Paper under double-blind review

Abstract

011 Complex multi-step reasoning tasks, such as solving mathematical problems or generating code, remain a significant hurdle for even the most advanced large 012 language models (LLMs). Verifying LLM outputs with an Outcome Reward Model 013 (ORM) is a standard inference-time technique aimed at enhancing the reasoning 014 performance of LLMs. However, this still proves insufficient for reasoning tasks 015 with a lengthy or multi-hop reasoning chain, where the intermediate outcomes 016 are neither properly rewarded nor penalized. Process supervision addresses this 017 limitation by assigning intermediate rewards during the reasoning process. To 018 date, the methods used to collect process supervision data have relied on either 019 human annotation or per-step Monte Carlo estimation, both prohibitively expensive to scale, thus hindering the broad application of this technique. In response to 021 this challenge, we propose a novel divide-and-conquer style Monte Carlo Tree Search (MCTS) algorithm named *OmegaPRM* for the efficient collection of highquality process supervision data. This algorithm swiftly identifies the first error 023 in the Chain of Thought (CoT) with binary search and balances the positive and negative examples, thereby ensuring both efficiency and quality. As a result, we 025 are able to collect over 1.5 million process supervision annotations to train Process 026 Reward Models (PRMs). This fully automated process supervision alongside the 027 weighted self-consistency algorithm is able to enhance LLMs' math reasoning 028 performances. We improved the success rates of the instruction-tuned Gemini Pro 029 model from 51% to 69.4% on MATH500 and from 86.4% to 93.6% on GSM8K. Similarly, we boosted the success rates of Gemma2 27B from 42.3% to 58.2% 031 on MATH500 and from 74.0% to 92.2% on GSM8K. The entire process operates 032 without any human intervention or supervision, making our method both financially and computationally cost-effective compared to existing methods.

1 INTRODUCTION

Despite the impressive advancements achieved by scaling Large Language Models (LLMs) on established benchmarks (Wei et al., 2022a), cultivating more sophisticated reasoning capabilities, particularly in domains like mathematical problem-solving and code generation, remains an active 040 research area. Chain-of-thought (CoT) generation is crucial for these reasoning tasks, as it decomposes 041 complex problems into intermediate steps, mirroring human reasoning processes. Prompting LLMs 042 with CoT examples (Wei et al., 2022b) and fine-tuning them on question-CoT solution pairs (Perez 043 et al., 2021; Ouyang et al., 2022) have proven effective, with the latter demonstrating superior 044 performance. Furthermore, the advent of Reinforcement Learning with Human Feedback (RLHF; 045 Ouyang et al., 2022) has enabled the alignment of LLM behaviors with human preferences through reward models, significantly enhancing model capabilities. 046

Beyond prompting and further training, developing effective decoding strategies is another crucial avenue for improvement. Self-consistency decoding (Wang et al., 2023) leverages multiple reasoning paths to arrive at a voted answer. Incorporating a verifier, such as an off-the-shelf LLM (Huang et al., 2022; Luo et al., 2023), can further guide LLMs in reasoning tasks by providing a feedback loop to verify final answers, identify errors, and suggest corrections. However, the gain of such approaches remains limited for complex multi-step reasoning problems. Reward models offer a promising alternative to verifiers, enabling the reranking of candidate outcomes based on reward signals to ensure higher accuracy. Two primary types of reward models have emerged: Outcome

Reward Models (ORMs; Yu et al., 2024; Cobbe et al., 2021), which provide feedback only at the end of the problem-solving process, and Process Reward Models (PRMs; Li et al., 2023; Uesato et al., 2022; Lightman et al., 2023), which offer granular feedback at each reasoning step. PRMs have demonstrated superior effectiveness for complex reasoning tasks by providing such fine-grained supervision.

Figure 1: Example tree structure built with our proposed OmegaPRM algorithm. Each node in the tree indicates a state of partial chain-of-thought solution, with information including accuracy of rollouts and other statistics. Each edge indicates an action, *i.e.*, a reasoning step, from the last state.
Yellow edges are correct steps and blue edges are wrong.

The primary bottleneck in developing PRMs lies in obtaining process supervision signals, which require supervised labels for each reasoning step. Current approaches rely heavily on costly and labor-intensive human annotation (Uesato et al., 2022; Lightman et al., 2023). Automating this process is crucial for scalability and efficiency. While recent efforts using per-step Monte Carlo estimation have shown promise (Wang et al., 2024a;b), their efficiency remains limited due to the vast search space. To address this challenge, we introduce OmegaPRM, a novel divide-and-conquer Monte Carlo Tree Search (MCTS) algorithm inspired by AlphaGo Zero (Silver et al., 2017) for automated process supervision data collection. For each question, we build a Monte Carlo Tree, as shown in Fig. 1, with the details explained in §3.3. This algorithm enables efficient collection of over 1.5 million high-quality process annotations without human intervention. Our PRM, trained on this dataset and combined with weighted self-consistency decoding, significantly improves the performance of instruction-tuned Gemini Pro from 51% to 69.4% on MATH500 (Lightman et al., 2023) and from 86.4% to 93.6% on GSM8K (Cobbe et al., 2021). We also boosted the success rates of Gemma2 27B from 42.3% to 58.2% on MATH500 and from 74.0% to 92.2% on GSM8K.

- 099 Our main contributions are as follows:
 - We propose a novel divide-and-conquer style Monte Carlo Tree Search algorithm for automated process supervision data generation.
 - The algorithm enables the efficient generation of over 1.5 million process supervision annotations, representing the largest and highest quality dataset of its kind to date. Additionally, the entire process operates without any human annotation, making our method both financially and computationally cost-effective.
- We combine our verifier with weighted self-consistency to further boost the performance of LLM reasoning. We significantly improves the success rates from 51% to 69.4% on

MATH500 and from 86.4% to 93.6% on GSM8K for instruction-tuned Gemini Pro. For Gemma2 27B, we also improved the success rates of from 42.3% to 58.2% on MATH500 and from 74.0% to 92.2% on GSM8K.

112 2 RELATED WORK

114 **Improving mathematical reasoning ability of LLMs.** Mathematical reasoning poses significant 115 challenges for LLMs, and it is one of the key tasks for evaluating the reasoning ability of LLMs. 116 With a huge amount of math problems in pretraining datasets, the pretrained LLMs (OpenAI, 2023; 117 Gemini Team et al., 2024; Touvron et al., 2023) are able to solve simple problems, yet struggle with 118 more complicated reasoning. To overcome that, the chain-of-thought (Wei et al., 2022b; Fu et al., 119 2023) type prompting algorithms were proposed. These techniques were effective in improving the 120 performance of LLMs on reasoning tasks without modifying the model parameters. The performance was further improved by supervised fine-tuning (SFT; Cobbe et al., 2021; Liu et al., 2024; Yu et al., 121 2023) with high quality question-response pairs with full CoT reasoning steps. 122

123

108

110

111

Application of reward models in mathematical reasoning of LLMs. To further improve the 124 LLM's math reasoning performance, verifiers can help to rank and select the best answer when 125 multiple rollouts are available. Several works (Huang et al., 2022; Luo et al., 2023) have shown that 126 using LLM as verifier is not suitable for math reasoning. For trained verifiers, two types of reward 127 models are commonly used: Outcome Reward Model (ORM) and Process Reward Model (PRM). 128 Both have shown performance boost on math reasoning over self-consistency (Cobbe et al., 2021; 129 Uesato et al., 2022; Lightman et al., 2023), yet evidence has shown that PRM outperforms ORM 130 (Lightman et al., 2023; Wang et al., 2024a). Generating high quality process supervision data is the 131 key for training PRM, besides expensive human annotation (Lightman et al., 2023), Math-Shepherd 132 (Wang et al., 2024a) and MiPS (Wang et al., 2024b) explored Monte Carlo estimation to automate the data collection process with human involvement, and both observed large performance gain. Our 133 work shared the essence with MiPS and Math-Shepherd, but we explore further in collecting the 134 process data using MCTS. 135

136

Monte Carlo Tree Search (MCTS). MCTS (Świechowski et al., 2021) has been widely adopted in reinforcement learning (RL). AlphaGo (Silver et al., 2016) and AlphaGo Zero (Silver et al., 2017) were able to achieve great performance with MCTS and deep reinforcement learning. For LLMs, there are planning algorithms that fall in the category of tree search, such as Tree-of-Thought (Yao et al., 2023) and Reasoning-via-Planing (Hao et al., 2023). Recently, utilizing tree-like decoding to find the best output during the inference-time has become a hot topic to explore as well, multiple works (Feng et al., 2023; Ma et al., 2023; Zhang et al., 2024; Tian et al., 2024; Feng et al., 2024; Kang et al., 2024) have observed improvements in reasoning tasks.

144 145 146

3 Methods

147 148 3.1 PROCESS SUPERVISION

149 Process supervision is a concept proposed to differentiate from outcome supervision. The reward 150 models trained with these objectives are termed Process Reward Models (PRMs) and Outcome 151 Reward Models (ORMs), respectively. In the ORM framework, given a query q (e.g., a mathematical 152 problem) and its corresponding response x (e.g., a model-generated solution), an ORM is trained 153 to predict the correctness of the final answer within the response. Formally, an ORM takes q and xand outputs the probability p = ORM(q, x) that the final answer in the response is correct. With a 154 training set of question-answer pairs available, an ORM can be trained by sampling outputs from a 155 policy model (e.g., a pretrained or fine-tuned LLM) using the questions and obtaining the correctness 156 labels by comparing these outputs with the golden answers. 157

In contrast, a PRM is trained to predict the correctness of each intermediate step x_t in the solution. Formally, $p_t = PRM([q, x_{1:t-1}], x_t)$, where $x_{1:i} = [x_1, \dots, x_i]$ represents the first *i* steps in the solution. This provides more precise and fine-grained feedback than ORMs, as it identifies the exact location of errors. Process supervision has also been shown to mitigate incorrect reasoning in the domain of mathematical problem solving. Despite these advantages, obtaining the intermediate signal for each step's correctness to train such a PRM is non-trivial. Previous work (Lightman et al., 2023)
 has relied on hiring domain experts to manually annotate the labels, which is and difficult to scale.

164 165

166

3.2 PROCESS ANNOTATION WITH MONTE CARLO METHOD

167 In two closely related works, Math-Shepherd (Wang et al., 2024a) and MiPS (Wang et al., 2024b), 168 the authors propose an automatic annotation approach to obtain process supervision signals using the Monte Carlo method. Specifically, a "completer" policy is established that can take a question q and a prefix solution comprising the first t steps $x_{1:t}$ and output the completion — often referred to as a 170 "rollout" in reinforcement learning — of the subsequent steps until the final answer is reached. As 171 shown in Fig. 2(a), for any step of a solution, the completer policy can be used to randomly sample 172 k rollouts from that step. The final answers of these rollouts are compared to the golden answer, 173 providing k labels of answer correctness corresponding to the k rollouts. Subsequently, the ratio of 174 correct rollouts to total rollouts from the t-th step, as represented in Eq. (1), estimates the "correctness 175 level" of the prefix steps up to t. Regardless of false positives, $x_{1:t}$ should be considered correct as 176 long as any of the rollouts is correct in the logical reasoning scenario.

- 177 178
- 179
- 180

 $c_t = \text{MonteCarlo}(q, x_{1:t}) = \frac{\text{num}(\text{correct rollouts from } t\text{-th step})}{\text{num}(\text{total rollouts from } t\text{-th step})}$ (1)

Taking a step forward, a straightforward strategy to annotate the correctness of intermediate steps in a solution is to perform rollouts for every step from the beginning to the end, as done in both Math-Shepherd and MiPS. However, this brute-force approach requires a large number of policy calls. To optimize annotation efficiency, we propose a binary-search-based Monte Carlo estimation.

185 Monte Carlo estimation using binary search. As suggested by Lightman et al. (2023), supervising 186 up to the first incorrect step in a solution is sufficient to train a PRM. Therefore, our objective is 187 locating the first error in an efficient way. We achieve this by repeatedly dividing the solution and 188 performing rollouts. Assuming no false positives or negatives, we start with a solution with potential 189 errors and split it at the midpoint m. We then perform rollouts for $s_{1:m}$ with two possible outcomes: 190 (1) $c_m > 0$, indicating that the first half of the solution is correct, as at least one correct answer can 191 be rolled out from *m*-th step, and thus the error is in the second half; (2) $c_m = 0$, indicating the error is very likely in the first half, as none of the rollouts from m-th step is correct. This process 192 narrows down the error location to either the first or second half of the solution. As shown in Fig. 2(b), 193 by repeating this process on the erroneous half iteratively until the partial solution is sufficiently 194 small (*i.e.*, short enough to be considered as a single step), we can locate the first error with a time 195 complexity of $O(k \log M)$ rather than O(kM) in the brute-force setting, where M is the total number 196 of steps in the original solution.

197

199

3.3 MONTE CARLO TREE SEARCH

200 Although binary search improves the efficiency of locating the first error in a solution, we are still not 201 fully utilizing policy calls as rollouts are simply discarded after stepwise Monte Carlo estimation. In 202 practice, it is necessary to collect multiple PRM training examples (a.k.a., triplets of question, partial solution and correctness label) for a question (Lightman et al., 2023; Wang et al., 2024a). Instead 203 of starting from scratch each time, we can store all rollouts during the process and conduct binary 204 searches from any of these rollouts whenever we need to collect a new example. This approach 205 allows for triplets with the same solution prefix but different completions and error locations. Such 206 reasoning structures can be represented as a tree, as described in previous work like Tree of Thought 207 (Yao et al., 2023). 208

Formally, consider a *state-action tree* representing detailed reasoning paths for a question, where a state *s* contains the question and all preceding reasoning steps, and an action *a* is a potential subsequent step from a specific state. The root state is the question without any reasoning steps: $r_{\text{root}} = q$. The policy can be directly modeled by a language model as $\pi(a|s) = \text{LM}(a|s)$, and the state transition function is simply the concatenation of the preceding steps and the action step, *i.e.*, s' = Concatenate(s, a).

215

Figure 2: Illustration of the process supervision rollouts, Monte Carlo estimation using binary search 242 and the MCTS process. (a) An example of Monte Carlo estimation of a prefix solution. Two out of 243 the three rollouts are correct, producing the Monte Carlo estimation $MC(q, x_{1:t}) = 2/3 \approx 0.67$. (b) 244 An example of error locating using binary search. The first error step is located at the 7th step after 245 three divide-and-rollouts, where the rollout positions are indicated by the vertical dashed lines. (c) 246 The MCTS process. The dotted lines in Select stage represent the available rollouts for binary search. 247 The bold colored edges represent steps with correctness estimations. The yellow color indicates a 248 correct step, *i.e.*, with a preceding state s that MC(s) > 0 and the blue color indicates an incorrect step, *i.e.*, with MC(s) = 0. The number of dashes in each colored edge indicates the number of steps. 249 250

Collecting PRM training examples for a question can now be formulated as constructing such a state-action tree. This reminds us the classic Monte Carlo Tree Search (MCTS) algorithm, which 253 has been successful in many deep reinforcement learning applications (Silver et al., 2016; 2017). 254 However, there are some key differences when using a language model as the policy. First, MCTS typically handles an environment with a finite action space, such as the game of Go, which has fewer 256 than 361 possible actions per state (Silver et al., 2017). In contrast, an LM policy has an infinite action 257 space, as it can generate an unlimited number of distinct actions (sequences of tokens) given a prompt. 258 In practice, we use temperature sampling to generate a fix number of k completions for a prompt, 259 treating the group of k actions as an approximate action space. Second, an LM policy can sample 260 a full rollout until the termination state (i.e., reaching the final answer) without too much overhead 261 than generating a single step, enabling the possibility of binary search. Consequently, we propose an 262 adaptation of the MCTS algorithm named **OmegaPRM**, primarily based on the one introduced in 263 AlphaGo (Silver et al., 2016), but with modifications to better accommodate the scenario of PRM training data collection. We describe the algorithm details as below. 264

265

241

251

Tree Structure. Each node s in the tree contains the question q and prefix solution $x_{1:t}$, together with all previous rollouts $\{(s, r_i)\}_{i=1}^k$ from the state. Each edge (s, a) is either a single step or a sequence of consecutive steps from the node s. The nodes also store a set of statistics,

{

$$[N(s), \mathrm{MC}(s), Q(s, r)]$$

295 296

297

298

306

311

312

313

314 315

316

320 321 322

where N(s) denotes the visit count of a state, MC(s) represents the Monte Carlo estimation of a state as specified in Eq. (1), and Q(s, r) is a state-rollout value function that is correlated to the chance of selecting a rollout during the selection phase of tree traversal. Specifically,

$$Q(s,r) = \alpha^{1 - \mathrm{MC}(s)} \cdot \beta^{\frac{\mathrm{len}(r)}{L}}, \qquad (2)$$

275 where $\alpha, \beta \in (0, 1]$ and L > 0 are constant hyperparameters; while len(r) denotes the length of a 276 rollout in terms of number of tokens. Q is supposed to indicate how likely a rollout will be chosen for 277 each iteration and our goal is to define a heuristic that selects the most valuable rollout to search with. 278 The most straightforward strategy is uniformly choosing rollout candidates generated by the policy in previous rounds; however, this is obviously not an effective way. Lightman et al. (2023) suggests 279 surfacing the *convincing wrong-answer* solutions for annotators during labeling. Inspired by this, we 280 propose to prioritize supposed-to-be-correct wrong-answer rollouts during selection. We use the term 281 supposed-to-be-correct to refer to the state with a Monte Carlo estimation MC(s) closed to 1; and 282 use wrong-answer to refer that the specific rollout r has a wrong final answer. The rollout contains 283 mistakes made by the policy that should have been avoided given its high MC(s). We expect a PRM 284 that learns to detect errors in such rollouts will be more useful in correcting the mistakes made by the policy. The first component in Eq. (2), $\alpha^{1-MC(s)}$, has a larger value as MC(s) is closer to 1. 285 286 Additionally, we incorporate a length penalty factor $\beta^{\frac{\text{len}(r)}{L}}$, to penalize excessively long rollouts. 287

Select. The selection phase in our algorithm is simpler than that of AlphaGo (Silver et al., 2016), which involves selecting a sequence of actions from the root to a leaf node, forming a trajectory with multiple states and actions. In contrast, we maintain a pool of all rollouts $\{(s_i, r_j^i)\}$ from previous searches that satisfy $0 < MC(s_i) < 1$. During each selection, a rollout is popped and selected according to tree statistics, $(s, r) = \arg \max_{(s,r)}[Q(s, r) + U(s)]$, using a variant of the PUCT (Rosin, 2011) algorithm,

$$U(s) = c_{\text{puct}} \frac{\sqrt{\sum_{i} N(s_i)}}{1 + N(s)},\tag{3}$$

where c_{puct} is a constant determining the level of exploration. This strategy initially favors rollouts with low visit counts but gradually shifts preference towards those with high rollout values.

Binary Search. We perform a binary search to identify the first error location in the selected rollout, as detailed in §3.2. The rollouts with 0 < MC(s) < 1 during the process are added to the selection candidate pool. All divide-and-rollout positions before the first error become new states. For the example in Fig. 2(b), the trajectory $s[q] \rightarrow s[q, x_{1:4}] \rightarrow s[q, x_{1:6}] \rightarrow s[q, x_{1:7}]$ is added to the tree after the binary search. The edges $s[q] \rightarrow s[q, x_{1:4}]$ and $s[q, x_{1:4}] \rightarrow s[q, x_{1:6}]$ are correct, with MC values of 0.25 and 0.5, respectively; while the edge $s[q, x_{1:6}] \rightarrow s[q, x_{1:7}]$ is incorrect with MC value of 0.

307 **Maintain.** After the binary search, the tree statistics N(s), MC(s), and Q(s, r) are updated. 308 Specifically, N(s) is incremented by 1 for the selected (s, r). Both MC(s) and Q(s, r) are updated 309 for the new rollouts sampled from the binary search. This phase resembles the *backup* phase in 310 AlphaGo but is simpler, as it does not require recursive updates from the leaf to the root.

Tree Construction. By repeating the aboved process, we can construct a state-action tree as the example illustrated in Fig. 1. The construction ends either when the search count reaches a predetermined limit or when no additional rollout candidates are available in the pool.

3.4 PRM TRAINING

Each edge (s, a) with a single-step action in the constructed state-action tree can serve as a training example for the PRM. It can be trained using the standard classification loss

$$\mathcal{L}_{\text{pointwise}} = \sum_{i=1}^{N} \hat{y}_i \log y_i + (1 - \hat{y}_i) \log(1 - y_i), \tag{4}$$

where \hat{y}_i represents the correctness label and $y_i = \text{PRM}(s, a)$ is the prediction score of the PRM. Wang et al. (2024b) have used the Monte Carlo estimation as the correctness label, denoted as $\hat{y} = MC(s).$ Alternatively, Wang et al. (2024a) have employed a binary labeling approach, where $\hat{y} = \mathbf{1}[MC(s) > 0],$ assigning $\hat{y} = 1$ for any positive Monte Carlo estimation and $\hat{y} = 0$ otherwise. We refer the former option as *pointwise soft* label and the latter as *pointwise hard* label. In addition, considering there are many cases where a common solution prefix has multiple single-step actions, we can also minimize the cross-entropy loss between the PRM predictions and the normalized pairwise preferences following the Bradley-Terry model (Christiano et al., 2017). We refer this training method as *pairwise* approach, and the detailed pairwise loss formula can be found in Section Appendix B.

We use the pointwise soft label when evaluating the main results in §4.1, and a comparion of the three objectives are discussed in §4.3.

333 334 335

336

4 EXPERIMENTS

337 **Data Generation.** We conduct our experiments on the challenging MATH dataset (Hendrycks 338 et al., 2021). We use the same training and testing split as described in Lightman et al. (2023), 339 which consists of 12K training examples and a subset with 500 holdout representative problems from 340 the original 5K testing examples introduced in Hendrycks et al. (2021). We observe similar policy 341 performance on the full test set and the subset. For creating the process annotation data, we use the questions from the training split and set the search limit to 100 per question, resulting 1.5M per-step 342 process supervision annotations. To reduce the false positive and false negative noise, we filtered out 343 questions that are either too hard or too easy for the model. Please refer to Appendix A for details. 344 We use $\alpha = 0.5$, $\beta = 0.9$ and L = 500 for calculating Q(s, r) in Eq. (2); and $c_{\text{puct}} = 0.125$ in Eq. (3). 345 We sample k = 8 rollouts for each Monte Carlo estimation. 346

347

Models. In previous studies (Lightman et al., 2023; Wang et al., 2024a;b), both proprietary models 348 such as GPT-4 (OpenAI, 2023) and open-source models such as Llama2 (Touvron et al., 2023) were 349 explored. In our study, we perform experiments with both proprietary Gemini Pro (Gemini Team 350 et al., 2024) and open-source Gemma2 (Gemma Team et al., 2024) models. For Gemini Pro, we 351 follow Lightman et al. (2023); Wang et al. (2024a) to initially fine-tune it on math instruction data, 352 achieving an accuracy of approximately 51% on the MATH test set. The instruction-tuned model is 353 then used for solution sampling. For open-source models, to maximize reproducibility, we directly 354 use the pretrained Gemma2 27B checkpoint with the 4-shot prompt introduced in Gemini Team et al. 355 (2024). The reward models are all trained from the pretrained checkpoints.

356 357

Metrics and baselines. We evaluate the PRM-based majority voting results on GSM8K (Cobbe 358 et al., 2021) and MATH500 (Lightman et al., 2023) using PRMs trained on different process super-359 vision data. We choose the product of scores across all steps as the final solution score following 360 Lightman et al. (2023), where the performance difference between product and minimum of scores 361 was compared and the study showed the difference is minor. Baseline process supervision data 362 include PRM800K (Lightman et al., 2023) and Math-Shepherd (Wang et al., 2024a), both publicly 363 available. Additionally, we generate a process annotation dataset with our Gemini policy model using 364 the brute-force approach described in Wang et al. (2024a;b), referred to as Math-Shepherd (our impl) 365 in subsequent sections.

366 367

368

4.1 MAIN RESULTS

369 Table 1 and Fig. 3 presents the performance comparison of PRMs trained on various process an-370 notation datasets. OmegaPRM consistently outperforms the other process supervision datasets. 371 Specifically, the fine-tuned Gemini Pro achieves 69.4% and 93.6% accuracy on MATH500 and 372 GSM8K, respectively, using OmegaPRM-weighted majority voting. For the pretrained Gemma2 27B, 373 it also performs the best with 58.2% and 92.2% accuracy on MATH500 and GSM8K, respectively. 374 It shows superior performance comparing to both human annotated PRM800K but also automatic 375 annotated Math-Shepherd. More specifically, when the number of samples is small, almost all the 376 PRM models outperforme the majority vote. However, as the number of samples increases, the performance of other PRMs gradually converges to the same level of the majority vote. In contrast, 377 our PRM model continues to demonstrate a clear margin of accuracy.

Figure 3: A comparison of PRMs trained with different process supervision datasets, evaluated by their ability to search over many test solutions using a PRM-weighted majority voting. We visualize the variance across many sub-samples of the 128 solutions we generated in total per problem.

Table 1: The performance comparison of PRMs trained with different process supervision datasets. The numbers represent the percentage of problems solved using PRM-weighted majority voting with k = 64.

4.2

STEP DISTRIBUTION

An important factor in process supervision is the number of steps in a solution and the length of each step. Previous works (Lightman et al., 2023; Wang et al., 2024a;b) use rule-based strategies to split a solution into steps, *e.g.*, using newline as delimiters. In contrast, we propose a more flexible method for step division, treating any sequence of consecutive tokens in a solution as a valid step. We observe that many step divisions in Math-Shepherd lack semantic coherence to some extent. Therefore, we hypothesize that semantically explicit cutting is not necessary for training a PRM.

In practice, we first examine the distribution of the number of steps per solution in PRM800K and
 Math-Shepherd, as shown in Fig. 4, noting that most solutions have less than 20 steps. During binary search, we aim to divide a full solution into 16 pieces. To calculate the expected step length, we

Table 2: Comparison of different training objectives for PRMs.

| | Soft Label | Hard Label | Pairwise |
|------------------|------------|------------|----------|
| PRM Accuracy (%) | 70.1 | 63.3 | 64.2 |

As outlined in §3.4, PRMs can be trained using multiple objectives. We construct a small process supervision test set using the problems from the MATH test split. We train PRMs using pointwise soft label, pointwise hard label and pairwise loss respectively, and evaluate how accurately they can classify the per-step correctness. Table 2 presents the comparison of different objectives, and the pointwise soft label is the best among them with 70.1% accuracy.

476 477 478

4.4 ALGORITHM EFFICIENCY

As described in Section §3.2 and §3.3, we utilize binary search and Monte Carlo Tree Search to improve the efficiency of OmegaPRM process supervision data collection by effectively identifying the first incorrect step and reusing rollouts in Monte Carlo estimation. To quantitatively measure the efficiency of OmegaPRM, we collected process supervision data using both brute-force-style method (Wang et al., 2024a;b) and OmegaPRM with the same computational budget. As a result, we were able to generate 200K data points using the brute-force algorithm compared to 15 million data points with OmegaPRM, demonstrating a 75-times efficiency improvement. In practice, we randomly down-sampled OmegaPRM data to 1.5 million for PRM training.

505

There are some limitations with our paper, which we reserve for future work:

490 Automatic process annotation is noisy. Our method for automatic process supervision annotation 491 introduces noise in the form of false positives and negatives, but experiments indicate that it can 492 still effectively train a PRM. The PRM trained on our dataset performs better than one trained on the human-annotated PRM800K dataset. The precise impact of noise on PRM performance remains 493 494 uncertain. For future research, a comprehensive comparison of human and automated annotations should be conducted. One other idea is to integrate human and automated annotations, which could 495 result in more robust and efficient process supervision. 496

Human supervision is still necessary. Unlike the work presented in AlphaGo Zero (Silver et al., 498 2017), our method requires the question and golden answer pair. The question is necessary for LLM 499 to start the MCTS and the golden answer is inevitable for the LLM to compare its rollouts with and determine the correctness of the current step. This will limit the method to the tasks with such question and golden answer pairs. Therefore, we need to adapt the current method further to make it suitable for open-ended tasks. 503

6 CONCLUSION

506 In conclusion, we introduce OmegaPRM, a divide-and-conquer Monte Carlo Tree Search algorithm, 507 designed to automate the process supervision data collection for LLMs. By efficiently pinpointing 508 the first error in the Chain-of-Thought and balancing data quality, OmegaPRM addresses the short-509 comings of existing methods. Our automated approach enables the collection of over 1.5 million 510 process supervision annotations, which are used to train a PRM. Leveraging this automated process 511 supervision with the weighted self-consistency algorithm, we improve LLM mathematical reasoning 512 performance, achieving a 69.4% success rate on the MATH benchmark — a 18.4% absolute increase 513 over the base model which amounts to a relative improvement of 36%. Additionally, our method 514 significantly reduces data collection costs compared to human annotation and brute force Monte-Carlo 515 sampling. These findings highlight OmegaPRM's potential to enhance LLM capabilities in complex multi-step reasoning tasks. 516

APPENDIX

QUESTION FILTERING A

During the evaluation of partial solution correctness using MC estimation, false negative noise may be introduced when a question is too hard for the model, thus no correct rollout can be found even with correct partial solution. Or false positive noise may be introduced when a question is too easy, that model can conclude in correct answer given partial solution with wrong step. It is not possible to exclude such noise completely, but we can reduce the chance by filtering out questions that are either too hard or too easy for the model. Specifically, we ran a k = 32 rollouts for each question in the 12K training data, and filter out the questions that with no correct answer (too hard) or no wrong answer (too easy) in the 32 rollouts.

В PAIRWISE LOSS FORMULA

When training with pairwise labels, the Bradley-Terry model (people typically use this objective to train reward models in RLHF) generally accepts two probability scalars summing up to 1. When we select the two actions as a pair, there are two cases. The first case is that one sample with a zero MC value, and the other sample with a positive MC value. The second case is that both samples are with positive MC values. The first case is straight-forward, and a normalization step is required for the second case.

Assume the two MC values are p and q, and they follow the Bernoulli distribution: P(X = 1) = pand P(Y = 1) = q. We need to calculate the probability that action X is preferred over action Y and vice versa.

P(X > Y) = P(X = 1, Y = 0) = p(1 - q),P(X < Y) = P(X = 0, Y = 1) = (1 - p)q,(5)P(X = Y) = P(X = 0, Y = 0) + P(X = 1, Y = 1) = (1 - p)(1 - q) + pq.

For the tied situation, each action has half the chance of being preferred. Thus,

$$P(\text{action X is preferred}) = P(X > Y) + 1/2 * P(X = Y) = 1/2 * (1 + p - q),$$

$$P(\text{action Y is preferred}) = P(X < Y) + 1/2 * P(X = Y) = 1/2 * (1 + q - p).$$
(6)

Now the MC values are normalized and we can train with the pairwise loss.
