

The Fair Value of Data Under Heterogeneous Privacy Constraints in Federated Learning

Anonymous authors

Paper under double-blind review

Abstract

Modern data aggregation often involves a platform collecting data from a network of users. Now users are requesting that the data they provide is protected with a guarantee of privacy. With privacy options for users, platforms must solve the problem of how to allocate incentives to users to convince them to share their data. The main goal of this paper is to characterize a *fair* amount to compensate users for their data at a given privacy level. We propose an axiomatic definition of fairness, along the lines of the celebrated Shapley value. The notion of fairness we propose is ultimately related to the average marginal contribution of a user. To the best of our knowledge, these are the first fairness concepts for data that explicitly consider privacy constraints. We also formulate a heterogeneous federated learning problem for the platform with privacy level options for users. By studying this problem, we investigate the amount of compensation users receive under fair allocations with different privacy levels, amounts of data and degrees of heterogeneity. Under certain conditions, we characterize the optimal behavior of the platform when incentives are constrained to be fair, revealing that the optimal behavior of the platform can be separated into three regimes, depending on the privacy sensitivity of the users. When privacy sensitivity is low, the platform will set incentives to ensure that it collects all the data with the lowest privacy options. When the privacy sensitivity is above a given threshold, the platform will provide no incentives to users. Between these two extremes, the platform will set the incentives so some fraction of the users chooses the higher privacy option and the other chooses the lower privacy option.

1 Introduction

From media to healthcare to transportation, the vast amount of data generated by people living their everyday lives has been used to great effect to solve difficult problems across many domains. For example, nearly all machine learning algorithms, including those based on deep learning rely heavily on data. Many of the largest companies to ever exist center their business around the precious resource of data. This includes directly selling access to data to others for profit, selling targeted advertisements based on data, or by exploiting data through data-driven engineering, to better develop and market products. Simultaneously, as users become more privacy conscious, online platforms are increasingly providing *privacy level* options for users. Platforms may provide incentives to users to influence their privacy level decisions. This manuscript investigates how platforms can fairly compensate users for their data contribution at a given privacy level.

Consider a platform offering geo-location services with three user privacy level options:

- i) Users send no data to the platform — all data processing is local and private.
- ii) An intermediate option with federated learning (FL) for privacy. Data remains with the users, but the platform can ask for gradients with respect to a particular loss function, or data statistics.
- iii) A non-private option, where the platform can collect any relevant data from a user device.

If users choose option (i), the platform does not stand to gain from using that data in other tasks. If the user chooses (ii), the platform is better off, but still has limited access to the data via FL and may not be able to fully leverage its potential. Therefore, the platform wants to incentivize users to choose option (iii).

This may be done by providing services, discounts or money to users that choose this option. Effectively, by choosing an option, users are informally selling (or not selling) their data to platforms.

Due to the lack of a formal exchange, it can be difficult to understand if this sale of user data is *fair*. Are platforms making the cost of choosing private options like (i) or (ii) too high? Is the value of data much higher than the platform is paying? The development of an economic theory for the value of data is still nascent (Ghorbani & Zou, 2019; Jia et al., 2019; Acemoglu et al., 2019), and the dynamics of formal data markets are largely not understood. As the sale of data and data-based products becomes a larger part of the global economy, understanding these transactions will become critical for regulators and other stakeholders.

A major shortcoming of the current understanding of data value is that in many cases, it fails to explicitly consider a critical factor in an individual’s decision to share data—privacy. This work puts forth two rigorous notions of the fair value of data in Section 3 that explicitly include privacy and make use of the axiomatic framework of the *Shapley value* from game theory (Shapley, 1952).

Compelled by the importance of data in our modern economy and a growing social concern about privacy, this paper presents frameworks for quantifying the fair value of private data. Specifically, we consider a setting where users are willing to provide their data to a platform in exchange for some sort of payment and under some privacy guarantees depending on their level of privacy requirements. The platform is responsible for running the private learning algorithm on the gathered data and making the fair payments with the objective of maximizing its utility including statistical accuracy and total amount of payments. Our goal is to understand fair mechanisms for this procedure as depicted in Fig. 1.

1.1 Related Work

With widespread use of the internet and data-driven methods, interactions involving those that have data and those that seek to acquire it have become an important area of theoretical study (Balazinska et al., 2011), but also a practical necessity (Spiekermann et al., 2015b). Among these interactions, the economics of data from privacy conscious users has received significant attention in Acquisti et al. (2016), Wieringa et al. (2021). Federated Learning (Kairouz et al., 2021) has become a popular option for providing privacy in data-driven problems. In this work, we consider an example of fairly allocating payments in a Federated Learning setting. Differential Privacy (DP) (Dwork, 2008) and its variations, (Bun & Steinke, 2016) are also widely studied as a formal framework for privacy, used in conjunction with FL or independently. Ghosh & Roth (2015) studies the purchase of private data, where privacy is quantified under DP. Ghosh & Roth (2015) assumes that each player has binary data and its own heterogeneous privacy sensitivity parameter that they report, potentially strategically. In Fallah et al. (2022), the authors consider an optimal data acquisition problem in the context of private mean estimation in two different heterogeneous DP settings.

Hu & Gong (2020) consider FL, where each play has a unique privacy sensitivity function parameterized by a scalar variable. Players report their sensitivity parameter, and the platform assigns each user a privacy level, paying them via a proportional scheme. For linear privacy sensitivity functions, an efficient way to compute the Nash equilibrium is derived. In Oh et al. (2020), a multi-stage data market is studied where data-brokers acquire data from users, competing to sell data to a platform that further sells services based on the data.

The economic and social implications of privacy and data markets are considered in Spiekermann et al. (2015a). In Acemoglu et al. (2019) the impact of data externalities is investigated. The leakage of data

leading to the suppression of its market value is considered. In Jia et al. (2019), Ghorbani & Zou (2019) and Ghorbani et al. (2020) a framework for determining the fair value of data is proposed. These works extend the foundational principles of the Shapley value (Shapley, 1952), which was originally proposed as a concept for utility division in coalitional games to the setting of data. Our work takes this idea further and explicitly includes privacy in the definition of the fair value of data.

Finally, we note that we consider the concept of fairness in data valuation, not algorithmic fairness, which relates to the systematic failure of machine learning systems to account for data imbalances.

1.2 Main Contributions

The main contribution of this work is the development of a rigorous notion of fairness in the context of user data acquisition with privacy. While the existing literature has investigated how a platform should design incentives for users to optimize its utility, the definitions of fairness that we propose in this work can offer another way to evaluate these mechanisms. We summarize the main contributions as follows:

- We present an axiomatic notion of fairness that is inclusive of the platforms and the users in Theorem 1. The utility to be awarded to each user and the platform is uniquely determined, providing a useful benchmark for comparison.
- In the realistic scenario that fairness is considered between users, Theorem 2 defines a notion of fairness based on axioms, but only places restriction only on relative amounts distributed to the players. This creates an opportunity for the platform to optimize utility under fairness constraints.
- Section 4 contains an example inspired by online platform advertisement to heterogeneous users. We use our framework to fairly allocate payments, noticing how those payments differ among different types of users, and how payments change as the degree of heterogeneity increases or decreases.
- Finally, Section 5 explores the platform mechanism design problem. In Theorem 3 we establish that there are three distinct regimes in which the platform’s optimal behavior differs depending on the common privacy sensitivity of the users. When privacy sensitivity is low, the platform will set incentives to ensure that it collects all the data with the lowest privacy options. When the privacy sensitivity is above a given threshold, the platform will provide no incentives to users. Between these two extremes, the platform will set the incentives so some fraction of the users choose the higher privacy option and some choose the lower privacy option.

2 PROBLEM SETTING

2.1 Privacy Levels and Utility Functions

Consider the setting depicted by Fig. 2. User $i \in [N]$, where $[N] = \{1, \dots, N\}$, selects a privacy level option $\epsilon_i \in \mathcal{E}$. They then transmit their data in accordance with their privacy level. In the example Fig. 2, $\epsilon_i = 0$ means the user will keep their data fully private, $\epsilon_i = 1$ is an intermediate privacy option where user data is obfuscated and only transmitted in part and finally if $\epsilon_i = 2$, the users send all their data to the platform. This mirrors notation in DP where $\epsilon_i = 0$ means the data cannot be used by the platform (full privacy), and $\epsilon_i = \infty$ means no privacy restrictions (DP will be defined shortly). If $\epsilon_i > \epsilon_j$, we say ϵ_i is a lower privacy level than ϵ_j . Though we mostly focus on a finite space of privacy levels, in general we restrict the space of privacy levels to be any non-negative (possibly infinite) value.

The platform applies an ϵ -private algorithm $A_\epsilon : \mathcal{X}^N \mapsto \mathcal{Y}$ to process the data, providing privacy level ϵ_i to data x_i . For example, if $\epsilon_i = 1$ indicates federated learning, then an ϵ private algorithm might first take all those users who chose $\epsilon_i = 2$, and train a model from scratch using their data. Then for those users with $\epsilon_i = 1$, the platform would update the model via FL.

The output of the algorithm $y = A_\epsilon(x)$ is used by the platform to derive utility U , which depends on the privacy level ϵ . For example, if the platform is estimating the mean of a population, the utility could depend on the mean square error of the private estimator.

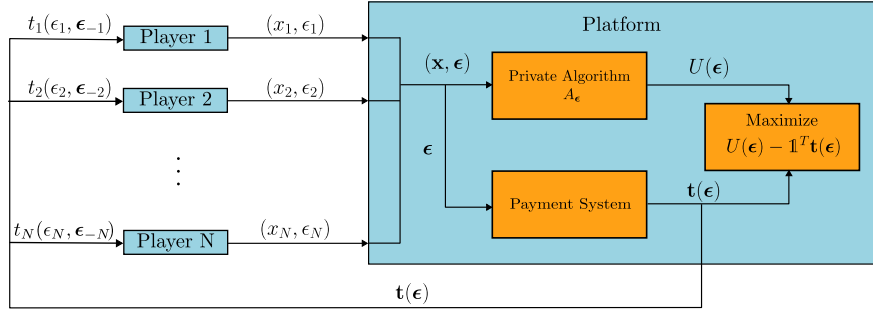

Figure 3: Players (users) send their data x_i and a privacy level ϵ_i to the central platform in exchange for payments $t_i(\epsilon_i; \epsilon_{-i})$. The central platform extracts utility from the data at a given privacy level and optimizes incentives to maximize the difference between the utility and the sum of payments $U(\epsilon) - \mathbf{1}^T \mathbf{t}(\epsilon)$.

This is a valid model if the platform is concerned about the statistical performance of the algorithm at the given privacy level, such as risk minimization in a learning problem.

Note that this formulation differs from typical formulations in the literature of optimal data acquisition, where some *privacy sensitivity* is instead reported by users, and the platform then chooses the privacy level ϵ_i based on this sensitivity. This typical formulation allows for the relatively straightforward application of notions such as incentive compatibility and individual rationality from mechanism design theory. In this work, however, we wish to emphasize the fact that the utility U depends on the privacy levels ϵ directly, so considering actions in the space of privacy levels \mathcal{E} is natural. Furthermore, in reality, users do choose a privacy level, rather than report the somewhat nebulously defined privacy sensitivity. Despite this difference, the notions of fairness described in the following section can be applied more broadly. One way to define privacy level consistent with this notion is pure ϵ -DP, defined below.

Definition 1. A random function $A : \mathcal{X}^N \rightarrow \mathcal{Y}$ is ϵ_i -DP, $\epsilon_i \geq 0$ in coordinate i if for any $\mathbf{x}' \in \mathcal{X}^N$ that differs from $\mathbf{x} \in \mathcal{X}^N$ only in coordinate i , for all measurable sets $S \in \mathcal{Y}$ we have:

$$\Pr(A(\mathbf{x}) \in S) \leq e^{\epsilon_i} \Pr(A(\mathbf{x}') \in S). \quad (1)$$

Definition 2. A random function $A : \mathcal{X}^N \rightarrow \mathcal{Y}$ is ϵ -DP if A is ϵ_i -DP in coordinate i for all $i \in [N]$.

2.2 The Data Acquisition Problem

The platform generates a transferable and divisible utility $U(\epsilon)$ from the user data. In exchange, the platform distributes a portion of the utility $t_i(\epsilon_i; \epsilon_{-i})$ to user i , where ϵ_{-i} denotes the vector of privacy levels ϵ with the i th coordinate deleted. These incentives motivates users to lower their privacy level, but each user will also have some sensitivity to their data being shared, modelled by a sensitivity function $c_i : \mathcal{E} \rightarrow [0, \infty)$, $c_i(0) = 0$. The behavior of users can be modelled with the help of a utility function:

$$u_i(\epsilon) = t_i(\epsilon_i, \epsilon_{-i}) - c_i(\epsilon_i). \quad (2)$$

The payment to user i will tend to increase with a lower privacy level, as the platform can better exploit the data, but their sensitivity c_i will increase with ϵ_i , creating a trade-off. By specifying a set of $t_i(\epsilon_i; \epsilon_{-i})$, the

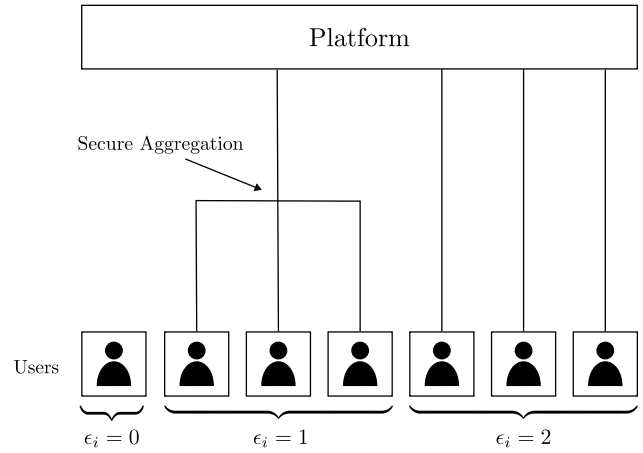

Figure 2: Users have a choice between three levels of privacy. If $\epsilon_i = 0$, users send no data to the platform. If $\epsilon_i = 1$, a user's model is securely combined with other users who also choose $\epsilon_i = 1$, and the platform receives only the combined model. If $\epsilon_i = 2$, users send their model directly to the platform.

platform effectively creates a game among the users. This situation is depicted in Fig. 3. Each user’s action is the level of privacy that they request for the data they share. Users (players) select their privacy level ϵ_i by considering their utility function u_i and the potential actions of the other players. From the perspective of the platform, the goal is to design the payments $t_i(\epsilon_i; \epsilon_{-i})$ such that it maximizes the difference between the utility it receives and the payments made to the players. One way to formulate this problem is to consider maximizing this difference at equilibrium points:

$$\begin{aligned} & \underset{\mathbf{t}(\cdot), \mathcal{P}}{\text{maximize}} && U(\mathcal{P}) - \mathbf{1}^T \mathbf{t}(\mathcal{P}) \\ & \text{subject to} && \mathcal{P} \in \text{NE}(\mathbf{t}). \end{aligned} \quad (3)$$

In equation 3, $\text{NE}(\mathbf{t})$ denotes the set of Nash Equilibrium strategies induced by the payment function \mathbf{t} , which is the vector with payment function t_i at index i . Recall that the Nash Equilibrium is a stable state of a system such that no user can gain by a unilateral change of strategy if the strategies of the other users remain unchanged. We allow these equilibrium points to be mixed strategies over the privacy space, such that \mathcal{P} represents a distribution over the privacy space \mathcal{E} . In addition, we have used the shorthand $f(\mathcal{P}) = \mathbb{E}_{\epsilon \sim \mathcal{P}} [f(\epsilon)]$. Note that in order to solve equation 3, the platform requires knowledge of the privacy sensitivity c_i of each user. This can be a reasonable assumption when the platform has interacted with the users many times in the past and has learned c_i . One could also formulate the problem where the privacy sensitivity c_i must be learned in an online fashion, but we avoid this complication here by our aforementioned assumption.

Restrictions must be placed on \mathbf{t} , otherwise it can be made arbitrarily negative. *Individual rationality* is a common condition in mechanism design that says that a user can be made no worse off by participation. Finally, we note that the compensation $t_i(\epsilon_i; \epsilon_{-i})$ may not be a direct monetary transfer. Individuals are often compensated for data through discounts or access to services. A shortcoming of our model is that we assume a divisible and transferable utility, which may fail to capture these nuances of compensation.

3 Axiomatic Fairness with Privacy

Somewhat in contrast to the resource allocation view just described, we can view users and platforms as a coalition that comes together and pool their resources to generate utility. A natural question to ask is: How should the utility be divided fairly among members of this coalition? The answer to this question turns out to be connected to the celebrated Shapley value (Shapley, 1952). Shapley value is one of the most important normative utility division schemes for coalitional games. Following an axiomatic approach to fairness, the Shapley value describes how to fairly divide utility among a coalition. In this section we develop an axiomatic Shapley value-based approach to fairness for users providing private data to platforms.

3.1 Platform as a Coalition Member

We define a coalition of users and a platform as a collection of s users, with $0 \leq s \leq N$ and up to 1 platform. Let $a \in \{0, 1\}$ represent the action of the platform. Let $a = 1$ when the platform chooses to join the coalition, and $a = 0$ otherwise. Let $U(\epsilon)$ be as defined in Section 2. We augment the utility to take into account that the utility is zero if the platform does not participate, and define ϵ_S as follows:

$$U(a, \epsilon) := \begin{cases} U(\epsilon) & a = 1 \\ 0 & a = 0 \end{cases}, \quad [\epsilon_S]_i := \begin{cases} \epsilon_i & i \in S \\ 0 & \text{else} \end{cases}. \quad (4)$$

Let $\phi_p(a, \epsilon)$ and $\phi_i(a, \epsilon)$, $i \in [N]$ represent the “fair” amount of utility awarded to the platform and each user i respectively, given a and ϵ , otherwise described as the “value” of a user. Note that these values depend implicitly on both the private algorithm A_ϵ and the utility function U , but for brevity, we avoid writing this dependence explicitly. The result of Hart & Mas-Colell (1989) show that these values are unique and well defined if they satisfy the following three axioms:

A.i) (**Fairness**) For any $i, j \in [N] : U(a, \epsilon_{S \cup \{i\}}) = U(a, \epsilon_{S \cup \{j\}}) \ \forall S \subset [N] \setminus \{i, j\} \implies \phi_i(a, \epsilon) = \phi_j(a, \epsilon)$.

In addition, for any user $i \in [N]$, $U(1, \epsilon_{S \cup \{i\}}) - U(1, \epsilon_S) = 0 \ \forall S \subset [N] \setminus \{i\} \implies \phi_i(a, \epsilon) = 0$.

A.ii) (**Efficiency**) The sum of values is the total utility $U(a, \epsilon) = \phi_p(a, \epsilon) + \sum_i \phi_i(a, \epsilon)$.

A.iii) (**Additivity**) Let $\phi_p(a, \epsilon)$ and $\phi_i(a, \epsilon)$ be the value of the platform and users respectively for the utility function U , under the ϵ -private A_ϵ . Let V be a separate utility function, also based on the output of A_ϵ , and let $\phi'_p(a, \epsilon)$ and $\phi'_i(a, \epsilon)$ be the utility of the platform and individuals with respect to V . Then under the utility $U + V$, the value of user i is $\phi_i(a, \epsilon) + \phi'_i(a, \epsilon)$ and the value of the platform is $\phi_p(a, \epsilon) + \phi'_p(a, \epsilon)$.

Theorem 1. Let $\phi_p(a, \epsilon)$ and $\phi_i(a, \epsilon)$ satisfying axioms (A.i-iii) represent the portion of total utility awarded to the platform and each user i from utility $U(a, \epsilon)$. Then they are unique and take the form:

$$\phi_p(a, \epsilon) = \frac{1}{N+1} \sum_{S \subseteq [N]} \frac{1}{\binom{N}{|S|}} U(a, \epsilon_S), \quad (5)$$

$$\phi_i(a, \epsilon) = \frac{1}{N+1} \sum_{S \subseteq [N] \setminus \{i\}} \frac{1}{\binom{N}{|S|+1}} (U(a, \epsilon_{S \cup \{i\}}) - U(a, \epsilon_S)). \quad (6)$$

Theorem 1 is proved in Appendix A.2. We now consider a simple setting where we can apply this result.

Example 1. Let X_i represent the independent and identically distributed data of user i respectively, with $\Pr(X_i = 1/2) = p$ and $\Pr(X_i = -1/2) = 1 - p$, with $p \sim \text{Unif}(0, 1)$. The goal of the platform is to construct an ϵ -DP estimator for $\mu := \mathbb{E}[X_i] = p - 1/2$ that minimizes the Bayes risk. A general procedure for finding the Bayes optimal ϵ -DP estimator does not exist. We restrict our attention to ϵ -DP linear-Laplace estimators of the form:

$$A(\mathbf{X}) = \mathbf{w}(\epsilon)^T \mathbf{X} + Z, \quad (7)$$

where $Z \sim \text{Laplace}(1/\eta(\epsilon))$. In Fallah et al. (2022) the authors argue that unbiased linear estimators are nearly optimal in a minimax sense for bounded random variables. We assume a squared error loss $L(a, \mu) = (a - \mu)^2$ and let $\mathcal{A}(\epsilon)$ be the set of ϵ -DP estimators satisfying equation 7. Then, we define:

$$A_\epsilon = \arg \min_{A \in \mathcal{A}(\epsilon)} \mathbb{E}[L(A(\mathbf{X}), \mu)] \quad (8)$$

$$r(\epsilon) = \mathbb{E}[L(A_\epsilon(\mathbf{X}), \mu)]. \quad (9)$$

In words, A_ϵ is an ϵ -DP estimator of the form equation 7, where $\mathbf{w}(\epsilon)$ and $\eta(\epsilon)$ are chosen to minimize the Bayes risk of the estimator, and $r(\epsilon)$ is the risk achieved by A_ϵ . Since the platform's goal is to accurately estimate the mean of the data, it is natural for the utility $U(\epsilon)$ to depend on ϵ through the risk function $r(\epsilon)$. Note that if U is monotone decreasing in $r(\epsilon)$, then U is monotone increasing in ϵ .

Let us now consider the case of $N = 2$ users, choosing from an action space of $\mathcal{E} = \{0, \epsilon'\}$, for some $\epsilon' > 0$. Furthermore, take U to be an affine function of $r(\epsilon)$: $U(\epsilon) = c_1 r(\epsilon) + c_2$. For concreteness, take $U(\mathbf{0}) = 0$ and $\sup_{\epsilon \in \mathbb{R}} U(\epsilon) = 1$. Note that this ensures that U is monotone increasing in ϵ , and is uniquely defined (exact calculations are available in Appendix A.1). Consider the example of a binary privacy space $\mathcal{E} = \{0, \infty\}$. By equation 36, the utility can be written in matrix form as:

$$\mathbf{U} = \begin{bmatrix} 0 & 2/3 \\ 2/3 & 1 \end{bmatrix}. \quad (10)$$

Note from equation 5 and equation 6, it is clear that $\phi_p(0, \epsilon) = \phi_i(0, \epsilon) = 0$. Let Φ_p and $\Phi_i^{(1)}$ represent the functions $\phi_p(1, \epsilon)$ and $\phi_i(1, \epsilon)$ in matrix form akin to \mathbf{U} . Then using equation 5 and equation 6, we find that the fair allocations of the utility are given by:

$$\Phi_p = \begin{bmatrix} 0 & 1/3 \\ 1/3 & 5/9 \end{bmatrix}, \quad \Phi_1^{(1)} = \begin{bmatrix} 0 & 1/3 \\ 0 & 2/9 \end{bmatrix}, \quad \Phi_2^{(1)} = \begin{bmatrix} 0 & 0 \\ 1/3 & 2/9 \end{bmatrix}. \quad (11)$$

3.2 Fairness Among Users

Though we can view the interactions between the platform and the users as a coalition, due to the asymmetry that exists between the platform and the users, it also makes sense to discuss fairness among the users alone. In this case, we can consider an analogous set of axioms that involve only the users.

B.i) **(Fairness)** For any $i, j \in [N] : U(\epsilon_{S \cup \{i\}}) = U(\epsilon_{S \cup \{j\}}) \quad \forall S \subset [N] \setminus \{i, j\} \implies \phi_i(\epsilon) = \phi_j(\epsilon)$.

In addition, for any user $i \in [N]$, $U(\epsilon_{S \cup \{i\}}) - U(\epsilon_S) = 0 \quad \forall S \subset [N] \setminus \{i\} \implies \phi_i(\epsilon) = 0$.

B.ii) **(Pseudo-Efficiency)** The sum of values is the total utility $\alpha(\epsilon)U(\epsilon) = \sum_i \phi_i(\epsilon)$. Where if $U(\epsilon) = U(\tilde{\epsilon})$ then $\alpha(\epsilon) = \alpha(\tilde{\epsilon})$ and $0 \leq \alpha(\epsilon) \leq 1$.

B.iii) **(Additivity)** Let $\phi_i(\epsilon)$ be the value of users for the utility function U , under the ϵ -private algorithm A_ϵ . Let V be a separate utility function, also based on the output of the algorithm A_ϵ , and let $\phi'_i(\epsilon)$ be the utility of the users with respect to V . Then under the utility $U + V$, the value of user i is $\phi_i(\epsilon) + \phi'_i(\epsilon)$.

The most notable difference between these axioms and (A.i-iii) is that the efficiency condition is replaced with a pseudo-efficiency condition. Under this condition, the platform may determine the sum of payments awarded to the players, but this sum should in general depend only on the utility itself, and not on how that utility is achieved.

Theorem 2. Let $\phi_i(\epsilon)$ satisfying axioms (B.i-iii) represent the portion of total utility awarded to each user i from utility $U(\epsilon)$. Then for $\alpha(\epsilon)$ satisfies axiom (B.ii) ϕ_i takes the form:

$$\phi_i(\epsilon) = \frac{\alpha(\epsilon)}{N} \sum_{S \subseteq [N] \setminus \{i\}} \frac{1}{\binom{N-1}{|S|}} (U(\epsilon_{S \cup \{i\}}) - U(\epsilon_S)). \quad (12)$$

The proof of Theorem 2 can be found in Appendix A.2.

Example 2. Consider the utility function defined in equation 10, for the $N = 2$ user mean estimation problem with $\mathcal{E} = \{0, \infty\}$. By Theorem 2 the fair allocation satisfying (B.i-iii) must be of the form:

$$\Phi_1^{(2)} = \mathbf{A} \odot \begin{bmatrix} 0 & 2/3 \\ 0 & 1/2 \end{bmatrix}, \quad \Phi_2^{(2)} = \mathbf{A} \odot \begin{bmatrix} 0 & 0 \\ 2/3 & 1/2 \end{bmatrix}, \quad \mathbf{A} = \mathbf{A}^T, \quad 0 \leq [\mathbf{A}]_{ij} \leq 1. \quad (13)$$

4 Fair Incentives In Federated Learning

FL is a distributed learning process used when data is either too large or too sensitive to be directly transferred in full to the platform. Instead of combining all the data together and learning at the platform, each user performs some part of the learning locally and the results are aggregated at the platform, providing some level of privacy. Recently, Donahue & Kleinberg (2021) consider a setting where heterogeneous users voluntarily opt-in to federation. A natural question to ask is: how much less valuable to the platform is a user that chooses to federate with others as compared to one that provides full access to their data? This section provides some interesting insights towards answering this question.

Let each user $i \in [N]$ have a unique mean and variance $(\theta_i, \sigma_i^2) \sim \Theta$, where Θ is some global joint distribution. To motivate this example, let θ_i represent some information about the user critical for advertising. We wish to learn θ_i as accurately as possible to maximize our profits, by serving the best advertisements possible to each user. User i draws n_i samples i.i.d. from its local distribution $\mathcal{D}_i(\theta_i, \sigma_i^2)$, that is, some distribution with mean θ_i and variance σ_i^2 . Let $s^2 = \text{Var}(\theta_i)$ and $t^2 = \mathbb{E}[\sigma_i^2]$. When $s^2 \gg \frac{t^2}{n_i}$ the data is very heterogeneous, and it is generally not helpful to include much information from the other users when estimating θ_i , however, if $s^2 \ll \frac{t^2}{n_i}$, the situation is reversed, and information from the other users will be very useful.

The goal of the platform is to construct estimators $\hat{\theta}_i^p$ that minimize the expected mean squared-error of each estimate, while respecting the privacy vector ϵ :

$$\text{EMSE}_i(\epsilon) := \mathbb{E} \left[\left(\hat{\theta}_i^p(\epsilon) - \theta_i \right)^2 \right]. \quad (14)$$

Fig. 2 summarizes our FL formulation. Users can choose from a 3-level privacy space $\mathcal{E} = \{0, 1, 2\}$. In this case the privacy space is not related to DP, but instead encodes how users choose to share their data with the platform. Let N_j be the number of users that choose privacy level j . When $\epsilon_i = 2$, user i provides its

Figure 4: Each user $i \in [N]$ has mean and variance $(\theta_i, \sigma_i^2) \sim \Theta$, where Θ is a global joint distribution. Let $t^2 = \text{Var}(\theta_i)$ and $s^2 = \mathbb{E}[\sigma_i^2]$. In this case s^2 is large relative to t^2 , and the data is very heterogeneous.

local estimator $\hat{\theta}_i$ directly to the platform. When $\epsilon_i = 1$, user i 's local estimator is securely aggregated with all other users that choose this same privacy:

$$\hat{\theta}^f = \frac{1}{N_1} \sum_{i:\epsilon_i=1} \hat{\theta}_i, \quad (15)$$

and the platform receives access to $\hat{\theta}^f$, rather than the local estimators. As before, $\epsilon_i = 0$ means user i chooses not to provide any information to the platform. Note that the error in estimating θ_i depends not just on the privacy level of the i th user ϵ_i , but on the entire privacy vector. Let the users be ordered such that ϵ_i is a non-increasing sequence. Then for each i the platform constructs estimators of the form:

$$\hat{\theta}_i^p = w_{i0} \hat{\theta}^f + \sum_{j=1}^{N_2} w_{ij} \hat{\theta}_j, \quad (16)$$

where, $\sum_j w_{ij} = 1$ for all i . In Proposition 5, we calculate the optimal choice of w_{ij} which depends on ϵ . From these estimators, the platform generates utility $U(\epsilon)$. The optimal w_{i0} and w_{ij} in equation 16 are well defined in a Bayesian sense if $\epsilon_i > 0$ for some i , but this does not make sense when $\epsilon = \mathbf{0}$. We can get around this by defining $\text{EMSE}_i(\mathbf{0}) := t^2 + 2s^2$. For the purposes of our discussion, we assume the following logarithmic utility function:

$$U(\epsilon) := \sum_{i=1}^n a_i \log \left(\frac{(t^2 + 2s^2)}{\text{EMSE}_i(\epsilon)} \right). \quad (17)$$

a_i represents the relative importance of each user. Since some users may be willing to spend more than others, the platform may care more about computing their θ_i more accurately, adding another layer of heterogeneity.

4.1 Fair Payments Under Optional Federation: Numerical Study

In this section, we focus on our definition of fairness in Theorem 2. Let there be $N = 10$ users. $N_1 = 5$ of these users opt for federating ($\epsilon_i = 1$), $N_2 = 4$ directly provide their data to the platform ($\epsilon_i = 2$), and finally, $N_0 = 1$ users chooses to not participate ($\epsilon_i = 0$). Without loss of generality, we assume $\alpha(\epsilon) = 1$, and the results of this section can be scaled accordingly.

4.1.1 Different Amounts of Data

Fig 5a plots the difference from an equal distribution of utility, i.e., how much each user's utility differs from $U(\epsilon)/N$. We assume $a_i = 1$ for all users. In the bars furthest to the left, where $s^2 = 100$ and $t^2 = 1$, we are in a very heterogeneous environment. Intuitively, this means that a user j will have data that may not be helpful for estimating θ_i for $j \neq i$, thus those users that choose $\epsilon_i = 2$ are paid the most, since at the very least, the information they provide can be used to target their own θ_i . Likewise, users that federate obfuscate where their data is coming from, making their data less valuable (since their own θ_i cannot be targeted), and thus we see that users with $\epsilon_i = 1$ are paid less than that they would receive in an even allocation. On the right side, we have a regime where $s^2 = 0.1$ and $t^2 = 100$, meaning users are similar and user data more exchangeable. Those users with larger n_i are paid above the average utility per user, while those with less are paid below.

We also see that users with $\epsilon_i = 2$ still receive more than those with $\epsilon_i = 1$ when n_i is fixed, and this difference is significant when $n_i = 100$. In the center we have an intermediate regime of heterogeneity, where $s^2 = 1$ and $t^2 = 10$. Differences in payments appear less pronounced, somewhat interpolating between the two extremes.

4.1.2 More Valuable Users

Fig 5b is similar to Fig 5a, except now in each set of graphs, exactly one user has $a_i = 100$, meaning that estimating θ_i for user i is 100 times more important than the others. Looking at the two leftmost sets of bars in Fig 5b we see that when user i with $\epsilon_i = 2$ and $n_i = 100$ is the most important one, when s^2 is large compared to t^2 , it is user i who receives most of the benefit in terms of its payment but when s^2 is smaller, other users also benefit. This can be intuitively explained as follows: if users are very heterogeneous, other users $j \neq i$ do not have data that is helpful for determining θ_i , thus they do not benefit when user i has a larger a_i . Likewise, when s^2 is small compared to t^2 not just user i benefits, but also all those users that contribute more data, as those users with $\epsilon_i = 1$ and $n_i = 100$ are also paid over the average utility per user. Another key point is the similarity between the second and fourth set of graphs. This tells an interesting story: when users are not very heterogeneous, regardless of which user is has $a_i = 100$, it is those users with large n_i that will benefit.

Figure 5: (a) Plot of difference from the average utility per user $U(\epsilon)/N$ for each of the four different types of users, for three different regimes of s^2 and t^2 , with heterogeneity decreasing from left to right. In left (most heterogeneous) plot users who choose $\epsilon_i = 2$ are more valuable compared to those that choose $\epsilon_i = 1$. In the center there is an intermediate regime, where all users are paid closer to the average, with users with more data being favoured slightly. In the rightmost graph, with little heterogeneity users with more data are paid more, and privacy level has a lesser impact on the payments.

(b) In each case there is one user i with $a_i = 100$ (indicated with a star), while all other users $j \neq i$ have $a_j = 1$ (a_i represents the relative importance of the user in the utility function). In the two leftmost set of bars, we see that the user with $\epsilon_i = 2$ and $n_i = 100$ receives by far the most payment, when heterogeneity is high, but this becomes less dramatic as heterogeneity decreases. This shows that when users are very heterogeneous, if a_i is large for only user i , most of the benefit in terms of additional payments should go to user i . Likewise, comparing the second from the left and the rightmost plots we see little difference, showing that the opposite is true in the homogeneous case: any user can benefit from any other user having a large a_i .

5 Mechanism Design: The Platform's Actions

We have constructed a concrete definition of fairness and applied it to a problem with significant heterogeneity among users. In particular, we have constructed a recipe for constraining the platform to a class of fair payments in Theorem 2. The platform still has the ability to choose the fraction of utility that it keeps α , but the incentives it provides to users must be distributed in a fair way. This type of constraint can be viewed as a form of regulation on a platform. A natural question to ask is: What will the platform do when subject to this fairness constraint? This section addresses this problem by investigating the incentives of a platform designing a mechanism under the constraint of fairness.

Consider $N \geq 2$ users each with identical statistical marginal contribution, i.e., for any i, j we have $S \subseteq [N] \setminus \{i, j\}$, $U(\epsilon_{S \cup \{i\}}) = U(\epsilon_{S \cup \{j\}})$. The platform is restricted to making fair payments satisfying axioms (B.i-iii) with the additional constraint that $\alpha(\epsilon) = \alpha \in [0, 1]$. Users choose one of two available privacy levels $\epsilon_i \in \mathcal{E}^N$, with $\mathcal{E} = \{\epsilon'_1, \epsilon'_2\}$ and $\epsilon'_2 > \epsilon'_1$. We can write the utility of the user i as

$$u(\epsilon_i, \epsilon_{-i}) = \alpha \phi(\epsilon_i; \epsilon_{-i}) - c \mathbb{1}\{\epsilon_i = \epsilon'_2\}. \quad (18)$$

The user gains utility from the incentive provided by the platform, but incurs a cost of c if they choose the less private option. For now, we assume this c is the same for all users; later we discuss the case where c is different. Note that we can drop the index of ϕ_i due to the assumption of equal marginal contribution. To enrich the problem, we allow users to employ a mixed strategy denoted by $\mathbf{p} = [p, (1-p)]^T$, where users choose the ϵ'_1 with probability p and ϵ'_2 with probability $1-p$. This is justified because we expect users to repeatedly interact with platforms and sample from their mixed strategy and ultimately converge to their expected utility.

The platform is also trying to maximize the fraction of the total expected utility $U(\mathbf{p}) := \mathbb{E}_{\epsilon \sim \mathbf{p}} [U(\epsilon)]$ that it keeps. The platform's goal is to choose a payment value α such that it optimizes:

$$\begin{aligned} & \underset{\alpha}{\text{maximize}} \quad (1 - \alpha)U(\mathbf{p}^*(\alpha)) \\ & \text{subject to} \quad \mathbf{p}^*(\alpha) \in \text{NE}(\alpha). \end{aligned} \quad (19)$$

The constraint in equation 19, that the behavior of the agents must be a Nash equilibrium, implicitly encodes the user behavior governed by equation 18, and will change with the privacy sensitivity c . Theorem 3 characterizes the solution of equation 19 for different values of c . In addition, to make equation 19 amenable to insightful analysis, we must make some mild assumptions.

Assumption 1. *The utility U is monotone: $\epsilon_S^{(2)} \geq \epsilon_S^{(1)} \implies U(\epsilon_S^{(2)}) > U(\epsilon_S^{(1)}) \quad \forall S \subseteq [N]$.*

Assumption 2. *The utility U has diminishing returns. Let $n_{\text{private}}(\epsilon_S)$ represent the number of elements of $i \in S$ such that $\epsilon_i = \epsilon'_1$, i.e., the number of users choosing the higher privacy option. Furthermore, define $\Delta_i U(\epsilon_S) := U(\epsilon_S^{(i+)}) - U(\epsilon_S)$, where $\epsilon_S^{(i+)}$ is equal to ϵ_S except $\epsilon_i^{(i+)} = \epsilon'_2$. In other words, $\Delta_i U(\epsilon_S)$ is the marginal increase in utility when the i th user switches to the lower privacy option. Then U satisfies:*

$$n_{\text{private}}(\epsilon_S^{(1)}) \geq n_{\text{private}}(\epsilon_S^{(2)}) \implies \Delta_i U(\epsilon^{(1)}) > \Delta_i U(\epsilon^{(2)}). \quad (20)$$

It is helpful to define the *expected relative payoff*, where the expectation is taken with respect to the actions of the other players. When all other users choose a mixed strategy \mathbf{p} , the expected relative payoff is defined as:

$$\gamma(p) := \phi(\epsilon'_2; p) - \phi(\epsilon'_1; p) = \mathbb{E}_{\epsilon_{j \neq i} \sim \mathbf{p}} [\phi(\epsilon'_2; \epsilon_{-i}) - \phi(\epsilon'_1; \epsilon_{-i})]. \quad (21)$$

This quantity represents the expected gain in incentive (normalized to make it invariant to α) if a user switches to a less private level from the more private level given everyone else plays the mixed strategy \mathbf{p} .

Theorem 3. *Consider a binary privacy level game with N users and a platform. If U satisfies Assumptions 1 and 2, and the platform payments are fair as defined in Theorem 2 with constant α then the optimal α^* can be divided into three regimes depending on c . The boundaries of these regions are $\gamma_{\max} := \max_p \gamma(p)$ and some $c_{th} < \gamma_{\max}$ such that:*

1. When $c > \gamma_{\max}$, $\alpha^* = 0$ is the maximizer of 19.
2. When $c_{th} < c < \gamma_{\max}$ then α^* is the smallest $\alpha \in [0, 1]$ such that $p^*(\alpha) \in \gamma^{-1}(c/\alpha)$.
3. When $c < c_{th}$: α^* is the smallest $\alpha \in [0, 1]$ such that $p(\alpha) = 0$, where

$$c_{th} = \max \left\{ c \left| \frac{1 - c/\gamma_{\min}}{1 - \alpha} - \frac{U(p^*(\alpha))}{U(0)} \geq 0 \quad \forall \alpha < c/\gamma_{\min} \right. \right\}. \quad (22)$$

Theorem 3 can be interpreted as follows. If privacy sensitivity is above γ_{\max} for the given task, it is not worth the effort of the platform to participate. On the other hand, if privacy sensitivity is less than c_{th} , the platform should set α to be as small as possible, while still ensuring that all users choose the low privacy setting. Finally, if privacy sensitivities lie somewhere in between, α^* should be chosen based on the γ function, and generally will lead to a mixed strategy with some proportion of users choosing each of the two options.

A Note on Monotonicity of Utility When beginning this work, the dearth of algorithms that supported heterogeneous privacy constraints surprised us, given the increasing number of privacy options available to users. All of the algorithms that did exist were provably sub-optimal Hu & Gong (2020), or placed constraints on privacy parameters to prove approximate optimality Fallah et al. (2022). In both of these works, the pathology of the algorithm leads to error that is not monotonically decreasing in ϵ . For DP-based notions of privacy, which both of the aforementioned works are, one can prove that an optimal error must be monotonic. This observation inspired a recent work that studies a *saturation* phenomenon Chaudhuri & Courtade (2023). The idea is that an optimal algorithm will sometimes give users that choose a large ϵ_i more privacy than they asked for, to ensure that it still efficiently uses information from users j with $\epsilon_j \ll \epsilon_i$.

5.1 Mechanism Design in the Mean Estimation Example

In this section, we look at the problem we discussed in Example 1 and 2 with the fair payments that we calculated in Section 2, and examine how it behaves under mechanism design. Figure 6 depicts the solution to equation 19. As predicted by Theorem 3, we find that the solution is clearly divided into three regions. Equation 22 tells us that $c_{th} = \frac{1}{3}$ and $\gamma_{max} = \frac{2}{3}$, matching our observations in Fig. 6. In the first region when $c \leq \frac{1}{3}$ the platform is able to capture most of the utility for itself, paying less of it out to the users. We also see that throughout this regime, the total utility is maximized, as predicted by the theory. For $c \in [\frac{1}{3}, \frac{2}{3}]$, the total utility begins to decrease, as users no longer have enough incentive to always choose the less private option. Finally, for $c \geq \frac{2}{3}$, the platform no longer attempts to incentivize the users, and the total utility falls to zero.

Figure 6: Utility awarded to users and platform when platform solves equation 19. The solution is separated into three regions as Predicted by Theorem 3.

5.2 Considering Different Privacy Sensitivities

We now discuss the case where users no longer have the same privacy sensitivity parameter c . This problem differs from equation 19 only in that the equilibrium is governed by different user utility functions, making the problem asymmetric. For example, if user 1 and user 2 have privacy sensitivity c_1 and c_2 respectively, we have

$$u_1(\mathbf{p}_1, \mathbf{p}_2) = \mathbf{p}_1^T \Phi_1^{(2)} \mathbf{p}_2 - [0 \ c_1]^T \mathbf{p}_1, \quad (23)$$

$$u_2(\mathbf{p}_1, \mathbf{p}_2) = \mathbf{p}_1^T \Phi_2^{(2)} \mathbf{p}_2 - [0 \ c_2]^T \mathbf{p}_2. \quad (24)$$

Consider a setting where there are only two users (these can be thought of as representing two *groups* of users) with utility function u_1 and u_2 listed above. Thus, when the platform is trying to optimize its own utility, it must take into consideration that these two groups will play different strategies.

$$\begin{aligned} & \underset{\alpha}{\text{maximize}} && \mathbf{p}_1^T \mathbf{U} \mathbf{p}_2 - (1 - \alpha) \mathbf{p}_1^T \mathbf{U} \mathbf{p}_2 \\ & \text{subject to} && (\mathbf{p}_1, \mathbf{p}_2) \in \text{NE}(\alpha). \end{aligned} \quad (25)$$

Fig. 7 plots the results of simulating the solution of 25. It shows that there is one region when c_1 and c_2 are both small and close together ($< 1/3$), the platform chooses α to collect data from both users. If the difference is large, even in this region, the users may be asymmetrically engaged. When $c_1 > c_2 > 1/3$, the platform chooses α such that only user 2 chooses to participate, even if the difference is very small, and vice versa if $c_2 > c_1 > 1/3$, as before, when $c_1, c_2 > 2/3$ the sensitivity is too high and the platform can no longer offer enough payment to the users.

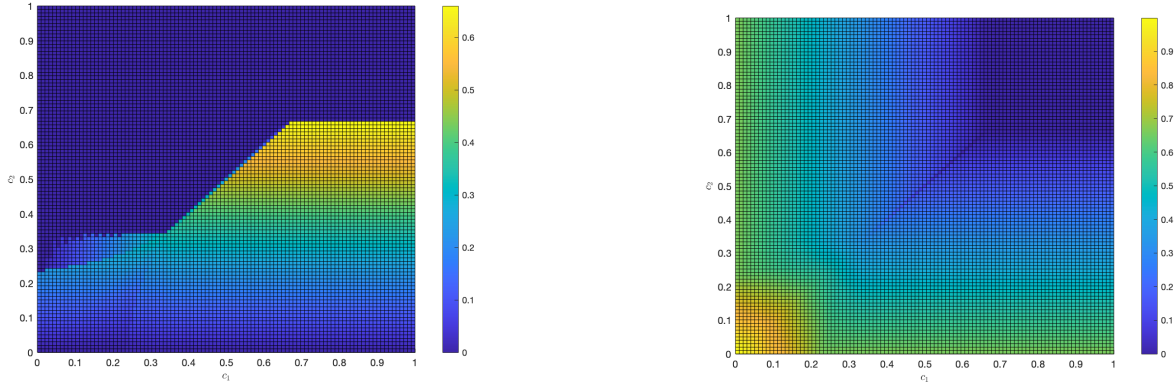

Figure 7: (Left) The payments to User 2 from the platform for a range of c_1, c_2 . (Right) The platform’s share of utility for the optimal α^* payments for a range of values c_1, c_2 .

Broader Impact Statement

One of the unique defining characteristics of data is that its generation process is inherently distributed, so no single entity exists to advocate for data sellers. In the past, platforms have been able to extract data from users, often with little to no compensation in return. As public consciousness around privacy changes, a nuanced relationship around privacy between platforms and users must develop. Transparency and understanding the value of user data is an important step in empowering regulators, consumers and platforms.

- Users making strategic decisions about when they share their data stand to gain from incentives.
- For regulators, understanding the amount of value that flows through the interactions between platforms can enable better policies around data. Frameworks similar to those discussed in Theorem 1 and 2 can be a starting point in understanding exactly how much this value is.
- For platforms, understanding which data tasks are economically viable, and how they allocate incentive is important. Our discussion in Section 5, and our three regimes help shed light on this.

6 Conclusion

This paper introduces two formal definitions of fair payments in the context of acquisition of private data. The first treats the users and the platform together and uses axioms like those of the Shapley value to determine a unique fair distribution of utility. In the second, we define a notion of fairness between the users only, leading to a definition of fairness that admits a range of values, of which the platform is free to choose the most favorable. By formulating a federated mean estimation problem, we show that heterogeneous users can have significantly different contributions to the overall utility, and that a fair incentive, according to our second notion, must take into account the amount of data, privacy level as well as the degree of heterogeneity.

While previous literature has investigated how platforms should design incentives for users in order to optimize its utility, the definitions of fairness we propose offers another important way to evaluate the fairness of these mechanisms. This is a critical step towards future research in ensuring that data acquisition mechanisms are *both* fair for users and efficient for platforms.

Though we provide a characterization of optimal fair mechanisms when privacy sensitivity is the same across users, designing mechanisms that consider fairness with heterogeneous privacy sensitivities, with an arbitrary number of users N is an important question that remains, since in practice the platform interacts with large and diverse groups of users. Furthermore, there is subjectivity in the choice of axioms, and other choices may lead to meaningful notions of fairness worthy of study. We have also assumed a non-divisible and transferable utility, but in many cases, users are paid for their data in the form of access to services. Investigating the impact of this will also be important for the practical application of a comprehensive theory for fairness.

A Missing Proofs

A.1 Proof of Equation 36

In this section, we present the calculations required to arrive at the utility values in equation 36. First let's treat the trivial case of $\epsilon_1 = 0$, $\epsilon_2 = 0$. The optimal ϵ -DP estimator is simply the optimal Bayes estimator with no data, i.e., the prior mean. Let us define this estimator as $\hat{\mu}_{(0,0)} = 0$. Its risk function is

$$R(\mu, \hat{\mu}_{(0,0)}) = \mathbb{E} [L(\hat{\mu}_{(0,0)}, \mu) | \mu] = \mu^2. \quad (26)$$

The Bayes risk of $\hat{\mu}_{(0,0)}$ is the expectation of this quantity taken using our prior:

$$r([0, 0]) = \mathbb{E} [\mu^2] = \frac{1}{12}. \quad (27)$$

Next, consider the case where user i chooses privacy level $\epsilon_1 = \epsilon' > 0$, and the other user chooses $\epsilon_2 = 0$. In this case the estimator depends on X_1 , $\hat{\mu}_{(\epsilon', 0)} = w_1 X_1 + Z$. Then the risk function is:

$$R(\mu, \hat{\mu}_{(\epsilon', 0)}) = \mathbb{E} [(w_1 X_1 + Z - \mu)^2 | \mu] = \left(\mu + \frac{1}{2}\right) \left(\mu - \frac{w_1}{2}\right)^2 + \left(-\mu + \frac{1}{2}\right) \left(\mu + \frac{w_1}{2}\right)^2 + \frac{2}{\eta^2}. \quad (28)$$

Now taking the expectation with respect to our prior over μ , we have:

$$\mathbb{E} [R(\mu, \hat{\mu}_{(\epsilon', 0)})] = \frac{1}{12} (3w_1^2 - 2w_1 + 1) + \frac{2}{\eta^2}, \quad (29)$$

here η is the inverse scale parameter for Z . Note that equation 29 is minimized when η is maximized. The ϵ -DP condition enforces the constraint $\eta \leq \frac{\epsilon'}{w_1}$. This constraint will be met with equality for the optimal w_1 . The optimal $w_1^* = \frac{1}{3 + \frac{24}{\epsilon'^2}}$. Thus, we have:

$$\hat{\mu}_{(\epsilon', 0)} = \frac{1}{3 + \frac{24}{\epsilon'^2}} X_1 + Z, \quad Z \sim \text{Laplace} \left(\frac{\epsilon'}{3\epsilon'^2 + 24} \right), \quad (30)$$

and the resulting Bayes risk is:

$$r([\epsilon', 0]) = r([0, \epsilon']) = \frac{1}{12} \left(1 - \frac{1}{3 + \frac{24}{\epsilon'^2}} \right). \quad (31)$$

For the case with $\epsilon_1 = \epsilon_2 = \epsilon'$ we can repeat the same process by defining $\hat{\mu}_{(\epsilon', \epsilon')} = w_1 X_1 + w_2 X_2 + Z$. By symmetry, we must have $w_1 = w_2$, so we drop the index. Then the risk function and its expectation are:

$$R(\mu, \hat{\mu}_{(\epsilon', \epsilon')}) = 2 \left(\mu + \frac{1}{2} \right) \left(-\mu + \frac{1}{2} \right) \mu^2 + \left(\mu + \frac{1}{2} \right)^2 (w - \mu)^2 + \left(-\mu + \frac{1}{2} \right)^2 (\mu + w)^2 + \frac{2}{\eta} \quad (32)$$

$$\mathbb{E} [R(\mu, \hat{\mu}_{(\epsilon', \epsilon')})] = \frac{1}{12} (8w^2 - 4w + 1) + \frac{2}{\eta^2}. \quad (33)$$

By a similar argument to the previous case, the Bayes optimal estimator and the corresponding Bayes risk is:

$$\hat{\mu}_{(\epsilon', \epsilon')} = \frac{1}{4 + \frac{12}{\epsilon'^2}} (X_1 + X_2) + Z, \quad Z \sim \text{Laplace} \left(\frac{\epsilon'}{4\epsilon'^2 + 12} \right), \quad (34)$$

$$r([\epsilon', \epsilon']) = \frac{1}{12} \left(1 - \frac{1}{2 + \frac{6}{\epsilon'^2}} \right). \quad (35)$$

Finally letting $U(\epsilon) = c_1 r(\epsilon) + c_2$. Take $U(0) = 0 \implies c_1 = -12c_2$. And $\max_{\epsilon} U(\epsilon) = 1 \implies c_1 = 24(1 - c_2)$. Simplifying gives us our desired result:

$$\mathbf{U} = \begin{bmatrix} U([0, 0]^T) & U([0, \epsilon']^T) \\ U([\epsilon', 0]^T) & U([\epsilon', \epsilon']^T) \end{bmatrix} = \begin{bmatrix} 0 & 2 \left(3 + \frac{24}{(\epsilon')^2} \right)^{-1} \\ 2 \left(3 + \frac{24}{(\epsilon')^2} \right)^{-1} & \left(1 + \frac{3}{(\epsilon')^2} \right)^{-1} \end{bmatrix} \quad (36)$$

□

A.2 Proof of Theorem 1 and Theorem 2

We will begin with the proof of Theorem 2, which is standard and follows the typical proof of the Shapley value. We begin by proving $\phi_i(\epsilon)$ as defined in equation 12 satisfies axioms (B.i-iii). First assume $U(\epsilon_{S \cup \{i\}}) = U(\epsilon_{S \cup \{j\}}) \forall S \subset [N] \setminus \{i, j\}$, then:

$$\phi_i(\epsilon) = \frac{\alpha(\epsilon)}{N} \sum_{S \subseteq [N] \setminus \{i\}} \frac{U(\epsilon_{S \cup \{i\}}) - U(\epsilon_S)}{\binom{N-1}{|S|}} \quad (37)$$

$$= \frac{\alpha(\epsilon)}{N} \left(\sum_{S \subseteq [N] \setminus \{i, j\}} \frac{U(\epsilon_{S \cup \{i\}}) - U(\epsilon_S)}{\binom{N-1}{|S|}} + \sum_{S \subseteq [N] \setminus \{i, j\}} \frac{(U(\epsilon_{S \cup \{j\} \cup \{i\}}) - U(\epsilon_{S \cup \{j\}}))}{\binom{N-1}{|S|+1}} \right) \quad (38)$$

$$= \frac{\alpha(\epsilon)}{N} \left(\sum_{S \subseteq [N] \setminus \{i, j\}} \frac{U(\epsilon_{S \cup \{j\}}) - U(\epsilon_S)}{\binom{N-1}{|S|}} + \sum_{S \subseteq [N] \setminus \{i, j\}} \frac{(U(\epsilon_{S \cup \{i\} \cup \{j\}}) - U(\epsilon_{S \cup \{i\}}))}{\binom{N-1}{|S|+1}} \right) \quad (39)$$

$$= \phi_j(\epsilon), \quad (40)$$

proving axiom (B.i) is satisfied. For the proof that axiom (B.ii) is satisfied, we write:

$$\sum_i \phi_i(\epsilon) = \frac{\alpha(\epsilon)}{N} \sum_i \sum_{S \subseteq [N] \setminus \{i\}} \frac{U(\epsilon_{S \cup \{i\}}) - U(\epsilon_S)}{\binom{N-1}{|S|}} \quad (41)$$

$$= \frac{\alpha(\epsilon)}{N} \left(\sum_i \sum_{S \subseteq [N] \setminus \{i\}} \frac{U(\epsilon_{S \cup \{i\}})}{\binom{N-1}{|S|}} - \sum_i \sum_{S \subseteq [N] \setminus \{i\}} \frac{U(\epsilon_S)}{\binom{N-1}{|S|}} \right) \quad (42)$$

$$= \alpha(\epsilon)U(\epsilon) + \frac{\alpha(\epsilon)}{N} \left(\sum_i \sum_{\substack{S \subseteq [N] \setminus \{i\} \\ |S| < N-1}} \frac{U(\epsilon_{S \cup \{i\}})}{\binom{N-1}{|S|}} - \sum_i \sum_{S \subseteq [N] \setminus \{i\}} \frac{U(\epsilon_S)}{\binom{N-1}{|S|}} \right) \quad (43)$$

$$= \alpha(\epsilon)U(\epsilon) + \frac{\alpha(\epsilon)}{N} \left(\sum_i \sum_{\substack{S \subseteq [N] \\ i \in S \\ |S| < N-1}} \frac{U(\epsilon_S)}{\binom{N-1}{|S|-1}} - \sum_{\substack{S \subseteq [N] \\ |S| \leq N-1}} \frac{(N - |S|)U(\epsilon_S)}{\binom{N-1}{|S|}} \right) \quad (44)$$

$$= \alpha(\epsilon)U(\epsilon) + \frac{\alpha(\epsilon)}{N} \left(\sum_{\substack{S \subseteq [N] \\ |S| \leq N-1}} \frac{|S|U(\epsilon_S)}{\binom{N-1}{|S|-1}} - \sum_{\substack{S \subseteq [N] \\ |S| \leq N-1}} \frac{(N - |S|)U(\epsilon_S)}{\binom{N-1}{|S|}} \right) \quad (45)$$

$$= \alpha(\epsilon)U(\epsilon), \quad (46)$$

thus proving axiom (B.ii) is satisfied. Finally, we note that (B.iii) is satisfied by linearity. Next, we establish the uniqueness of equation 12. To prove uniqueness, we take an approach that is standard in the literature where we define the unanimity game, show the uniqueness of the $\phi_i(\epsilon)$ in that case, and then argue that uniqueness follows from additivity (B.iii).

Define the unanimity utility, indexed by some $T \subseteq [N]$:

$$U_T(\epsilon) = \begin{cases} 1 & \text{if } T \subseteq \text{supp}(\epsilon) \\ 0 & \text{if } \text{else.} \end{cases} \quad (47)$$

$\{U_T\}_{T \subseteq [N]}$ form a linear basis for utility function such that any utility U can be represented uniquely by a set of values $\{b_T\}_{T \subseteq [N]}$. In addition, by direct application of the axioms, it is easy to see that for the

unanimity utility, the fair allocation $\phi_i^{(T)}(\epsilon)$ is unique and is of the form:

$$\phi_i^{(T)}(\epsilon) = \begin{cases} \frac{\alpha(\epsilon)}{T} & \text{if } i \in T \\ 0 & \text{if } else. \end{cases} \quad (48)$$

Thus, for any utility U , the fair value is represented uniquely by $\sum_{T \subseteq [N]} b_T \phi_i^{(T)}(\epsilon)$, since this value is unique, it must be equivalent to equation 12.

Now we consider the proof of Theorem 1. By a similar argument to the above, we can establish that:

$$\phi_p(a, \epsilon) = \frac{1}{N+1} \sum_{S \subseteq [N]} \frac{U(a, \epsilon_S) - U(0, \epsilon_S)}{\binom{N}{|S|}} \quad (49)$$

as well as:

$$\phi_i(a, \epsilon) = \frac{1}{N+1} \sum_{\substack{S \subseteq [N] \setminus \{i\} \\ a' \in \{0, a\}}} \frac{1}{\binom{N}{|S|+1}} (U(a', \epsilon_{S \cup \{i\}}) - U(a', \epsilon_S)) \quad (50)$$

$$(51)$$

Applying the definition $U(0, \epsilon) = 0$ we have

$$\phi_p(a, \epsilon) = \frac{1}{N+1} \sum_{S \subseteq [N]} \frac{U(a, \epsilon_S)}{\binom{N}{|S|}} \quad (52)$$

$$\phi_i(a, \epsilon) = \frac{1}{N+1} \sum_{S \subseteq [N] \setminus \{i\}} \frac{1}{\binom{N}{|S|+1}} (U(a, \epsilon_{S \cup \{i\}}) - U(a, \epsilon_S)), \quad (53)$$

completing the proof.

A.3 Error Computation for Section 4

In this section we prove Proposition 4 and 5 from which exact error expressions follow.

Proposition 4. *For the federated mean estimation problem described in Section 4, the expected mean-squared error is given by:*

$$\mathbb{E} \left[\left(\hat{\theta}_i^p - \theta_i \right)^2 \right] = t^2 \left(\sum_{j=1}^{N_2} w_{ij}^2 \cdot \frac{1}{n_j} + \frac{1}{N_1} w_{i0}^2 \frac{1}{\bar{n}} \right) + s^2 \left(\sum_{\substack{j=1 \\ j \neq i}}^{N_2} w_{ij}^2 + \frac{1}{N_1^2} \sum_{\substack{j=N_2+1 \\ j \neq i}}^{N_2+N_1} w_{i0}^2 + \left(\sum_{\substack{j=1 \\ j \neq i}}^{N_2} w_{ij} + \frac{1}{N_1} \sum_{\substack{j=N_2+1 \\ j \neq i}}^{N_2+N_1} w_{i0} \right)^2 \right), \quad (54)$$

$$\text{where } \bar{n} = \left(\frac{1}{N_1} \sum_{j=N_2+1}^{N_1+N_2} \frac{1}{n_j} \right)^{-1}.$$

Proof. Consider an estimator of the form $\hat{\theta}_i^p = \sum_{j=1}^N v_{ij} \hat{\theta}_j$, where user j has n samples, and θ_j is the local model of user j . By Theorem 4.2 of Donahue & Kleinberg (2021), the error can be written as:

$$\mathbb{E} \left[\left(\hat{\theta}_i^p - \theta_i \right)^2 \right] = t^2 \sum_{j=1}^N v_{ij}^2 \cdot \frac{1}{n_j} + s^2 \left(\sum_{j \neq i} v_{ij}^2 + \left(\sum_{j \neq i} v_{ij} \right)^2 \right) \quad (55)$$

For $j = 1, \dots, N_2$, we have $v_{ij} = w_{ij}$. For $j = N_2 + 1, \dots, N_2 + N_1$, we have $v_{ij} = \frac{w_{i0}}{N_1}$. Finally, for $j > N_1 + N_2$, we have $v_{ij} = 0$. Thus the first term can be written as:

$$t^2 \sum_{j=1}^N v_{ij}^2 \cdot \frac{1}{n_j} = t^2 \left(\sum_{j=1}^{N_2} w_{ij}^2 \frac{1}{n_j} + \sum_{j=N_2+1}^{N_2+N_1} \frac{1}{n_j} \left(\frac{w_{i0}}{N_1} \right)^2 \right) \quad (56)$$

$$= t^2 \left(\sum_{j=1}^{N_2} w_{ij}^2 \frac{1}{n_j} + \frac{1}{N_1} w_{i0}^2 \frac{1}{\bar{n}} \right). \quad (57)$$

Making these same substitutions to $\sum_{j \neq i} v_{ij}^2$ and $\sum_{j \neq i} v_{ij}$ yields the desired result. \square

Proposition 5. *The error expression equation 54 is minimized if $\epsilon_i = 0$ with weights:*

$$w_{i0} = \frac{N_1}{N_1 + N_2 \frac{V_0}{V}}, \quad w_{ij} = \frac{V_0/V_j}{N_1 + N_2 \frac{V_0}{V}}. \quad (58)$$

If $\epsilon_i = 1$ equation 54 is minimized by:

$$w_{i0} = \frac{N_1}{N_1 + N_2 \frac{V_0}{V}} + \frac{N_2}{N_1 + N_2 \frac{V_0}{V}} \frac{s^2}{\bar{V}}, \quad (59)$$

$$w_{ij} = \frac{V_0/V_j}{N_1 + N_2 \frac{V_0}{V}} - \frac{1}{N_1 + N_2 \frac{V_0}{V}} \frac{s^2}{V_j}. \quad (60)$$

Finally, if $\epsilon_i = 2$, equation 54 is minimized by:

$$w_{i0} = \frac{N_1}{N_1 + N_2 \frac{V_0}{V}} - \frac{N_1}{N_1 + N_2 \frac{V_0}{V}} \frac{s^2}{V_i}, \quad (61)$$

$$w_{ij} = \frac{V_0/V_j}{N_1 + N_2 \frac{V_0}{V}} - \frac{V_0/V_j}{N_1 + N_2 \frac{V_0}{V}} \frac{s^2}{V_i} \quad (62)$$

$$w_{ii} = \frac{V_0/V_i}{N_1 + N_2 \frac{V_0}{V}} + \frac{N_1 + N_2 \frac{V_0}{V} - \frac{V_0}{V_i}}{N_1 + N_2 \frac{V_0}{V}} \frac{s^2}{V_i} \quad (63)$$

Proof. First we will consider the case where $\epsilon_i = 1$. Considering the point where the derivative of equation 54 with respect to w_{ik} , $k \geq 1$ is equal to zero gives:

$$\frac{2t^2}{n_k} w_{ik} - \frac{2t^2}{\bar{n}N_1} \left(1 - \sum_{j=1}^{N_2} w_{ij} \right) + s^2 \left(2w_{ik} - 2 \frac{N_1 - 1}{N_1^2} \left(1 - \sum_{j=1}^{N_2} w_{ij} \right) + \frac{2}{N_1^2} \left(N_1 - 1 + \sum_{j=1}^{N_2} w_{ij} \right) \right) = 0, \quad (64)$$

$$\left(\frac{t^2}{n_k} + s^2 \right) w_{ik} = \left(\frac{t^2}{\bar{n}} + s^2 \right) \frac{w_{i0}}{N_1} - \frac{s^2}{N_1}. \quad (65)$$

It is easily verified from the second derivative that solving this equation gives us the unique minimum of equation 54. For ease of notation, define $V_k := \left(\frac{t^2}{n_k} + s^2 \right)$ and $V_0 := \left(\frac{t^2}{\bar{n}} + s^2 \right)$, $\bar{V} = \left(\frac{1}{N_2} \sum_{k=1}^{N_2} \frac{1}{V_k} \right)^{-1}$. Thus, we have:

$$w_{ik} = \frac{V_0 \frac{w_{i0}}{N_1} - \frac{s^2}{N_1}}{V_k}. \quad (66)$$

Noting that $w_{i0} + \sum_{j=1}^{N_2} w_{ij} = 1$, we have:

$$w_{i0} + \frac{N_2}{N_1} \frac{V_0}{\bar{V}} w_{i0} - \frac{N_2}{N_1} \frac{s^2}{\bar{V}} = 1, \quad (67)$$

$$w_{i0} = \frac{N_1}{N_1 + N_2 \frac{V_0}{\bar{V}}} + \frac{N_2}{N_1 + N_2 \frac{V_0}{\bar{V}}} \frac{s^2}{\bar{V}}, \quad (68)$$

$$w_{ij} = \frac{V_0/V_j}{N_1 + N_2 \frac{V_0}{\bar{V}}} - \frac{1}{N_1 + N_2 \frac{V_0}{\bar{V}}} \frac{s^2}{V_j}. \quad (69)$$

This completes the proof for those users i such that $\epsilon_i = 1$. When $\epsilon_i = 2$, the gradient condition with respect to $k \geq 1$, $k \neq i$ is:

$$w_{ik} V_k = \frac{V_0}{N_1} w_{i0}, \quad (70)$$

and similarly, the gradient condition when $k = i$ is:

$$w_{ii} V_i + w_{i0} \frac{N_2 V_0}{N_1 \bar{V}} + \frac{s^2}{V_i} = 1. \quad (71)$$

Combining these together gives our desired result. $\epsilon_i = 0$ □

A.4 Proof of Theorem 3

The symmetric Nash equilibria of our game is characterized Cheng et al. (2004) by the minimizers of

$$\min_p \sum_{s \in \mathcal{E}} [u(s, p) - u(p, p)]_+^2, \quad (72)$$

where $u(s, p)$ is the utility a user when they choose privacy level $\epsilon_i = s$, and all other users play mixed strategy \mathbf{p} , and $u(p, p) = \mathbb{E}_{s \sim \mathbf{p}} [u(s, p)]$. Since our action space is binary, there are only two terms in this sum. Applying the definition of u and writing out both terms of this sum yields:

$$\sum_{s \in \mathcal{E}} [u(s, p) - u(p, p)]_+^2 = [u(\epsilon_1, p) - u(p, p)]_+^2 + [u(\epsilon_2, p) - u(p, p)]_+^2 \quad (73)$$

$$= [c(1-p) - \alpha(\phi(p, p) - \phi(\epsilon_1, p))]_+^2 + [c(1-p) - \alpha(\phi(p, p) - \phi(\epsilon_2, p))]_+^2 \quad (74)$$

$$= [(1-p)(c - \alpha\gamma(p))]_+^2 + [-p(c - \alpha\gamma(p))]_+^2, \quad (75)$$

where we define $\gamma(p) := \phi(\epsilon_2, p) - \phi(\epsilon_1, p)$. γ is an important quantity in this problem that described the relative increase in payment a user receives for choosing a higher privacy level when the other users choose mixed strategy \mathbf{p} . In general, to say something about the equilibria, we must say something about γ . We can now use Assumptions 1 and 2, as well as the definition of $\phi(\cdot; \cdot)$ to establish properties of γ . First we show $\gamma(p) \geq 0$ using monotonicity of U :

$$\gamma(p) = \phi(\epsilon_2, p) - \phi(\epsilon_1, p), \quad (76)$$

$$\begin{aligned} &= \mathbb{E}_{\substack{\epsilon_j \sim \mathbf{p} \\ \epsilon_i = \epsilon_2}} \left[\frac{1}{N} \sum_{S \subseteq [N] \setminus \{i\}} \frac{1}{\binom{N-1}{|S|}} (U(\epsilon_{S \cup \{i\}}) - U(\epsilon_S)) \right] \\ &\quad - \mathbb{E}_{\substack{\epsilon_j \sim \mathbf{p} \\ \epsilon_i = \epsilon_1}} \left[\frac{1}{N} \sum_{S \subseteq [N] \setminus \{i\}} \frac{1}{\binom{N-1}{|S|}} (U(\epsilon_{S \cup \{i\}}) - U(\epsilon_S)) \right], \end{aligned} \quad (77)$$

$$= \frac{1}{N} \sum_{S \subseteq [N] \setminus \{i\}} \frac{1}{\binom{N-1}{|S|}} \mathbb{E}_{\substack{\epsilon_j \sim \mathbf{p} \\ j \neq i}} \left[U(\epsilon_{S \cup \{i\}}^{(i+)}) - U(\epsilon_{S \cup \{i\}}^{(i-)}) \right] \geq 0. \quad (78)$$

In equation 77 we have used the definition of the fair value from Theorem 2, and in equation 78, we have simplified the expression, exchanged the sum and expectation, and used the fact that the expectation of a non-negative random variable is non-negative.

Next, we will show that under Assumption 2 (and our assumption of equal marginal contribution) we also have $\gamma'(p) \geq 0$. Assume $p_2 > p_1$, and let $b(n, p) = \binom{N}{n} p^n (1-p)^{N-n}$:

$$\gamma(p_2) - \gamma(p_1) = \frac{1}{N} \sum_{S \subseteq [N] \setminus \{i\}} \frac{1}{\binom{N-1}{|S|}} \left(\mathbb{E}_{\epsilon_j \sim \mathbf{p}_2} \left[U(\epsilon_{S \cup \{i\}}^{(i+)}) - U(\epsilon_{S \cup \{i\}}^{(i-)}) \right] - \mathbb{E}_{\epsilon_j \sim \mathbf{p}_1} \left[U(\epsilon_{S \cup \{i\}}^{(i+)}) - U(\epsilon_{S \cup \{i\}}^{(i-)}) \right] \right) \quad (79)$$

$$= \frac{1}{N} \sum_{S \subseteq [N] \setminus \{i\}} \frac{1}{\binom{N-1}{|S|}} \sum_{n=0}^N (b(n, p_2) - b(n, p_1)) \Delta_i U(\epsilon(n)) \quad \text{s.t. } n_{\text{private}}(\epsilon(n)) = N - n \quad (80)$$

Now note that $b(n, p_2) - b(n, p_1)$ is zero-mean, and decreasing, furthermore, $\Delta_i U(\epsilon(n))$ is non-negative and non-increasing. Let n^* represent the smallest value of n such that $b(n, p_2) - b(n, p_1)$ is negative. Then we have:

$$\Delta_i U(\epsilon(n)) = \sum_{n=0}^{n^*-1} (b(n, p_2) - b(n, p_1)) \Delta_i U(\epsilon(n)) + \sum_{n=n^*}^N (b(n, p_2) - b(n, p_1)) \Delta_i U(\epsilon(n)) \quad (81)$$

$$\geq \left(\sum_{n=0}^{n^*-1} b(n, p_2) - b(n, p_1) \right) (\Delta_i U(\epsilon(n^* - 1)) - \Delta_i U(\epsilon(n^*))) \quad (82)$$

$$\geq 0. \quad (83)$$

With the knowledge that $\gamma(p) \geq 0$ and $\gamma'(p) \geq 0$ we can compute p^* for three distinct cases. Defining $\gamma_{\max} := \max_p \gamma(p)$ and $\gamma_{\min} := \min_p \gamma(p)$, we have:

Case 1 $c - \alpha\gamma_{\max} > 0$:

$$\sum_{s \in \mathcal{E}} [u(s, p) - u(p, p)]_+^2 = [(1-p)(c - \alpha\gamma(p))]_+^2 \quad (84)$$

Since this quantity is non-negative, it is clearly minimized when $p^* = 1$, where it is exactly 0. Furthermore, since $c - \alpha\gamma_{\max} > 0$ is satisfied with strict inequality, it is the unique minimizer.

Case 2 $c/\alpha \in [\gamma_{\min}, \gamma_{\max}]$:

$$\sum_{s \in \mathcal{E}} [u(s, p) - u(p, p)]_+^2 = [(1-p)(c - \alpha\gamma(p))]_+^2 + [-p(c - \alpha\gamma(p))]_+^2, \quad (85)$$

In the above case, this is minimized when $p^* \in \gamma^{-1}(c/\alpha)$.

Case 3 $c - \alpha\gamma_{\min} < 0$:

$$\sum_{s \in \mathcal{E}} [u(s, p) - u(p, p)]_+^2 = [-p(c - \alpha\gamma(p))]_+^2, \quad (86)$$

In the above case, the expression is minimized when $p^* = 0$. To summarize, we have:

$$p^*(\alpha) = \begin{cases} 1 & \text{if } \alpha < \frac{c}{\gamma_{\max}} \\ \gamma^{-1}(c/\alpha) & \text{if } \alpha \in \left[\frac{c}{\gamma_{\max}}, \frac{c}{\gamma_{\min}} \right] \\ 0 & \text{if } \alpha > \frac{c}{\gamma_{\min}} \end{cases} \quad (87)$$

This establishes that the Nash equilibrium is cleanly separated into three regions. From this fact, we are able to show that the optimal strategy of the platform is also separated into three regions. We consider a platform that solves the following problem, where we define $U(p) := \mathbb{E}_{\epsilon_i \sim \mathbf{p}} [U(\epsilon)]$:

$$\min_{\alpha} (1 - \alpha) U(p^*(\alpha)), \quad (88)$$

Clearly, when privacy sensitivity is large, specifically, when $c \geq \gamma_{\max}$ then $\alpha^* = 0$ is the optimal solution, since $p^*(\alpha) = 1$ for all $\alpha < 1$, and for $\alpha > 1$ the objective becomes negative.

Alternatively, when c is very small, we can determine the optimal value as follows. We first note that Assumption 1 implies that $U(p)$ is a decreasing function of p . Thus the condition for $\alpha^* = \frac{c}{\gamma_{min}}$ is:

$$\frac{1 - c/\gamma_{min}}{1 - \alpha} > \frac{U(p^*(\alpha))}{U(0)} \quad \forall \alpha < c/\gamma_{min}. \quad (89)$$

Since the left-hand side takes value $\frac{1}{1-\alpha}$ at $c = 0$, while the right-hand side is 1, as well as the fact that both sides are continuous, by the Intermediate Value Theorem, (and our previous, which implies that for c large enough this condition does not hold), there is some minimum c_{th} , where this condition fails. Thus we conclude, there are three regions:

(1) a region where $c \leq c_{th}$ is small, and α^* is the smallest α such that $p^* = 0$, (2) an intermediate region where a symmetric mixed strategy is played, and (3) a region where $c \geq \gamma_{max}$, and $\alpha^* = 0, p^* = 1$.
