed out in She et al. (2021). Thus, in this experiment, we rely on blackbox attacks and present the results in Fig. 3. We attacked both APPROVED and FS using a modified version of SA (Andriushchenko et al., 2020), for which the attack objective has been modified to allow the attacker to fool both the detection method as well as the classifier. We rely on an hyperparameter α that weights the relative importance of the two parts of the objective.

Remark. Both methods have their advantages and drawbacks. Due to speed, memory requirements, and results on CIFAR10 when attacking a ViT-B, we decided to compare APPROVED to FS under adaptive attacks, and discard JTILA. (see subsection C.2). It is straightforward (cf. Fig. 3) that APPROVED is less sensitive to adaptive attacks than FS. This results further validates the use of the IRW depth to craft detection method and further assesses the superiority of APPROVED.

5.3 Finer Analysis

Per class analysis. As explained in Sec. 3.2, APPROVED is based on the IRW depth, which computes the depth score of the sample w.r.t. the original distribution by class. Fig. 4 shows the per-class performances averaged over the different attacks on CIFAR10, while Fig. 7, relegated to Appendix E due to space constraints, shows the performances on CIFAR100. It is clear from Fig. 4 that APPROVED does not have equal performances on every class. In particular, some classes present extremely high mean average AUROC \uparrow (i.e., class 7), others exhibit very low FPR $\downarrow_{90\%}$ (i.e., class 6), while some others have their adversarial and clean samples tough to distinguish (i.e., class 3 and 5). The same behavior is observable of CIFAR100 (see Fig. 7).

AUROC \uparrow vs FPR $\downarrow_{90\%}$. We conclude our analysis by looking at the trade-off between AUROC \uparrow and FPR $\downarrow_{90\%}$ (see Fig. 5). The ideal method would concentrate the results on the upper left of the figure, which corresponds to high AUROC \uparrow and low FPR $\downarrow_{90\%}$, while a poor detector would concentrate them in the bottom right corner of the figure, which corresponds to low AUROC \uparrow and high FPR $\downarrow_{90\%}$. We observe that on CIFAR10, the APPROVED points are more concentrated in the upper left corner, while the FS points are concentrated in the center of the figure and JTILA’s are spread across the entire figure. On CIFAR100 and

Figure 5: AUROC \uparrow as a function of FPR $\downarrow_{90\%}$ for APPROVED, FS, and JTILA on all considered datasets.

Tiny ImageNet, the results for our method are slightly more spread out in the top left and center of the figure, while for FS, they are still in the center and they are spread out in the center and lowest right corner for JTLA. Note that FS has a different behavior than expected, i.e., the line connecting the top left corner with the bottom right corner. This behavior change can be observed for $\text{FPR}_{\downarrow 90\%}$ between 25%-35% on CIFAR10 and between 50%-75% on CIFAR100 and Tiny ImageNet. On CIFAR10, FS presents a lower AUROC_{\uparrow} for a fixed $\text{FPR}_{\downarrow 90\%}$ than expected, whereas, on CIFAR100, it presents a lower AUROC_{\uparrow} (for $\text{FPR}_{\downarrow 90\%}$ values between 50%-60%) or higher (for $\text{FPR}_{\downarrow 90\%}$ values around 75%) than expected.

6 Conclusions and Limitations

We introduced APPROVED, an efficient unsupervised detection method designed to defend against adversarial attacks. In contrast with previous detection methods, which were built for ResNet architectures, APPROVED is well suited for vision transformers which nowadays represent the state-of-the-art. While the relevant information about the discrepancy between clean and adversarial samples is distributed across all layers of ResNets, for the transformers, it was empirically shown to be concentrated in the logit layer. This motivated us to build APPROVED on top of this logit layer by computing a similarity score between an input sample and the training distribution based on the statistical notion of *data depth*. We chose to use the Integrated Rank-Weighted depth, which lends itself to fast inference computations and is non-differentiable, making it harder for gradient-based adversarial methods to craft malicious samples. We conduct extensive numerical experiments and prove that APPROVED outperforms the other state-of-the-art methods significantly.

Future Research. We think our method paves the way for future research efforts. Indeed, there is still room for improvement: even if the AUROC_{\uparrow} performances are good, the $\text{FPR}_{\downarrow 90\%}$ are also fairly high. We believe the idea of leveraging information contained in layers of transformers through data depths can be fruitful in improving defense mechanisms against adversarial attacks. Our research is expected to have a positive societal impact by protecting the integrity of AI systems, especially necessary in critical systems such as autonomous cars (Morgulis et al., 2019) or stock predictions (Xie et al., 2022).

Broader Impact Statement

We believe our work will have a positive impact on society. Indeed, in this work, we propose a method to improve Deep Learning systems to improve our reliability in Deep Neural Networks, as their potential failure has been raising many concerns, limiting their adoption in critical applications.

A Training Details

We compare the different detection methods on three vision datasets: CIFAR10, CIFAR100 (Krizhevsky et al.) and Tiny ImageNet (Jiao et al., 2019) for which we use the ViT models presented in Sec. 4.1 to build a classifier.

We trained two different models: a ViT, and a ResNet18. The ResNet18 has been trained on 100 epochs, with a Stochastic Gradient Descent (SGD) optimizer, with a learning rate of 0.1, a momentum of 0.9, and a weight decay of 10^{-5} . We use the base model with 16 layers (85.8 million of parameters) from <https://github.com/jeonsworld/ViT-pytorch> trained on ImageNet (Deng et al., 2009) as our ViT classifier for CIFAR10 and CIFAR100. To train it we set the batch size to 512. The learning rate of SGD (Ruder, 2016) is set to 3×10^{-2} and we use 500 warming steps with no gradient accumulation (Vaswani et al., 2017). For Tiny ImageNet, we used as the underlying classifier a ViT with 16 layers, trained by (Huynh, 2022) and available at <https://github.com/ehuynh1106/TinyImageNet-Transformers>. Note that we only use the class token to output the layer-wise input’s representations.

Remark. We compare our proposed APPROVED method with FS and JTTLA, recalled in Sec. 2.2. We train JTTLA according to its original training procedure, while FS and our APPROVED, presented in Sec. 3.2, do not require any training.

B Approximation Algorithm

In this appendix, we display the algorithm used to compute the IRW depth (see Algorithm 1).

Algorithm 1 Approximation of the IRW depth

Initialization: test sample x , n_{proj} , $\mathbf{X} = [x_1, \dots, x_n]^\top$.

Construct $\mathbf{U} \in \mathbb{R}^{d \times n_{\text{proj}}}$ by sampling uniformly n_{proj} vectors $U_1, \dots, U_{n_{\text{proj}}}$ in \mathbb{S}^{d-1}

Compute $\mathbf{M} = \mathbf{X}\mathbf{U}$ and $x^\top \mathbf{U}$

Compute the rank value $\sigma(j)$, the rank of $x^\top \mathbf{U}$ in $\mathbf{M}_{:,j}$ for every $j \leq n_{\text{proj}}$

Set $D = \frac{1}{n_{\text{proj}}} \sum_{j=1}^{n_{\text{proj}}} \sigma(j)$

Output: $\tilde{D}_{\text{IRW}}^{\text{MC}}(x, \mathbf{X}) = D$

Complexity. The complexity of the algorithm is detailed as follows. Line 1 requires sampling n_{proj} Gaussian samples and normalizing them in order to define unit sphere directions and can be computed in $O(n_{\text{proj}}d)$. Line 2 requires $O(n_{\text{proj}}dn)$ to project data on the n_{proj} unit sphere Monte-Carlo directions. Line 3 requires computing the sorting operation on n_{proj} columns of the matrix M and then leads to a complexity of $O(n_{\text{proj}}n)$. Line 4 requires the computation of the mean and can be done in n_{proj} operations. Finally, the total complexity of the algorithm is then in $O(n_{\text{proj}}dn)$ which is linear in all of its parameters.

Remarks. Given that the algorithm is linear in all its parameters, computing the IRW depth can be scaled to any datasets. Note that the IRW data depth makes no assumption on the training distribution. In line 3 of Algorithm 1, “rank values” consists in ranking the elements of the projection of each input on \mathbf{U} . This is achieved by a sorting algorithm. This step allows us to define an ordering of the projected inputs, which is used to compute the final depth score.

C Time and Computational Requirements

C.1 To generate attacks

We here present the computational requirements to generate the attacks on the transformer, along with the required time to generate them. We use the Adversarial-Robustness Toolbox (ART) (Nicolae et al., 2018) to generate the attacks.

Table 7: Resources and time needed to generate different types of attack on CIFAR10

Attack	GPUs	CPUs	Time
FGSM	V100-32G	20G	0h25
BIM	V100-32G	20G	3h13

C.2 To deploy detectors

This section presents the computational requirements, along with the time needed to deploy each of the studied detection methods on a ViT-B on CIFAR10. For FS, we use the codes available at https://github.com/aldaahdooh/detectors_review. For JTLA, we used the code proposed by the authors, available at <https://github.com/jayaram-r/adversarial-detection>

Table 8: Resources and time needed to train and test each detection method

Method	GPUs	CPUs	Training Time	Testing Time
APPROVED	V100-32G	40G	N/A	0h11
FS	V100-32G	80G	N/A	0h53
JTLA	V100-32G	180G	0h42	1h26

D Success Rates of Attacks on CIFAR10

We here report the success rate per attack for all the different threat mechanisms (i.e., PGD¹, PGD², PGD[∞], BIM, FGSM, CW[∞], SA, STA, DF and HOP) on a ViT-B on CIFAR10. In orange are the attack performances on ViT while the ones on ResNet are in green (see Sec. 4 for a detailed analysis).

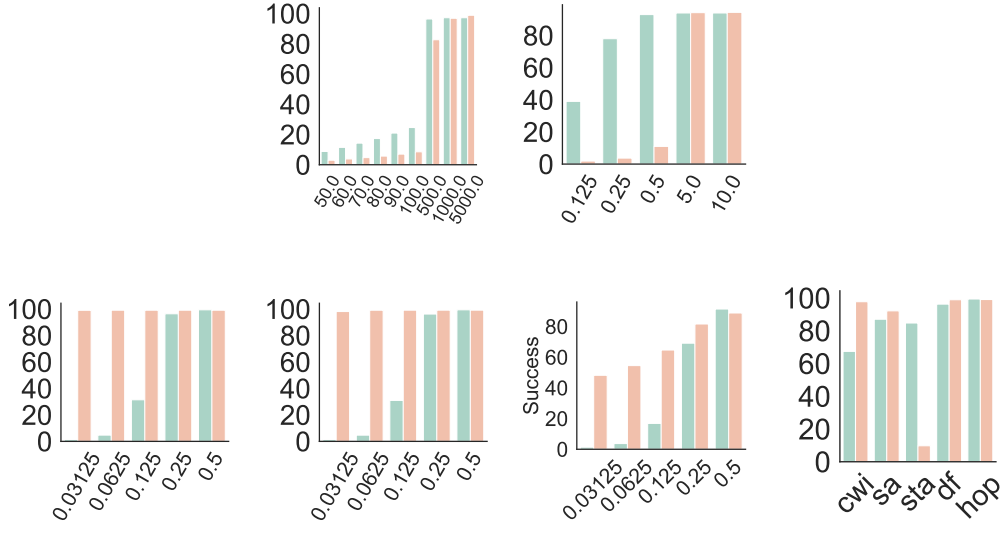

Figure 6: Percentage of successful attacks on a ViT-B depending on the L_p -norm constraint, the maximal perturbation ε and the attack algorithm on ResNet18 (orange) and ViT-B (blue).

E Per Class Analysis

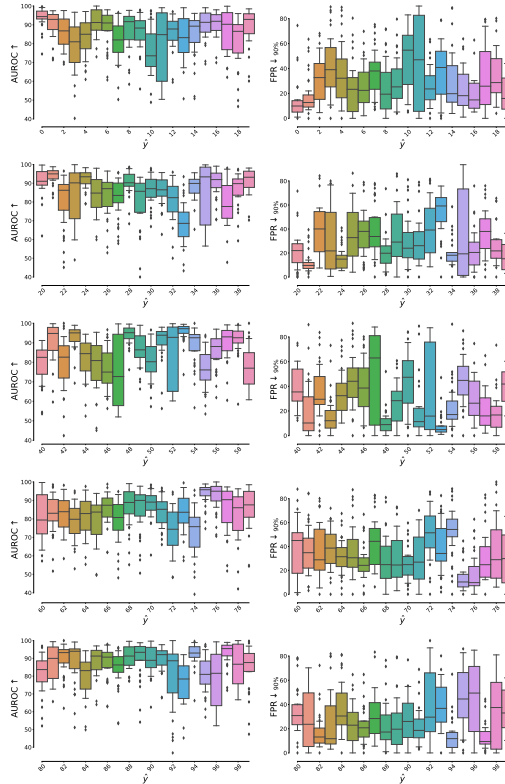

Figure 7: APPROVED's AUROC \uparrow and FPR $\downarrow_{90\%}$ per class, averaged over the attacks on CIFAR100 on a ViT-B.

As for CIFAR10 (see Sec. 5), the detector performances depend on the predicted class. Some classes are easy to detect (i.e., classes 0, 21, 53, 75, and 94), others are more difficult (i.e., classes 3, 10, 33, 47, 60, 74, and 93). Some have low variance (i.e., 0, 1, 24, 34, 75, 82 and, 94) while others have an extremely large dispersion (i.e., 11, 35, 47, 52, 96, and 98).

F Detailed results for CIFAR10, CIFAR100, and Tiny ImageNet

Table 9: AUROC \uparrow and FPR $\downarrow_{90\%}$ for each considered attack mechanisms, L_p -norm constraint and ε on CIFAR10 for APPROVED, FS, and JTLA on a ViT-B. The best result for each attack is shown in **bold**.

Table 14: AUROC \uparrow and FPR $\downarrow_{90\%}$ for each considered attack mechanisms, L_p -norm constraint and ε on Tiny ImageNet for APPROVED, FS, and JTTLA on a ViT-L. The best result for each attack is shown in **bold**.
