Which Data Attributes Stimulate Math and Code Reasoning? An Investigation via Influence Functions

Anonymous Authors¹

Abstract

012 Large language models (LLMs) have demonstrated remarkable reasoning capabilities in math and coding, often bolstered by post-training on the chain-of-thoughts (CoTs) generated by stronger 015 models. However, existing strategies for curating such training data predominantly rely on heuris-018 tics, limiting generalizability and failing to capture subtleties underlying in data. To address 019 020 these limitations, we leverage influence functions to systematically attribute LLMs' reasoning ability on math and coding to individual training examples, sequences, and tokens, enabling deeper insights into effective data characteristics. Our Influence-based Reasoning Attribution (Infra) 025 uncovers nontrivial cross-domain effects across math and coding tasks: high-difficulty math examples improve both math and code reasoning, while 028 029 low-difficulty code tasks most effectively benefit code reasoning. Based on these findings, we in-030 troduce a simple yet effective dataset reweighting strategy by flipping task difficulty, which doubles AIME24 accuracy from 10% to 20% and boosts 034 LiveCodeBench accuracy from 33.8% to 35.3% for Qwen2.5-7B-Instruct. Moreover, our fine-035 grained attribution reveals that the sequence-level exploratory behaviors enhance reasoning performance in both math and code, and the token-level 039 influence patterns are distinct for math and code reasoning: the former prefers natural language 041 logic connectors and the latter emphasizes structural syntax. 043

Large language models (LLMs) for reasoning, with OpenAIo1 (Jaech et al., 2024) and DeepSeek-R1 (Guo et al., 2025) as popular examples, have shown great promise in solving complex math and coding problems. Recently, the community has witnessed the prevalence of reproducing such reasoning capacities on open-source small- to mediumsized LLMs (Lambert et al., 2024; Gao et al., 2024; Qin et al., 2024). An initial stage of the solutions often involves post-training the model on some chain-of-thought (CoT) reasoning traces curated by leading models (e.g., R1) for diverse problems (Wen et al., 2025; Min et al., 2024; Muennighoff et al., 2025; Ye et al., 2025; Huang et al., 2024; NovaSky, 2024). As a data-centric paradigm, the core research question here is: which attributes of the training data are effective in stimulating reasoning capabilities?

Pioneering studies addressing this question predominantly adopt heuristic approaches. Typically, they first establish quantitative data quality metrics based on human expertise or empirical preferences, then selectively retain high-quality data for model training to cultivate robust reasoning capabilities with minimal data inputs. For example, s1K (Muennighoff et al., 2025) filters 1k (question, answer) pairs with well-structured formatting, longer CoT length, and broader domain from an initial pool of 59k data for training math reasoning LLMs. Similarly, LIMO (Ye et al., 2025) suggests incorporating more challenging questions with complex reasoning chains enables better math reasoning.

Beyond focusing exclusively on math, Sky-T1 (NovaSky, 2024) targets competitive reasoning performance across both math and coding tasks. It notices that the naive incorporation of code data from APPS (Hendrycks et al., a) degrades math performance and advocates mitigating this by introducing more difficult math questions and code tasks for training. Nevertheless, the underlying mechanism of such cross-domain influence remains underexplored. Furthermore, these heuristic strategies suffer from unreliable generalization to other reasoning scenarios and cannot clearly explain how some fine-grained reasoning patterns in the training data (e.g., verification, backtracking, etc.) affect the learned models.

To bridge the gap, we leverage influence functions (Koh & Liang, 2017)-a classical technique for tracing the impacts of individual training data on model behavior-to systematically identify which training examples, along

Preliminary work. Under review by the International Conference on Machine Learning (ICML). Do not distribute.

with their internal patterns and tokens, most significantly enhance the reasoning capabilities on math and coding 057 tasks. Following previous works on influence functions 058 for LLMs (Grosse et al., 2023; Ruis et al., 2024), we define 059 an easy-to-implement and cost-effective influence function 060 for reasoning-oriented supervised fine-tuning (SFT). We 061 further extend the instance-wise influence function to more 062 fine-grained variants at the sequence and token levels for an 063 in-depth data attribution. We dub our approach as Infra.

064 We begin by investigating cross-domain influence in basic 065 math and code reasoning scenarios without long CoT. To 066 this end, we fine-tune LLaMA3-8B-Base (Grattafiori et al., 067 2024) on a mixture of MetaMathQA (Yu et al., 2023) and 068 OSS-Instruct (Wei et al., 2024) datasets and compute the 069 influence function on the accuracy of GSM8k (Cobbe et al., 070 2021) and MBPP (Hendrycks et al., a). We rank all training data by their influence scores and find that, while in-domain data yield the highest scores as expected, cross-domain data also contribute nontrivially. Furthermore, aggregating these 074 scores by category and difficulty reveals that symbolic math 075 examples and high-difficulty math problems are particularly 076 effective in improving code reasoning. 077

078 Extending Infra to complex long CoT reasoning, we fine-079 tune Qwen2.5-7B-Instruct (Yang et al., 2024) on Bespoke-Stratos-17k¹ dataset and measure influence using AIME, 081 MATH500 (Hendrycks et al., b), and LiveCodeBench (Jain 082 et al., 2021) benchmarks. Consistent with earlier findings, 083 we observe cross-domain gains, with harder math problems better helping code reasoning. Going a step further, we find that both high-difficulty math and code examples are more 086 influential on math reasoning, whereas low-difficulty code 087 tasks contribute most significantly to code reasoning (see 088 *Figure 1*). Motivated by these insights, we flip easy math 089 problems as hard and hard code tasks as easy in the training 090 data. This reweighted dataset doubles AIME accuracy and 091 improves LiveCodeBench accuracy from 33.8% to 35.3%.

092 Furthermore, we perform attribution at sequence and token 093 levels in long CoT. Sequence-level attribution shows that 094 the exploration behavior of seeking alternative approaches 095 after reaching correctness (refer to Figure 6), which is com-096 mon in long CoTs, improves both math and code reasoning 097 performance. Despite being seen as overthinking (Chen 098 et al., 2024; Sui et al., 2025), our studies suggest it is advan-099 tageous. Besides, we observe distinct token-level influence 100 patterns for math and code reasoning. In math, the most influential tokens are natural language with logical connectors, whereas code CoTs rely more on syntax markers. This divergence explains why easier code problems with clearer 104 structural solutions benefit code reasoning when combined 105 with math CoT that already provides logical skills. 106

2. Related Work

LLM reasoning. Reasoning is a cognitive process that involves using evidence, arguments, and logic to arrive at conclusions or make judgments. A very recent approach to achieve reasoning capacity in LLMs is through post-training, such as OpenAI-o1 (Jaech et al., 2024), and Deepseek-R1 (Guo et al., 2025), which expose the model to largescale curated reasoning examples after the initial pretraining phase to refine its inferential abilities (Kumar et al., 2025). These reasoning datasets predominantly fall into two categories: (1) Mathematical reasoning: In earlier work, the construction of high-quality mathematical datasets primarily relied on increasing the quantity of problems and enhancing their difficulty levels (Li et al., 2024; Yue et al., 2023). Nevertheless, LIMO dataset (Ye et al., 2025) demonstrated that complex reasoning capabilities can be elicited through surprisingly small datasets (hundreds of examples). In addition, some researchers also opted to distill high-quality reasoning data from strong LLMs (NovaSky, 2024), leveraging their outputs to construct more targeted and informative training sets for enhancing reasoning performance in weak LLMs. (2) Code generation: As a highly structured and formalized type of data, code has a non-negligible impact on the development of reasoning abilities in large language models. Beyond simply testing LLMs on newly coding test cases (Jain et al., 2021), many efforts have focused on investigating how and when code data influences the development of reasoning abilities in language models (Zhang et al., 2025; Li et al., 2025). In our work, we consider mathematical capacity and coding ability as two distinct manifestations of advanced reasoning, and we aim to analyze and understand the interactions between these capabilities to gain deeper insights into the underlying mechanisms of LLM reasoning.

Data attribution and influence functions. Training Data Attribution (TDA) methods seek to interpret a model's predictions by analyzing the particular training instances that contributed to shaping its learned representations. Most modern TDA methods can broadly be divided into two categories: retraining-based methods (Ling, 1984; Shapley et al., 1953; Ilyas et al., 2022) and gradient-based methods (Yeh et al., 2018; Pruthi et al., 2020; Koh & Liang, 2017). However, applying traditional data attribution methods to large language models has remained a significant challenge, primarily due to issues of computational tractability and the sheer scale of model parameters. Nonetheless, there are several works successfully apply data attribution on LLMs by influence function. Researchers in Anthropic adapt EK-FAC influence functions to large-scale Transformers, by which they figured out what kind of pretraining data influences completions of models up to 50B parameters (Grosse et al., 2023). More specifically, for reasoning capabilities, studies have shown that code data encountered during the pretraining-phase plays a critical role in the development of

Figure 1: An illustration of our key findings towards the question: *Which attributes of training data effectively stimulate reasoning capabilities?* Mixing challenging math problems with easier coding tasks leads to the highest influence scores for mathematical and coding reasoning (*left*). Guided by this insight, we curate an improved dataset and observe enhanced performance (*right*).

mathematical reasoning abilities in language models. (Ruis
et al., 2024). In this work, we extend similar methodological
approaches by employing influence functions to attribute
the development of reasoning capabilities during the supervised fine-tuning (SFT) phase, with a particular focus on
analyzing the interplay between code and math data.

This section reviews the basics of influence functions (Koh
& Liang, 2017; Grosse et al., 2023) and presents Infra, our
adaptation for attributing LLM reasoning performance on
math and code problems. In particular, we compute instancelevel influence scores using a mean log-likelihood proxy,
and further shift to sequence and token levels to uncover how
specific reasoning steps and tokens shape model behavior.

3.1. Preliminary: Influence Functions

Given a model parameterized by θ and trained on a dataset $\mathcal{D}_{\text{train}} = \{z_i\}_{i=1}^N$, influence functions (Koh & Liang, 2017) estimate the influence of a training point z_m on θ (or a function thereof) without retraining the model. Specifically, it is measured by computing the change in θ if z_m is upweighted by an infinitesimal amount ϵ . This perturbation can be formalized as the response function²:

$$\boldsymbol{\theta}(\epsilon) = \operatorname*{arg\,min}_{\boldsymbol{\theta} \in \mathbb{R}^{D}} \mathcal{J}\left(\boldsymbol{\theta}, \mathcal{D}_{\mathrm{train}}, \epsilon\right) \tag{1}$$

 $= \underset{\boldsymbol{\theta} \in \mathbb{R}^{D}}{\operatorname{arg\,min}} \frac{1}{N} \sum_{i=1}^{L} \mathcal{L}(z_{i}, \boldsymbol{\theta}) + \epsilon \mathcal{L}(z_{m}, \boldsymbol{\theta}), \quad ($

where $\mathcal{L}(\cdot)$ is the training loss. The influence of z_m on θ is then defined as the first-order Taylor approximation to the response function around $\epsilon = 0$ and can be computed using the implicit theorem:

$$\mathcal{I}_{\boldsymbol{\theta}}(z_m) = \left. \frac{d\boldsymbol{\theta}}{d\epsilon} \right|_{\epsilon=0} = -\mathbf{H}^{-1} \nabla_{\boldsymbol{\theta}} \mathcal{L}\left(z_m, \boldsymbol{\theta} \right), \qquad (3)$$

where $\mathbf{H} = \nabla_{\boldsymbol{\theta}}^2 \mathcal{J}(\boldsymbol{\theta}, \mathcal{D}_{\text{train}})$ is the Hessian of the cost function. Direct interpretation of $\mathcal{I}_{\boldsymbol{\theta}}(z_m)$ can be difficult due to its high dimensionality, so it is common to instead compute the influence of \boldsymbol{z}_m on a scalar-valued function of the parameters $f(\boldsymbol{\theta})$. Using the chain rule for derivatives, this influence admits the closed-form:

$$\mathcal{I}_{f}(z_{m}) = \left. \frac{df(\boldsymbol{\theta})}{d\epsilon} \right|_{\epsilon=0} = -\nabla_{\boldsymbol{\theta}} f\left(\boldsymbol{\theta}\right)^{T} \mathbf{H}^{-1} \nabla_{\boldsymbol{\theta}} \mathcal{L}\left(z_{m}, \boldsymbol{\theta}\right).$$
⁽⁴⁾

A complete derivation of Equation 4 is delayed to Appendix A. Consequently, $f(\theta)$ is expected to increase after upweighting the sample z_m and then retraining the model if $\mathcal{I}_f(z_m) > 0$, as

$$f(\boldsymbol{\theta}(\epsilon)) - f(\boldsymbol{\theta}) \approx \mathcal{I}_f(z_m) \epsilon = -\nabla_{\boldsymbol{\theta}} f(\boldsymbol{\theta})^T \mathbf{H}^{-1} \nabla_{\boldsymbol{\theta}} \mathcal{L}(z_m, \boldsymbol{\theta}) \epsilon$$
(5)

For transformer-based LLMs with billions of parameters, the above **H** is intractable. To address this, Grosse et al. (2023) propose to approximate **H** using the Eigenvalue-Corrected Kronecker-Factored Approximate Curvature (EK-FAC) method (George et al., 2018), which introduces simplifying assumptions such as layer-wise independence and restricts computation only to the MLP parameters within the model. Given the effectiveness of such a strategy, we also employ it to effectively estimate influence scores.

3.2. Attributing LLM Reasoning to Training Data via Influence Functions

We now introduce Infra, our adaptation of influence functions to attribute LLM reasoning on challenging math and code tasks. As mentioned, our setting is mainly an SFT

²For simplicity, we show the response function for optimal parameters. For non-converged or non-convex models, the actual response function is the Proximal Bregman response function (refer to (Grosse et al., 2023) for details).

165 process with CoTs generated by a stronger model to im-166 prove the reasoning abilities of the LLM at hand. We are 167 interested in identifying the most influential training data 168 to improve model performance. Since task accuracy is non-169 differentiable with respect to θ , we instead adopt a smooth 170 surrogate: the mean log-likelihood over a set of correctly 171 answered examples. Let $\mathcal{D}_{correct} = \{(\boldsymbol{x}_i, \boldsymbol{y}_i)\}_{i=1}^n$ denote a 172 collection of problems x_i paired with correct answers y_i , 173 we define the surrogate objective as:

174

177

198

209

210 211

216

217

218

219

$$f(\boldsymbol{\theta}) = \frac{1}{n} \sum_{i=1}^{n} \log p(\boldsymbol{y}_i | \boldsymbol{x}_i; \boldsymbol{\theta}), \tag{6}$$

where *n* is the size of $\mathcal{D}_{correct}$. The robustness of $\mathcal{D}_{correct}$ against variation is ablated in Appendix C.

180 Instance-level influence scores. Plugging Equation 6 into 181 Equation 4 yields the instance-level influence score assigned 182 to each SFT training example z_m reflecting its effect on 183 $f(\theta)$. Consistent with (Grosse et al., 2023), we restrict 184 our focus to positively influential data, which refers to data 185 points that yield an increase in the log-likelihood of correct 186 answers and thus more effectively enhances the model's 187 reasoning performance. 188

Sequence-level influence scores. Reasoning traces of re-189 190 cent models often exhibit sequence-level cognitive behav-191 iors, such as verification or exploration (refer to Figure 6). To attribute the contribution of an individual sentence y in 193 z_m , we employ a simple counterfactual tactic: we remove 194 y from the example and measure how the influence scores changes. Let $z_m^{\setminus y}$ denote the input with sentence y erased. 195 196 Then the sequence-level influence of y is given by 197

$$\mathcal{I}_f(\boldsymbol{y}) = \mathcal{I}_f(z_m) - \mathcal{I}_f(z_m^{\backslash \boldsymbol{y}}), \tag{7}$$

which isolates the influence of \boldsymbol{y} on the target function $f(\boldsymbol{\theta})$.

201Token-level influence scores.Tokens that mark critical202transitions—such as 'wait'—frequently appear in long CoT.203Attributing influence at the token level may therefore help204elucidate the underlying mechanisms that guide the model's205reasoning. Due to the autoregressive nature of LLMs, the206training gradient of a training sequence z_m of length T207decomposes as:

$$\nabla_{\boldsymbol{\theta}} \mathcal{L} \left(z_m, \boldsymbol{\theta} \right) = \sum_{t=1}^{T} - \nabla_{\boldsymbol{\theta}} \log p(z_{m,t} | z_{m,$$

212 where $z_{m,t}$ denotes the *t*-th token and $z_{m,<t} = \{z_{m,1}, \ldots, z_{m,t-1}\}$. Plugging this into Equation 4 yields the token-level influence of $z_{m,t}$:³

$$\mathcal{I}_{f}(z_{m,t}) = \nabla_{\boldsymbol{\theta}} f(\boldsymbol{\theta})^{T} \mathbf{H}^{-1} \nabla_{\boldsymbol{\theta}} \log p(z_{m,t} | z_{m,(9)$$

4. Experiments

We begin by detailing the experimental setup (\$4.1), and then present the main findings, progressing from coarse- to fine-grained analyses (\$4.2-\$4.4).

4.1. Experimental Setup

We conduct experiments under two SFT settings and interpret math and code reasoning behaviors using influence functions in both scenarios.

Base models trained w/o long CoT. We fine-tune the Llama3-8B-Base model (Grattafiori et al., 2024) using a mixed training dataset comprising MetaMathQA-100k (Yu et al., 2023) and OSS-Instruct-75k (Wei et al., 2024). MetaMathQA-100k includes reformulated questions boot-strapped from training splits of GSM8k (Cobbe et al., 2021) and MATH (Hendrycks et al., b) paired with brief answers (~100 tokens) generated from GPT-3.5-Turbo (OpenAI, 2022). OSS-Instruct-75k provides synthetically generated instructions covering a range of coding tasks. We evaluate the resulting model on the test splits of GSM8k and MBPP (Austin et al., 2021), filtering correctly answered data to compute influence scores. The MBPP benchmark consists of 1,000 Python programming problems, each comprising a task description and three automated test cases.

Instruction-tuned models trained w/ long CoT. We finetune the Qwen2.5-7B-Instruct model (Yang et al., 2024) on the Bespoke-Stratos-17k reasoning dataset (BS-17k), which includes SFT distillation data from DeepSeek-R1 (Guo et al., 2025), comprising questions, reasoning traces, and answers. We employ the AIME24, AIME25, MATH500, and Live-CodeBench (Jain et al., 2021) benchmarks to evaluate reasoning performance. AIME is a prestigious high school mathematics competition known for its challenging problems. MATH500 is a subset of 500 problems drawn from the MATH (Hendrycks et al., b) benchmark. LiveCodeBench evaluates LLMs on diverse coding tasks, including selfrepair, code execution, and test output prediction, and currently hosts 400 coding problems.

Influence scores computation. We estimate the Hessian using EK-FAC on the full SFT training set, truncating sequences to 4096 tokens to reduce memory usage. We set n = 100 in Equation 6 by randomly sampling correctly answered math and code examples.

4.2. Instance-level Attribution

Finding 1: Code data can positively influence math performance,

and vice versa.

To investigate cross-domain influence after fine-tuning

³This term captures the influence of $z_{m,t}$ as the output for the model to fit, ignoring its role as input in other cases, for simplicity.

Figure 2: Cross-domain influence analysis of LLaMA3-8B-Base fine-tuned on combined MetaMathQA and OSS-Instruct for math and code performance. The most beneficial examples for math performance predominantly come from the math domain, while code-domain data also contributes non-trivially (left). A similar cross-domain benefit is observed for code performance (right).

Figure 3: Average influence score of the training dataset combining MetaMathQA and OSS-Instruct, evaluated on MBPP and GSM8K performance. Results are grouped by training data category (left) and MATH problem difficulty (right).

LLaMA3-8B-Base on MetaMathQA and OSS-Instruct, we 258 rank training samples based on their positive influence on 259 the mean likelihood of correct answers in math and coding tasks, respectively, and categorize them by domain. As 261 shown in Figure 2 (a), the most influential samples for improving math performance predominantly originate from 263 the math domain. However, influence scores from code-264 domain data are not narrowly concentrated in the low range 265 (0-10); instead, a substantial number exhibit scores in the 266 15-20 range, indicating a non-trivial contribution from code to math. A similar pattern of cross-domain benefit is observed in Figure 2 (b), suggesting that training data from 269 one domain can provide valuable knowledge that enhance 270 performance in the other, demonstrating a meaningful trans-271 fer of reasoning skills across domains. This also holds in 272 long CoT reasoning scenarios as shown in Appendix B.

To investigate how various training data types influence code reasoning, we further aggregate training samples by category and compute average influence scores per category. As illustrated in Figure 3 (a), in-domain Python data yields the highest average influence on MBPP (a benchmark of 1,000

tions from MetaMathQA.

Python problems). Within the math domain, symbolic problem-answer pairs—such as those introducing variables

x in FOBAR and SV formats shown in Figure 4—most effectively enhance coding capabilities. Moreover, collegelevel math questions from the MATH dataset, which utilize LaTeX-based formal expressions, contribute more positively to code performance than simpler, conversational high-school problems from GSM8k. This suggests that, beyond domain relevance, the complexity and formality of the data—especially the use of precise symbolic language—also play a critical role in enabling models to generalize effectively to code reasoning tasks.

Finding 2:

Challenging math problems exhibit higher influence scores on both math and code reasoning, while simpler code problems more effectively enhance code tasks when combined with math data. The optimal strategy for co-optimizing reasoning across both domains is to mix challenging math problems with easier code tasks. To examine how training data difficulty contributes to model performance, we first categorize MATH training data into different difficulty levels and compute the average influence score for each level. As shown in Figure 3(b), higherdifficulty problems (Level 5 and 4) contribute more significantly to performance improvements on GSM8k and MBPP compared to lower-difficulty ones (Level 3, 2, and 1). This may be attributed to the fact that high-difficulty MATH problems induce more complex reasoning chains and thus better transfer logical capabilities to reasoning-intensive tasks.

To further investigate the role of difficulty in long CoT reasoning scenarios, we fine-tune Qwen2.5-7B-Instruct on the BS17k dataset and analyze influence scores grouped by difficulty levels. The results, shown in Figure 5(a), indicate that challenging tasks in both mathematics and coding are more beneficial for math reasoning. In contrast, easier math problems offer limited gains across both math and coding evaluations. This observation aligns with findings from the w/o long CoT setting and prior works such as LIMO (Ye

384

357 et al., 2025), which highlight the utility of difficult math 358 problems in developing reasoning capabilities. On the other 359 hand, we find that simpler code problems are more effective 360 for improving performance on coding tasks when mixed 361 with math data. We hypothesize that, in addition to logical 362 reasoning, programming tasks rely heavily on learning struc-363 tural and syntactic patterns. When paired with math data 364 that enhances logical thinking, simple coding tasks with clearer structure and more consistent syntax facilitate the model's acquisition of fundamental programming patterns, 367 thereby improving code generation performance.

369 Based on these insights, we design an optimized data mixing strategy: we replace simple math problems in the original 370 371 dataset with more challenging ones sourced from a larger scale OpenThoughts-114k⁴ dataset, and conversely, we re-373 place difficult coding problems with simpler ones. The 374 modified dataset retaining the original size of 17k examples, 375 compared in Figure 5(b), is used to retrain the model. As 376 shown in Table 1, this new difficulty flipped mixing strategy yields consistent improvements across AIME, MATH, and LiveCodeBench benchmarks. In contrast, applying the re-378 379 verse strategy-simplifying hard math problems and compli-

thoughts/OpenThoughts-114k. Note that this dataset is
 curated using the same pipeline as BS-17k, with identical question
 sources and answers distilled from Deepseek-R1.

cating easy coding tasks—results in the worst performance, further validating our finding.

4.3. Sequence-level Attribution

Finding 3:

The presence of 'searching for another approach after reaching correct answers' in math reasoning traces benefits to both math and code reasoning. While previously considered unnecessary overthinking, our sequence-level influence analysis and SFT ablations demonstrate its positive impact, suggesting such exploratory behaviour may promote generalizable reasoning skills.

We are interested in the influence of different cognitive behaviors on reasoning performance. Following prior work (Gandhi et al., 2025), we focus on five key behaviors: exploration (seeking alternative approaches after reaching a correct answer), verification (systematic error-checking), backtracking (abandoning ineffective strategies), subgoal setting (breaking problems into manageable steps), and backward chaining (reasoning from desired outcomes to initial inputs). To identify these behaviors in the BS-17k dataset, we use Qwen-32B-instruct as a classifier, with details provided in Appendix E.

200	0 1 doesn 't result in a five -digit palindrome . Hmm , let 's start by understanding the	contiguous sub arrays such that every element in the left is less than or equal to every
386	problem step by step . First , a palindrome is a number that reads the same forwards	element in the right . The left should be as small as possible . Hmm . Let 's think . So the
387	and backwards. Three -digit pal ind rom es range from 1 0 1 to 9 9 9 . The condition is that	key here is to find the smallest possible left sub array . The left and right must be non -
200	when you multiply this three -digit palindrome by 1 0 1 , the result is not a five -digit	empty, so the left 's length can range from 1 to n - 1. The main condition is that the
388	palindrome . So , first , maybe I should figure out what happens when you multiply a three -	maximum of the left part is less than or equal to the minimum of the right part . Wait ,
389	digit palindrome by 1 0 1 . Let 's take an example . Let 's take 1 0 1 . Multiply by 1 0 1 : 1 0 1 \ast	but checking all possible partitions and their max and min might be time -consuming for
390	101. Let 's compute that . 101*100 is 10100, plus 101*1 is 101, so total is 102	large arrays . () So in Python : def partition Dis joint (self , A : List [int])
590	01. Is 10201 a palindrome? Yes, because creading forwards and backwards ()	-> int : We need to process the array A . So first , compute left _max . n = len (A) left
391	Wait , let's think about how multiplying by 1 0 1 works . Multip lying by 1 0 1 is like	_max = [0]* n left _max [0] = A [0] for i in range (1 , n): left _max [i] = max (left
392	multiplying by 1 0 0 and adding the original number . So , if the original number is ABC (_max [i - 1], A [i]) Then compute right _min . right _min = [0]* n right _min [-1] =
	where A, B, C are digits and A = C because it 's a palindrome), () Wait, no, actually , to	A [-1] for i in range (n - 2, - 1, - 1): right _min [i] = min (A [i], right _min [i + 1])
393	add A BA 0 0 and A BA , they need to be aligned by place value $\ $. ABA 0 0 is A BA shifted	Then iterate through each possible i . () Correct . So this approach works . Now ,
394	two places to the left , so it 's A B A 0 0 . Adding A BA (which is 0 0 A B A) shifted right by	space -wise , for $n = 3 e 4$, we have two arrays of size $n each$. Which is acceptable .
205	two places ? Wait , no . Wait , when you multiply by 1 0 1 , it 's equivalent to multiplying by	Time -wise, O (n) for each step. So O (n) time. So the code is correct. So the code
395	1 0 0 and adding multiplying by 1 . () Ah , so here 's the key . If A is 5 or less , ()	would be : class Solution : def partition Dis joint (self , A : List [int
396	For example, if $A = 5$, then $5 + 5 = 10$, so we write 0 and carry over 1 to the next digit () \rightarrow int : n = len (A) left max = [0]*n left max [0] = A [0] for i in range (1)
397	position 4). But position 4 in the sum is B (from A BA 0 0) plus 0 (from A BA) plus the	, n): left max $[i] = max$ (left max $[i-1]$, A $[i]$) () But according to the problem
391	carry over 1 . So position 4 would be B + 1 . However , position 2 in the sum is B (from A	statement, there 's at least one valid partition, so the loop will find it and return before
398	BA 0 0 's position 2 , which is 0 + B from A BA). () But wait , let 's verify this. ()	reaching the end . So this should work .
399		-

Figure 7: Visualization of top 5% influential tokens in math (*Left*) and code (*Right*) CoT.

401 As shown in Figure 6 (right), exploration behavior is preva-402 lent in the training dataset. However, prior work often con-403 siders it detrimental, viewing it as overthinking that reduces 404 efficiency (Chen et al., 2024; Sui et al., 2025). We thus 405 assess whether this behavior has a positive or negative im-406 pact using influence functions. Specifically, we truncate 407 sentences in training data containing exploration and exam-408 ine the change in influence score, as defined in Equation 7. 409 The results in Table 2 (left) show that exploration is not 410 redundant; on the contrary, it positively affects both math 411 and code reasoning, even surpassing verification in impact. 412

413 To further validate this, we use GPT-40 to truncate all explo-414 ration behaviors in the BS-17k dataset for SFT, with instruc-415 tion details in Appendix D. The SFT results in Table 2 (right) 416 show a significant performance drop when exploration is 417 removed. We attribute this decline to exploration's role 418 in enabling flexible problem-solving, essential for diverse 419 reasoning tasks. Beyond exploration, we compare average 420 influence scores across other cognitive behaviors. As shown 421 in Figure 6 (right), backtracking is crucial for mathemati-422 cal reasoning, while subgoal setting is more impactful in 423 programming. This may be because programming requires 424 breaking down high-level goals into modular components, 425 making subgoal setting essential.

4.4. Token-level Attribution

Token-wise attribution analysis reveals distinct paradigms in math and code reasoning. In math CoT, influential tokens are natural language with logical connectors, whereas code CoT are dominated by structured code with syntax markers.

To investigate the most influential tokens for stimulating reasoning, we select the top 100 highly influential examples on math and code reasoning, compute token-wise influence scores using Equation 9, and highlight the top 5% most influential tokens. Interestingly, as shown in Figure 7, the initial tokens in CoT-such as 'Okay, so I ... '-are frequently highlighted, suggesting that these openers help orient the model's cognitive process to initiate reasoning. Further analysis reveals that, in math CoTs, the influential tokens are predominantly natural language logical connectors, such as 'Wait', 'However', 'Verify', 'Hence', 'First', 'Therefore', and 'Alternatively'. In contrast, in code CoTs, the most influential tokens are structural or syntactic elements such as markdown-style headings (e.g., ### Solution), fenced code blocks (e.g., ``` bash```), and syntax markers (e.g., def (self, A: List [int])-> int:), which reflect the highly structured nature of code reasoning. This contrast highlights a divergence in reasoning paradigms: math reasoning relies more heavily on logical discourse, while code reasoning is facilitated by explicit structure and formatting. These divergent patterns may explain why easier code problems with clearer structural formats are particularly beneficial for enhancing code reasoning when integrated with math CoTs that already provide strong logical skills.

5. Conclusion

In this paper, we propose a fine-grained influence function framework to trace how training data on SFT phase shapes LLM reasoning in math and code tasks. Our analysis reveals that cross-domain examples—especially highdifficulty math and low-difficulty code—boost reasoning performance across domains. We further extend influence functions to the sequence level, revealing that exploratory behaviors in long CoT consistently enhance performance, challenging prior assumptions that such behaviors reflect overthinking. Token-level analysis reveals distinct paradigms in math and code reasoning. Our work highlights the utility of influence-based attribution for data-centric optimization and opens a path toward more targeted and interpretable reasoning supervised training.

Figure 8: Cross-domain influence analysis of Qwen2.5-7B-Instruct fine-tuned on Bespoke-Stratos-17k dataset for math and code reasoning performance.

A. Derivation of Influence Score

Given the influence of z_m on model parameters θ

$$\mathcal{I}_{\boldsymbol{\theta}}(z_m) = \left. \frac{d\boldsymbol{\theta}}{d\epsilon} \right|_{\epsilon=0} = -\mathbf{H}^{-1} \nabla_{\boldsymbol{\theta}} \mathcal{L}\left(z_m, \boldsymbol{\theta}\right), \tag{10}$$

we can obtain its influence on a function of parameters $f(\theta)$ by applying the chain rule for derivatives:

$$\mathcal{I}_{f}(z_{m}) = \left. \frac{df(\boldsymbol{\theta})}{d\epsilon} \right|_{\epsilon=0}$$

$$= \nabla_{\boldsymbol{\theta}} f(\boldsymbol{\theta})^{T} \left. \frac{d\boldsymbol{\theta}}{d\epsilon} \right|_{\epsilon=0}$$

$$= -\nabla_{\boldsymbol{\theta}} f(\boldsymbol{\theta})^{T} \mathbf{H}^{-1} \nabla_{\boldsymbol{\theta}} \mathcal{L}(z_{m}, \boldsymbol{\theta}).$$
(11)

B. Cross Domain Influence Analysis in Long CoT Scenarios

In this section, we provide additional instance-level attribution experiment on long CoT reasoning scenarios. We fine-tune Qwen2.5-7B-Instruct on Bespoke-Stratos-17K reasoning dataset. As shown in Figure 8(a), the most influential samples for improving math performance predominantly from the math domain, but the samples from code domain are also significant. In Figure 8(b), there is a similar pattern of cross-domain benefit. This is consistent with the conclusions we obtained in the experimental section 4.2.

C. Robustness on *n*

In this section, we evaluate the robustness of the influence function esti-mates with respect to the size of the correct subset $\mathcal{D}_{correct}$. Specifically, we fine-tune the LLaMA3-8B-Base model on a mixed training corpus comprising MetaMathQA and OSS-Instruct, and compute influence scores on the math and code performance. We calculate the Pearson correlation between the rankings of training examples induced by influence scores using varying values of n, using n = 100 as the reference. Results in Table 3 shows the robustness of n for influence scores estimation.

Table 3: Pearson correlation coefficient of rankings on training data across different choices of n.

$n \rightarrow$	10	25	50	100
Math	0.52	0.60	0.70	1.0
Code	0.51	0.62	0.60	1.0

Which Data Attributes Stimulate Math and Code Reasoning? An Investigation via Influence Functions

Figure 9: To assess whether the exploration behavior has a positive or negative impact, we use GPT-40 to truncate all exploration behaviors in the BS-17K dataset for SFT. If reasoning contains any searching for another approach after reaching correct answers, like "Alternatively, maybe there's a different way to approach the problem?", the exploration content will be truncated.

D. Case of Truncating Exploration Behavior

To evaluate the impact of exploration behaviors in reasoning processes, we systematically truncate exploratory content from the BS-17K during SFT. Specifically, any post-correct-answer exploration (e.g., "Alternatively, maybe there's a different way to approach the problem") is removed to isolate the core problem-solving trajectory, as shown in Figure 9.

E. Examples for Reasoning Behaviors Classifier

The five cases below show the prompts of five behaviors on reasoning performance and the corresponding answers. As shown in Figure 10 and 11, the prompts include task description, examples of each reasoning behavior, task format, etc..

## Thoughts The writer explores multiple ways to approach the problem of proving that a sequence satisfying certain conditions must be a polynomial. After initially considering the properties of polynomials and the given conditions, the writer continues to explore different methods and perspectives, such as using finite differences, induction, and theorems about integer-valued polynomials. The writer does not stop at the first satisfactory approach but continues to question and explore further, indicating a behavior of seeking alternative methods even after reaching a correct or satisfactory solution. ## Does alternative thinking? yes	## Thoughts The provided text is a detailed exploration of a mathematical problem involving sequences and polynomials. The writer discusses various approaches and theorer that could be used to prove that a sequence satisfying certain conditions must be polynomial. However, the text does not explicitly check any calculations or resul against known values or re-verify any steps taken in the reasoning process. ## Does verification? no ## Number of verification steps

Figure 10: *Left:* Exploration: When performing reasoning, seeking alternative approaches after reaching a correct answer.
We capture this behavior and calculate the number of exploration steps by analyzing the content like "Another way to look at this is..." etc.. *Right:* Verification: The behavior of reasoning from desired outcomes to initial inputs when performing reasoning. We capture and calculate the number of backward chaining instances by finding the content like "To solve this equation, let's start with what we want to prove" etc..

Backtracking	Backward Chaining
