# BRIDGING JENSEN GAP FOR MAX-MIN GROUP FAIRNESS OPTIMIZATION IN RECOMMENDATION

**Anonymous authors**

Paper under double-blind review

## ABSTRACT

Group max-min fairness (MMF) is commonly used in fairness-aware recommender systems (RS) as an optimization objective, as it aims to protect marginalized item groups and ensures a fair competition platform. However, our theoretical analysis indicates that integrating MMF constraint violates the assumption of sample independence during optimization, causing the loss function to deviate from linear additivity. Such nonlinearity property introduces the Jensen gap between the model’s convergence point and the optimal point if mini-batch sampling is applied. Both theoretical and empirical studies show that as the mini-batch size decreases and the group size increases, the Jensen gap will widen accordingly. Some methods using heuristic re-weighting or debiasing strategies have the potential to bridge the Jensen gap. However, they either lack theoretical guarantees or suffer from heavy computational costs. To overcome these limitations, we first theoretically demonstrate that the MMF-constrained objective can be essentially reformulated as a group-weighted optimization objective. Then we present an efficient and effective algorithm named FairDual, which utilizes a dual optimization technique to minimize Jensen gap. Our theoretical analysis demonstrates that FairDual can achieve a sub-linear convergence rate to the globally optimal solution and the Jensen gap can be well bounded under a mini-batch sampling strategy with random shuffle. [Extensive experiments conducted using six large-scale RS backbone models on three publicly available datasets demonstrate that FairDual outperforms all baselines in terms of both accuracy and fairness.](#)

## 1 INTRODUCTION

Group max-min fairness (MMF) has gained significant attention in industrial recommender systems (RS), as it seeks to provide support for marginalized item groups, where item groups are usually divided by item categories or providers (Xu et al., 2023; Patro et al., 2020; Xu et al., 2024). For example, optimizing MMF can alleviate the low exposure problem of small sellers in the Amazon RS platform (Patro et al., 2020). As illustrated in European competition law (Jones et al., 2014), protecting these weak supplier groups is essential for preventing large platforms from engaging in unfair strategies, thereby ensuring fair competition (Matten et al., 2008).

Formally, the group MMF optimization objective entails calculating the overall utility of each group and maximizing the utility of the least advantaged group. Typically, group utility computation often necessitates aggregating the overall recommendation ranking list over a specified period (Xu et al., 2023; Do et al., 2021; Xu et al., 2024), for example, the group utility could be the exposures of action movies within a day. Due to the limited ranking slots, adjusting the exposure of items to improve the utility of one item group will inevitably affect the ranking outcomes of other item groups. Therefore, the loss function with the MMF constraint for RS violates a crucial assumption: the independence of samples, resulting in the MMF loss of different item groups not adhering to linear additivity (see theoretical proof in Section 4).

We theoretically and empirically show that the non-linear additivity property of the MMF-constrained objective will introduce a Jensen gap (Gao et al., 2017; Ullah et al., 2021) between the model’s convergence point and the optimal point when if mini-batch sampling is applied for optimization (see Section 4). Meanwhile, it is proved that as the mini-batch size decreases and the group size increases, the Jensen gap will become more pronounced in the optimization process, significantly harming

---

054 the model’s performance. However, mini-batch sampling strategies are essential for accelerating  
055 the model training process, especially as data and model sizes in RS continue to grow, such as the  
056 development of large language models (LLMs) based RS (Li et al., 2023; Bao et al., 2023a;b).

057 Some previous approaches have the potential to bridge the Jensen gap for RS. One type of heuristic  
058 approach can be applied to bridge the Jensen gap, such as sample re-weighting strategies (Chen  
059 et al., 2023b; Wen et al., 2022), which dynamically assigns a higher weight to the weaker group  
060 across different batches. However, the effectiveness of this research line is limited due to the lack of  
061 theoretical guarantees. Another type of work utilizes machine learning techniques that can help to  
062 optimize the non-linear additive loss functions. For example, Abernethy et al. (2022); Cousins (2022)  
063 have proposed sampling strategies to obtain unbiased samples, while some methods utilize debiasing  
064 gradient descent (Demidovich et al., 2023; Agarwal et al., 2018) to introduce a bias correction term in  
065 the gradient. However, these methods cannot be applied to existing large-scale industrial RS, as they  
066 often require a convex optimization process that is impractical for RS that typically serves millions of  
067 users and hundreds of groups.

068 To overcome the challenges for bridging the Jensen gap, in this paper, we firstly theoretically demon-  
069 strate that the optimization objectives when incorporating group MMF constraint can be essentially  
070 reformulated as a group-weighted accuracy optimization objective on different groups. Then, we in-  
071 troduce a large-scale friendly, and effective algorithm called FairDual to optimize the group-weighted  
072 objective for minimizing the Jensen gap. Specifically, we formulate the fairness-constraint problem  
073 as its dual, where the dual variable (referred to as the shadow price in economics (Drèze and Stern,  
074 1990)) can be interpreted as the sample weight assigned to each sample in the mini-batch optimization  
075 process. Then, FairDual leverages dual-optimization techniques to optimize the weight of different  
076 group losses utilizing dual mirror gradient techniques efficiently.

077 Our theoretical analysis demonstrates that FairDual can achieve a sub-linear convergence rate to the  
078 globally optimal point under a random shuffling mini-batch training style. Moreover, the Jensen  
079 gap can be well bounded (See Section 5.2.3) even when confronted with small mini-batch sizes  
080 and large group sizes. Extensive experiments using three large-scale RS backbone models on three  
081 publicly available datasets show that FairDual consistently reduces the Jensen gap and outperforms all  
082 baselines with a large margin in terms of both accuracy and fairness while achieving better efficiency.

## 084 2 RELATED WORK

087 **Fairness Concept in RS.** One common categorization is based on the involvement of different  
088 stakeholders (Abdollahpouri et al., 2020; Abdollahpouri and Burke, 2019), divides fairness into  
089 individual fairness (Marras et al., 2022; Li et al., 2021), which aims to ensure equitable treatment for  
090 individual users, and group fairness, which classifies items into various groups (Xu et al., 2023; 2024;  
091 Patro et al., 2020; Naghiaei et al., 2022; Wu et al., 2021). Various approaches have been proposed to  
092 optimize fairness utilizing different fairness objectives. For instance, Patro et al. (2020) proposed  
093 using the Shapley value, while Do and Usunier (2022) suggested optimizing the Gini Index. On the  
094 other hand, works such as Xu et al. (2023); Do et al. (2021); Xu et al. (2024) advocate for optimizing  
095 MMF, which requires every group should receive a “minimum wage”. Typically, we mainly focus on  
096 the group MMF, which is closer to the industrial scenarios since certain studies propose to ensure  
097 minimum item exposures for attracting providers to join or enhancing the visibility of specific item  
098 categories (Patro et al., 2020; Xu et al., 2024; Zhu et al., 2020).

099 **Optimizing Fairness in RS.** When optimizing fairness, previous research often categorizes methods  
100 into three categories based on recommendation phases, including pre-processing (Calmon et al.,  
101 2017; Xiong et al., 2024), post-processing (Xu et al., 2023; Patro et al., 2020; Wu et al., 2021) and  
102 in-processing (Narasimhan et al., 2020; Tang et al., 2023). In this paper, we theoretically demonstrate  
103 that the in-processing method constrained by group MMF can be essentially reformulated as a  
104 re-weighting approach. Prior research employed static or dynamic group weights to achieve fairness.  
105 For static weights, Jiang et al. (2024); Xiong et al. (2024) proposes to set item weight according to  
106 its popularity and the Wasserstein distance of two groups, respectively. For dynamic weighting, some  
107 work (Chen et al., 2023b; Chai and Wang, 2022; Wen et al., 2022) propose to design weights based  
on the training state, while Hu et al. (2023) employs a dynamic re-weighting strategy to mitigate  
distribution shifts between training and test data. Roh et al. (2020) also proposes to set different batch

sizes to optimize fairness. However, these methods are either designed for simple cases involving only two groups, or they lack theoretical guarantees when applied to group MMF settings.

**Optimizing Fairness in ML.** In machine learning (ML), previous work aims to optimize different fairness functions to achieve various social welfare objectives. For example, the power-mean welfare family seeks to balance accuracy and fairness objectives by applying the exponential form (Cousins, 2021; 2023) and max-min fairness (Abernethy et al., 2022; Agarwal et al., 2018) aims to support the worst-off groups. When optimizing fairness, we commonly try to optimize a nonlinear fairness function. When adopting optimization methods such as stochastic gradient descent (SGD), an unavoidable bias will exist (Demidovich et al., 2023; Hu et al., 2020). To bridge this bias, previous ML methods have employed sampling strategies (Abernethy et al., 2022; Cousins, 2022) to obtain unbiased samples, while some methods have utilized debiasing SGD (Demidovich et al., 2023; Agarwal et al., 2018) to mitigate the bias. However, these works cannot be applied to large-scale industrial RS since they often require a convex optimization process that is impractical for RS tasked with serving millions of users and hundreds of groups. To efficiently bridge the Jensen gap, our method improves debiasing SGD by developing a large-scale friendly mirror SGD learning algorithm.

### 3 FORMULATION

In RS, let  $\mathcal{U}, \mathcal{I}$  be the set of users and items, and each item  $i \in \mathcal{I}$  is associated with a unique group  $g \in \mathcal{G}$ , where the set of items associated with  $g$  is denoted as  $\mathcal{I}_g$ . In RS, an item  $i$  may belong to a different group  $g$  (e.g., a movie can be categorized under various genres such as action, or drama). We define the number of groups to which the item  $i$  belongs as  $n_i$ .

Suppose that the RS manages a set of user-item historical interactions  $\mathcal{D} = \{(u, i, c_{u,i})\}$ , where each tuple  $(u, i, c_{u,i})$  records that a user  $u \in \mathcal{U}$  accessed the system and interacted with an item  $i \in \mathcal{I}$  with behavior  $c_{u,i} \in \{0, 1\}$ .  $c_{u,i} = 1$  means that the user  $u$  clicked/purchased the item  $i$ , and 0 otherwise. The task of recommendation becomes, based on the user-item interactions in  $\mathcal{D}$ , learning an empirical estimation  $\hat{c}_{u,i} = f(u, i)$  for real label  $c_{u,i}$ . Then RS will suggest  $K$  items to the user according to predicted preference scores  $\hat{c}_{u,i}$ , with the ranking list denoted as  $L_K(u) \in \mathcal{I}^K$ . In general, the  $f(\cdot)$  can be either the traditional matrix factorization model (He et al., 2016) or more advanced LLMs-based recommender models (Bao et al., 2023a).

Following the practice in recommendation tasks (He et al., 2017; 2016), the cross-entropy loss  $-c_{u,i} \log(\hat{c}_{u,i})$  is regarded as a common and better choice compared to other loss functions. Meanwhile, to fulfill the group MMF requirement (Patro et al., 2020; Xu et al., 2024), the recommendation model also strives to maintain the expected utility of a specific group  $g$  (where the group’s utility is defined as the negative sum of the entropy loss within the group) exceeds a basic threshold  $M$ . MMF constraint aims to ensure every group can receive the required group-specific “minimum wage” during the training phases. Formally, we can write the ideal optimization objective as follows:

$$\mathcal{L} = \min_{\hat{c}_{u,i}} \underbrace{- \sum_{u \in \mathcal{U}} \sum_{i \in \mathcal{I}} c_{u,i} \log(\hat{c}_{u,i})}_{\text{recommendation accuracy loss}} \quad \text{s.t.} \quad \underbrace{\max_{g \in \mathcal{G}} \sum_{u \in \mathcal{U}} \sum_{i \in L_K(u)} - \frac{\mathbb{I}(i \in \mathcal{I}_g)}{n_i m_g} c_{u,i} \log(\hat{c}_{u,i})}_{\text{MMF constraint: loss of worst-off group } g \text{ should at or smaller than } M} \leq M, \quad (1)$$

where  $\mathbb{I}(\cdot)$  denotes the indicator function, and the number of users  $|\mathcal{U}|$  could represent the daily or weekly user traffic. The  $m_g$  can be regarded as the weight for different group  $g$ . [Note that, following the practice in time-aware RS \(Kang and McAuley, 2018b; Sun et al., 2019\), we utilize the recent  \$H\$  interactions, which represent the truncated user historical behavior numbers.](#)

### 4 PROBLEM ANALYSIS

In real-world scenarios, the number of users  $|\mathcal{U}|$  is often large, and a mini-batch sampling strategy with a batch size of  $B$  is often necessary due to the large computational costs. Each batch only contains a subset of users. However, we show that the non-linear additivity property of the MMF-based objective will introduce the Jensen gap between the model’s convergence point and the optimal point when employing mini-batch sampling strategies.

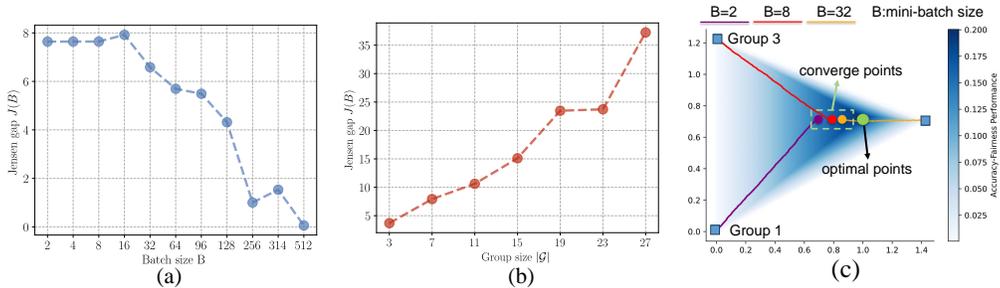

Figure 1: Loss converges simulation with 1000 users and 1000 items. Sub-figure (a) and (b) illustrate the distance away from the optimal point (*i.e.*, Jensen gap) *w.r.t.* mini-batch and group size, respectively. Figure (a) was conducted with the same group size ( $G=7$ ) under different batch sizes, while Figure (b) was conducted with the same batch size ( $B=32$ ) under different group sizes. Sub-figure (c) describes the converged trace under different batch sizes.

In this section, we analyze why the Jensen gap exists and how it will influence the model’s convergence in both theoretical and empirical ways.

#### 4.1 THEORETICAL ANALYSIS

Firstly, we will re-write the optimization objective using the following theorem:

**Theorem 1.** For a vector  $\mathbf{x} \in \mathbb{R}^n$ ,  $\mathbf{x}^i$  denotes the element of the vector raised to the power of  $i$ . Similarly,  $\log(\mathbf{x})$  denotes the element of the vector reduced as  $\log(x_i)$ . Let  $\mathbf{A} \in \mathbb{R}^{|\mathcal{I}| \times |\mathcal{G}|}$  is the item-group adjacent matrix, and  $\mathbf{A}_{i_g} = 1$  indicates item  $i \in \mathcal{I}_g$ , and 0 otherwise. Let  $\mathbf{w} \in \mathbb{R}^{|\mathcal{I}|} = [-\sum_{u \in \mathcal{U}} c_{u,i} \log(\hat{c}_{u,i})]_{i \in \mathcal{I}}$  and its feasible region is  $\mathcal{W} = \{\mathbf{w} | \sum_{i \in \mathcal{I}} c_{u,i} \leq K, \forall u \in \mathcal{U}, c_{u,i} \in [0, 1]\}$ . Then there exist  $t \in [0, \infty)$  (value of  $t$  relates to the value of  $M$ ) and a weight vector  $\mathbf{b} \in \mathbb{R}^{|\mathcal{G}|} \geq 0$ , s.t. Equation (1) can be optimized as:

$$\mathcal{L} = \min_{\mathbf{w} \in \mathcal{W}} \mathbf{b}^\top (\hat{\mathbf{A}}^\top \mathbf{w})^{1+t} \quad (2)$$

where  $\hat{\mathbf{A}}$  is the row-normalized matrix for  $\mathbf{A}$ :  $\hat{\mathbf{A}} = \text{diag}(\mathbf{A}\mathbf{1})^{-1} \mathbf{A}$ .  $\text{diag}(\mathbf{x})$  denotes to construct a diagonal matrix based on vector  $\mathbf{x}$ .

The detailed proof of Theorem 1 can be seen in Appendix A. When transforming the original optimization process in Equation (1) into Equation (2), we can easily observe that the loss function does not adhere to linear additivity. Then the Jensen gap will arise under mini-batch sample strategy by formulating it using the following theorem:

**Theorem 2.** Under mini-batch sample strategies, we partition the user set  $\mathcal{U}$  into  $|\mathcal{U}|/B$  subsets and perform optimization on each subset. Let  $\mathbf{e}^j \in \mathbb{R}^{|\mathcal{G}|}$  be the group accumulated utility under  $j$ -th partition, where each element  $e_{j,g} = -\sum_{u \in \mathcal{U}_j} \sum_{i \in \mathcal{I}_g} c_{u,i} \log(\hat{c}_{u,i})$ . Let  $f(\mathbf{x}) = x^{t+1}$ . We can write the mini-batch optimizing loss objective  $\mathcal{L}^B$  as:  $\mathcal{L}^B = \min \sum_{j=1}^{|\mathcal{U}|/B} \mathbf{b}^\top f(\mathbf{e}_j)$ , where  $\mathcal{U}_j$  is the  $j$ -th partition of the user set  $\mathcal{U}$ . Then, Jensen gap (Gao et al., 2017; Ullah et al., 2021) is defined as:

$$J(B) = |\mathcal{L}^B - \mathcal{L}| = |\mathcal{L}^B - \min \mathbf{b}^\top f(\sum_{j=1}^{|\mathcal{U}|/B} \mathbf{e}_j)| \neq 0. \quad (3)$$

When optimizing Equation (2) under the mini-batch sampling style, the mini-batch size  $B$  becomes smaller and group size  $\mathcal{G}$  becomes larger, the Jensen gap  $J(B)$  will become larger. Moreover, when the mini-batch size becomes smaller, we are more likely to underestimate the original loss, *i.e.*,  $\mathcal{L}^B \leq \mathcal{L}$ . The loss underestimation will result in the Jensen gap.

The detailed proof of Theorem 2 can be seen in Appendix C. The intuitive reason behind the Jensen gap raised by group MMF is that the accuracy-fairness trade-off problem does not adhere to linear additive attributes. Essentially, the combination of different batches forms a concave function. Mini-batch size and group size both measure the degree of data partitioning, where smaller batch sizes

and larger group sizes lead to fewer data partitions. As a result, due to the non-linear and intricate function form of a neural network (Sun, 2019), these errors in estimating the loss function impede the model from converging to the optimal point, thus diminishing the performance. Next, we will give an empirical analysis to prove this.

## 4.2 EMPIRICAL ANALYSIS

In this section, we illustrate a simulation (Figure 1) conducted under the assumption of knowing every user-item true preference score to validate the correctness of our theoretical analysis. We use the simple recommendation model: Matrix Factorization (Singh and Gordon, 2008) since we can have a closed-form expression on parameter updating. Then we apply a common mini-batch training strategy to optimize user accuracy and group MMF based on the parameters outlined in Xu et al. (2023); Patro et al. (2020), with the accuracy-fairness coefficient of 0.5, across different mini-batch and group sizes.

As shown in Figure 1 (a) and (b), we uncover that the Jensen gap (distance away from the optimal point) will deviate with smaller mini-batch sizes and larger group sizes. Figure (c) describes the converge trace under different batch sizes by mapping the top-K simplex space of three groups of recommendation ranking to a 2-dimensional space through a topological homeomorphic transformation (Kozlov, 2008). Figure 1 (c) also indicates that different batch sizes result in different gradient optimization directions, with smaller batch sizes leading to larger shifts in the error of the optimization direction. These empirical results confirm the correctness of our theoretical analysis.

Other fairness optimization objectives, such as the power-mean welfare family (Cousins, 2021) and the Gini welfare function (Do and Usunier, 2022), also exhibit non-linear properties, leading to analogous Jensen gap phenomena. This paper mainly uses max-min fairness as an example to analyze and propose solutions. Our paper mainly calls on communities to pay attention to the bias caused by the Jensen gap when optimizing the objective constrained by fairness requirements.

## 5 METHOD

In this section, we will introduce our method FairDual, which effectively and efficiently bridges the Jensen gap on large-scale datasets within large recommender models (e.g., large language models).

### 5.1 OPTIMIZING MAX-MIN FAIRNESS AS GROUP-WEIGHTED OBJECTIVE

In this section, in order to tackle this problem, we show that the MMF-constrained objective can be regarded as the group-weighted optimization problem using the following theorem:

**Theorem 3.** *By introducing the dual variable  $\boldsymbol{\mu}$ , the dual form of the Equation (1) is*

$$\mathcal{L}' = \min_{\hat{c}_{u,i}} - \sum_{u \in \mathcal{U}} \sum_{g \in \mathcal{G}} s_g \sum_{i \in \mathcal{I}_g} c_{u,i} \log(\hat{c}_{u,i}), \quad (4)$$

where  $s_g = 1 - \mu_g$  and  $\boldsymbol{\mu} = \arg \min_{\boldsymbol{\mu} \in \mathcal{M}} \left( \max_{u \in \mathcal{U}} \sum_{g \in \mathcal{G}} s_g \sum_{i \in \mathcal{I}_g} c_{u,i} \log(\hat{c}_{u,i}) + \lambda r^*(\boldsymbol{\mu}) \right)$ ,

where  $r^*(\boldsymbol{\mu}) = \max_{\mathbf{w}_g \leq m_g} \left( \min_{g \in \mathcal{G}} m_g (\hat{\mathbf{A}} \mathbf{w})_g + \hat{\mathbf{A}}^\top \mathbf{w} \boldsymbol{\mu} / \lambda \right) = \sum_g m_g \mu_g / \lambda + 1$ ,  $\mathcal{M} = \left\{ \boldsymbol{\mu} \mid \sum_{g \in \mathcal{S}} \mu_g m_g \geq -\lambda, \forall \mathcal{S} \in \mathcal{G}_s \right\}$ , where  $\mathcal{G}_s$  is the set of all subsets of  $\mathcal{G}$  (i.e., power set).

The detailed proof of Theorem 3 can be seen in Appendix F. From Theorem 3, we observe that the recommendation task constrained by max-min fairness can be viewed as a re-weighting approach across different groups on the original loss function solely optimized for accuracy.

Intuitively,  $s_g = 1 - \mu_g$  is the negative shadow price (Drèze and Stern, 1990). The high shadow price  $\mu_g$  indicates that this constraint is the primary factor constraining accuracy optimization. Conversely, a low or zero shadow price suggests that the fairness constraint currently imposes little restriction on accuracy. Specifically, a high  $s_g$  signifies that this constraint is the primary factor limiting fairness optimization for group  $g$ , whereas a low or zero  $s_g$  implies that the accuracy constraint for group  $g$  currently has little impact on the overall optimization.

---

**Algorithm 1: FairDual**

---

**Require:** Dataset  $\mathcal{D} = \{u, i, c_{u,i}\}$ , item-group adjacent matrix  $\mathbf{A}$ , dual learning rate  $\eta$ , trade-off coefficient  $\lambda$ ,  $m_{\text{freeze}}^i(\cdot)$  updating step  $\beta$ , batch size  $B$  and sample item number  $Q$  and the weight  $m_g$  for each group  $g$ .  $\hat{\mathbf{A}} = \text{diag}(\mathbf{A}\mathbf{1})^{-1}\mathbf{A}$ .

**Ensure:** The model parameters of  $m^i(\cdot)$ ,  $m^u(\cdot)$ .

- 1: **for**  $n = 1, \dots, N$  **do**
- 2:   Set  $\gamma_{1,g} = m_g, \forall g \in \mathcal{G}$
- 3:   **for**  $j = 1, \dots, |\mathcal{U}|/B$  **do**
- 4:     **if**  $(n * |\mathcal{N}|/B + j) \% \beta = 0$  **then**
- 5:       Copy parameters from  $m^i(\cdot)$  to  $m_{\text{freeze}}^i(\cdot)$  and get all item embedding  $\mathbf{E}$
- 6:       Initialize dual solution  $\boldsymbol{\mu} = 0$ , and momentum gradient  $\mathbf{g} = 0$  and  $t = 0$ .
- 7:       **end if**
- 8:       Get sub-dataset  $\{u, i, c_{u,i}\}_{b=1}^B$  and user feature  $\mathbf{e}_u$  and item feature  $\mathbf{e}_i$
- 9:        $\mathcal{L}^j = [-c_{u,i} \log(\hat{c}_{u,i})]_{b=1}^B, \quad \mathbf{s}^j = \mathbf{1} - \hat{\mathbf{A}}^j \boldsymbol{\mu}$
- 10:       Apply gradient descent based on loss  $(\mathbf{s}^j)^\top \mathcal{L}^j$
- 11:        $\tilde{\mathbf{w}}_b = \sum_{k=1}^K (\mathbf{e}_{u_b}^\top \mathbf{E}^b)_{[k]}, \forall b$
- 12:        $\tilde{\mathbf{g}}^j = -(\hat{\mathbf{A}}^j)^\top \tilde{\mathbf{w}} + \gamma_j, \quad \mathbf{g}^j = \alpha \tilde{\mathbf{g}}^j + (1 - \alpha) \mathbf{g}, \quad \mathbf{g} = \mathbf{g}^j$
- 13:        $\gamma_j = \gamma_{j-1} - (\hat{\mathbf{A}}^j)^\top \tilde{\mathbf{w}}$
- 14:        $\boldsymbol{\mu} = \arg \min_{\boldsymbol{\mu}_0 \in \mathcal{M}} [(\mathbf{g}^j)^\top \boldsymbol{\mu}_0 + \eta \|\boldsymbol{\mu}_0 - \boldsymbol{\mu}\|_2^2]$
- 15:     **end for**
- 16: **end for**

---

## 5.2 FAIRDUAL

We then will introduce our method FairDual under random shuffling mini-batch training strategies. The overall workflow of FairDual under every two batches  $j$  and  $j + 1$  can be seen in Figure 2. According to analysis in Theorem 3, under each epoch, the overall optimization process will become:

$$\mathcal{L}'^B = \min \sum_{j=1}^{|\mathcal{U}|/B} (\mathbf{s}^j)^\top \mathbf{l}^j, \quad (5)$$

where  $\mathbf{l}^j \in \mathbb{R}^B$ ,  $\mathbf{s}^j \in \mathbb{R}^B$  is loss and its weight under  $j$ -th batch. Next, we will explain how  $\mathbf{l}^j$  and  $\mathbf{s}^j$  update on each batch  $j$ . Detailed algorithm workflow can be seen in Algorithm 1. Note that, following the practice in Bao et al. (2023a), we utilize the user’s historical behaviors to represent each user, thereby treating each sample as a unique user.

### 5.2.1 ACCURACY LOSS CONSTRUCTING

In the mainstream recommender architectures, the primary objective is to make the predicted score close to the true user preference. That is, at each batch  $j$ , there are  $B$  user-item pair  $[(u, i)]_{b=1}^B$  arrives. Then the loss vector  $\mathcal{L}^j$  is computed as:

$$\mathbf{l}^j = [-c_{u,i} \log(\hat{c}_{u,i})]_{b=1}^B, \quad (6)$$

where  $\hat{c}_{u,i} = -d(\mathbf{e}_u, \mathbf{e}_i) \leq 1$ , where  $d(\cdot)$  is the normalized distance between embedding  $\mathbf{e}_u, \mathbf{e}_i$ . The commonly used distance metric is the dot-product, i.e.  $d(\mathbf{e}_u, \mathbf{e}_i) = -\mathbf{e}_u^\top \mathbf{e}_i$ , and the  $\mathbf{e}_u$  and  $\mathbf{e}_i$  are calculated by a complex model, i.e.  $\mathbf{e}_u = m^u(u), \mathbf{e}_i = m^i(i)$ , where  $m^u(\cdot)$  and  $m^i(\cdot)$  are two embedding extraction networks. Typically, the user  $u$  is represented by the item-clicked history sequences before clicking the item  $i$ :  $[i^1, i^2, \dots, i^n]$ , where  $n$  is the fixed item sequence length.

Note that in text-based recommendation models such as BigRec (Bao et al., 2023a) and Recformer (Li et al., 2023), each item  $i$  is represented as a sequence of words in natural language:  $i = [w^1, w^2, \dots, w^l]$ , where  $l$  is the length of the sentence and user behaviors are also represented in prompt form (Bao et al., 2023a). In such cases, Equation (6) is extended to  $\log \hat{c}_{u,i} = \sum_{i=1}^l \log(P(w^i))$ , where  $P(w)$  refers to the predicted probability of the word  $w$  generated by the LLMs, while other equations remain unchanged.

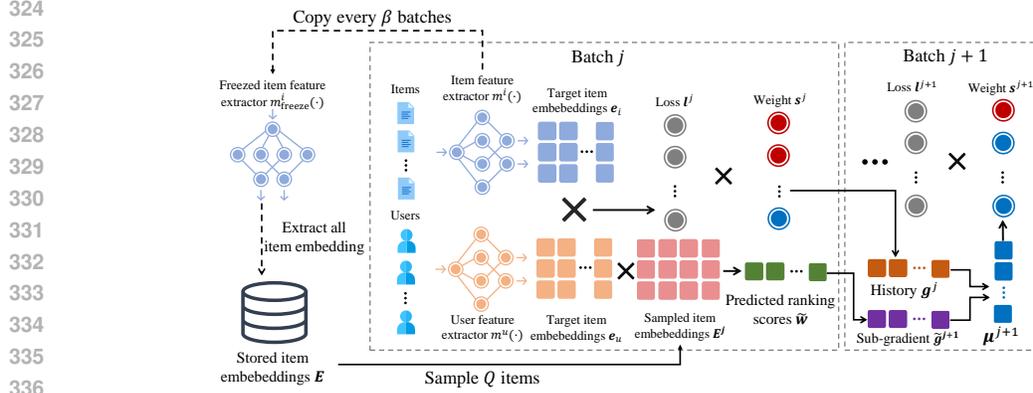

Figure 2: Overall workflow of FairDual under every two batches  $j$  and  $j + 1$ .

### 5.2.2 MIRROR GRADIENT DESCENT FOR GROUP WEIGHT

For each batch  $j$ , the model needs to decide the weight  $s^j$  for each sample. The weight  $s^j$  is computed utilizing mirror-gradient descent (Balseiro et al., 2021) technique. Specifically,

$$s^j = \mathbf{1} - \hat{\mathbf{A}}^j \boldsymbol{\mu}^j, \quad (7)$$

where  $\hat{\mathbf{A}}^j \in \mathbb{R}^{B \times |\mathcal{G}|}$  represents the row-normalized item-group adjacency matrix for  $\mathbf{A}$  in batch  $j$  (see details in Equation (2)), with  $A_{i_b, g} = 1$  indicating that the  $b$ -th item in batch  $i_b \in \mathcal{I}_g$  belongs to group  $g$ , and 0 otherwise. And  $\boldsymbol{\mu}^j$  is the dual variable at  $j$ -th batch, which updates as:

$$\boldsymbol{\mu}^j = \arg \min_{\boldsymbol{\mu}} [(\mathbf{g}^j)^\top \boldsymbol{\mu} + \eta \|\boldsymbol{\mu} - \boldsymbol{\mu}^{j-1}\|], \quad \text{s.t.} \sum_{j=1}^g \boldsymbol{\mu}_j m_j + \lambda \geq 0, \quad \forall g = 1, 2, \dots, |\mathcal{G}|, \quad (8)$$

where  $\eta$  is the learning rate,  $\mathbf{g}^j$  is the sub-gradient of the Equation (4) *w.r.t.* the dual variable  $\boldsymbol{\mu}^j \in \mathbb{R}^{|\mathcal{G}|}$ . The projection step can be efficiently solved using convex optimization solvers (Balseiro et al., 2021) since  $\mathcal{D}$  is coordinate-wisely symmetric.

Specifically, to ensure smoothness and make use of historical information, we utilize the momentum gradient descent to update  $\mathbf{g}^j$ :

$$\mathbf{g}^j = \alpha \tilde{\mathbf{g}}^j + (1 - \alpha) \mathbf{g}^{j-1}, \quad \tilde{\mathbf{g}}^j = \partial(s^j \mathcal{L}^j + \lambda r^*(\boldsymbol{\mu}^j)) = -(\mathbf{A}^j)^\top \tilde{\mathbf{w}} + \boldsymbol{\gamma}_j, \quad (9)$$

where  $\boldsymbol{\gamma}_j \in \mathbb{R}^{|\mathcal{G}|}$  is the vector, whose element of index  $g$  denotes the remaining required loss (*i.e.*, reward) for the group  $g$  at batch step  $j$ ,  $\tilde{\mathbf{w}} \in \mathbb{R}^B$  represents the estimated ranking score that each user query will receive. However, given the vast size of the item corpus in recommendation systems, conducting a full ranking on all items is impractical. Therefore, we randomly sample  $Q$  items to approximate the ranking scores across all items. The  $Q$  items' embeddings are denoted as  $\mathbf{E}^j \in \mathbb{R}^{Q \times d}$ . Formally, for the  $b$ -th element  $\tilde{w}_b$ , we can write:  $\tilde{w}_b = \sum_{k=1}^K (\mathbf{E}^j e_{u_b})_{[k]}$ , where  $x_{[k]}$  denote the  $k$ -th largest element in vector  $\mathbf{x}$  and  $K$  is the ranking size.

Note that  $\mathbf{E}^b$  is sampled from the pre-stored item embedding  $\mathbf{E} \in \mathbb{R}^{|\mathcal{I}| \times d}$ , which is pre-calculated using the freezer network  $m_{\text{freeze}}^i(\cdot)$ . This is done to mitigate the significant fluctuations in  $\tilde{\mathbf{w}}$  caused by unstable training (Fan et al., 2020). To achieve this, we freeze the item feature extractor  $m^i(\cdot)$  as  $m_{\text{freeze}}^i(\cdot)$  and transfer the parameters from  $m^i(\cdot)$  to  $m_{\text{freeze}}^i(\cdot)$  every  $\beta$  batches. **For the first batch process, we initialize  $\mathbf{g}^1$  as  $\mathbf{0}$ , which will not make an effect on the first batch.**

### 5.2.3 BOUND ON JENSEN GAP

We will provide the Jensen gap converge analysis of FairDual in the following theorem.

**Theorem 4** (Bound on Jensen Gap). *There exists  $H > 0$  such that  $\|\boldsymbol{\mu}^j - \boldsymbol{\mu}\|_2^2 \leq H$  and function  $\|\cdot\|_2^2$  is  $\sigma$ -strongly convex. Then, there exists  $L > 0$ , the Jensen gap of FairDual can be bounded as:*

$$J(B) \leq \frac{H}{\eta} + \frac{|\mathcal{U}|L|\mathcal{G}|^2}{B(1-\alpha)\sigma}\eta + \frac{L|\mathcal{G}|^2}{2(1-\alpha)^2\sigma\eta}. \quad (10)$$

When setting learning rate  $\eta = O(B^{-1/2})$ , the bound of Jensen gap is comparable with  $O(B^{-1/2})$ .

Table 1: Performance comparisons between ours and the baselines on three datasets under best-performing BigRec backbones. The \* means the improvements are statistically significant (t-tests and  $p$ -value  $< 0.05$ ). The bold number indicates that the accuracy value exceeds that of all the baselines.

The detailed proof can be seen in Appendix G. From Theorem 4, it is apparent that the Jensen gap will widen as the batch size  $B$  decreases and the group size  $|\mathcal{G}|$ , as well as the max-min fairness degree  $\lambda$ , increase. However, FairDual demonstrates a sub-linear convergence rate concerning the batch size  $B$ , and it maintains strong performance even with small batch sizes and large group sizes across various fairness degrees.

## 6 EXPERIMENT

We conduct experiments to demonstrate the effectiveness of the proposed FairDual.

## 6.1 EXPERIMENTAL SETTINGS

**Datasets.** The experiments are conducted on the commonly used two widely used and publicly available recommendation datasets, including MIND (Wu et al., 2020)<sup>1</sup>, Amazon-Book and Amazon-Electronic (He and McAuley, 2016)<sup>2</sup>. Their detailed statistical information is in Appendix I.

**Evaluation.** We arrange all interactions in the dataset chronologically by their timestamps and employ the first 80% interactions as training data. The remaining 20% of interactions are divided equally, with each 10% segment used for validation and testing, respectively, during evaluation.

Regarding the metric, following the practice in Dai et al. (2023), we utilize Normalized Discounted Cumulative Gain (NDCG) and mean Reciprocal Rank (MRR) to measure the accuracy:  $NDCG@K = \frac{1}{|\mathcal{U}|} \sum_{u=1}^{|\mathcal{U}|} \frac{\sum_{i \in L_K(u)} (2^{c_{u,i}} - 1) / (\log_2(j+1))}{(2^{\text{rank}_i} - 1) / (\log_2(\text{rank}_i + 1))}$ ,  $MRR@K = \frac{1}{|\mathcal{U}|} \sum_{u=1}^{|\mathcal{U}|} \frac{1}{\text{rank}_i}$ , where  $\text{rank}_i$  is the rank of the first correct answer. Meanwhile, we employ MMF@K to gauge the degree of fairness, which quantifies the aggregated ranking score of the 20% worst-off groups (Do et al., 2021; Xu et al., 2023).

**Backbones and Baselines.** For the backbone, we first select three large-scale recommender models: **NRMS** (Wu et al., 2019), **RecFormer** (Li et al., 2023) and **BigRec** (Bao et al., 2023a). Note that BigRec only utilizes 1024 samples to train due to large computational cost. Meanwhile, we also choose three non-LLMs recommender models: **BPR** Rendle et al. (2012), **GRU4Rec** Hidasi et al. (2015) and **SASRec** Kang and McAuley (2018a).

For the baselines, we choose several fair-aware re-weight baselines that aim to improve group MMF: **UNI** (without considering fairness), **DRO** (Hashimoto et al., 2018), **S-DRO** (Wen et al., 2022), **Prop** (Hu et al., 2023), **IFairLRS** (Jiang et al., 2024) and **Maxmin Sample** (Abernethy et al., 2022). Meanwhile, we also compare three group fair-aware recommender models: **FOCF** (Yao and Huang, 2017), **Reg** (Kamishima and Akaho, 2017), and **FairNeg** (Chen et al., 2023a). Note that FairNeg only can be applied to pair-wise RS models.

The detailed descriptions of the backbones and baselines are in Appendix I.

**Implementation Details.** We provide our detailed running environment, all hyper-parameter settings, utilized LLMs settings, and used the toolkit in Appendix I.

## 6.2 EXPERIMENTAL RESULTS ON FULL DATASETS

Firstly, we conduct experiments to show the performance of FairDual and other baselines across all large-scale recommendation backbones. Table 1 presents the experimental outcomes for our FairDual model and the baseline methods across all datasets, respectively. Table 2 presents the experimental

<sup>1</sup><https://microsoftnews.msn.com>

<sup>2</sup><http://jmcauley.ucsd.edu/data/amazon/>

---

486 outcomes for our FairDual model and the baseline methods across other different backbones on the  
487 MIND dataset. To make fair comparisons, all the baselines were tuned to their hyperparameters to  
488 obtain the best trade-off accuracy and fairness performance under our settings.

489 From the experiments, it is evident that FairDual consistently outperforms the baseline methods  
490 across all datasets and various base models, spanning different top-K ranking sizes. This is reflected  
491 in accuracy metrics such as NDCG and MRR, as well as the fairness metric MMF. The results  
492 conclusively demonstrate that FairDual effectively ensures the model reaches a better convergence  
493 point in terms of both accuracy and fairness by leveraging dual gradient descent.

### 495 6.3 EXPERIMENTAL ANALYSIS

496 In this section, we first replicate the simulation settings outlined in Section 4.2 to investigate how the  
497 Jensen gap changes. Then we conduct analysis on MIND dataset under BigRec base models.

498 **Jensen gap.** Firstly, we investigate the variations in the Jensen gap concerning batch size  $B$  and  
499 group size  $|\mathcal{G}|$  across both baseline methods and our proposed FairDual model. As shown in Figure 3  
500 (a), we can see that FairDual has a lower Jensen gap than other online models across different batch  
501 sizes and group sizes. Furthermore, it’s evident that the Jensen gap exhibited by FairDual remains  
502 consistently stable across various batch sizes, with only a marginal increase observed as the group  
503 size expands. This indicates that FairDual can consistently maintain a low Jensen gap level.

504 **Influence on co-efficient  $\lambda$ .** Then, we will investigate the impacts of trade-off co-efficient  $\lambda$ . Figure 3  
505 (b) illustrates that the fairness degree (MMF) increases proportionally with the rise in  $\lambda$ , aligning with  
506 our expectations. However, we also observe that the accuracy increases as  $\lambda$  changes from 0 to 5 and  
507 then decreases. This phenomenon occurs due to the presence of popularity bias in recommendation  
508 datasets (Jiang et al., 2024). A relatively higher fairness degree helps mitigate this bias, leading to  
509 increased accuracy. However, when  $\lambda$  becomes too large, it inevitably enlarges the Jensen gap, which  
510 hurts the model’s performance. We also conduct an experiment to analyze the effect of the popularity  
511 bias in Appendix M.

512 **Case study.** Finally, we conduct a case study on the head group *News*, which consistently exhibited  
513 superior exposure compared to other groups, in contrast to the tail group *Sports*, which typically had  
514 lower exposure levels. Firstly, from the two figures at the top of Figure 3 (c), we observe that as the  
515 training progresses, the tail group Sports gradually gains more weight ( $s_g$ ), while the head group  
516 News consistently receives relatively low weight. Consequently, this leads to the group scores  $w$  of  
517 the two groups being close to each other.

518 At the same time, we visualize the item embeddings using T-SNE (Van der Maaten and Hinton, 2008)  
519 for both the baseline UNI and our model FairDual, as shown in the bottom two sub-figures of Figure 3  
520 (c). From the figure, we compute the embedding KL divergence of two different groups between UNI  
521 (0.113) and our method FairDual (0.083). This shows that UNI establishes a clear classification line  
522 to distinguish between different groups. However, FairDual tends to bring the embeddings of the tail  
523 group closer to those of the head group, ultimately increasing the fairness.

524 **Other Experimental Analysis.** For analysis of other parameters dual learning rate  $\eta$ , updating gap  
525  $\beta$ , user history length  $H$ , the sample size  $Q$ , and the impact of the hidden layer numbers, please see  
526 the Appendix J. For the computational and storage costs analysis can be seen in Appendix K. We also  
527 test the performance of other fairness metric in Appendix L.

## 530 7 CONCLUSION

531 In this paper, we theoretically demonstrate that adapting mini-batch training with the objective  
532 constrained by group MMF inevitably leads to the Jensen gap, thereby impairing the performance of  
533 the RS model. We theoretically and empirically analyze the origins of the Jensen gap by demonstrating  
534 that the integration of the MMF constraint disrupts the assumption of sample independence during  
535 optimization, leading to a deviation of the loss function from linear additivity. Then, To efficiently  
536 bridge the Jensen gap, we develop a large-scale friendly algorithm named FairDual, which employs  
537 dual-optimization techniques to minimize the Jensen gap at a sub-linear rate. Extensive experiments  
538 conducted on three large-scale recommendation system backbone models using two publicly available  
539 datasets show that FairDual consistently outperforms all baseline methods.

756 APPENDIX

757  
758 A PROOF OF THEOREM 1

759 *Proof.* Let  $\mathbf{A} \in \mathbb{R}^{|\mathcal{I}| \times |\mathcal{G}|}$  is the item-group adjacent matrix, and  $\mathbf{A}_{ig} = 1$  indicates item  $i \in \mathcal{I}_g$ , and  
760 0 otherwise. Let  $\mathbf{w} \in \mathbb{R}^{|\mathcal{I}|} = [-\sum_{u \in \mathcal{U}} c_{u,i} \log(\hat{c}_{u,i})]_{i \in \mathcal{I}}$ .

761 Firstly, if an item belongs to multiple groups, it often has a greater impact on other items in the model.  
762 Therefore, we will conduct row normalization on the adjacency matrix  $\mathbf{A}$  with size  $I \times G$  to mitigate  
763 this influence: we conduct  $\hat{\mathbf{A}}$  is the row-normalized matrix for  $\mathbf{A}$ :  $\hat{\mathbf{A}} = \text{diag}(\mathbf{A}\mathbf{1})^{-1}\mathbf{A}$ .  $\text{diag}(\mathbf{x})$   
764 denotes to construct a diagonal matrix based on vector  $\mathbf{x}$ .

765 Then, in RS, since the ranking list  $L_K(u)$  is selected according to the highest preference score  $c_{u,i}$ ,  
766 therefore we can re-write Equation (1) as:

767  
768  
769

$$\begin{aligned} \min \quad & \mathbf{1}^\top (\hat{\mathbf{A}}^\top \mathbf{w}) \\ \text{s.t.} \quad & s_g = \sum_{u \in \mathcal{U}} \sum_{i \in L_K(u)} -\frac{\mathbb{I}(i \in \mathcal{I}_g)}{n_i} c_{u,i} \log(\hat{c}_{u,i}) \leq m_g M, \forall g \in \mathcal{G} \\ & \sum_{i \in \mathcal{I}} c_{u,i} \leq K, \forall u \in \mathcal{U}. \end{aligned} \quad (11)$$

770  
771  
772  
773  
774  
775  
776

777 Then we can still write the Equation as

778  
779

$$\begin{aligned} \min \quad & \mathbf{1}^\top (\hat{\mathbf{A}}^\top \mathbf{w}) \\ \text{s.t.} \quad & \max_{g \in \mathcal{G}} (\hat{\mathbf{A}}^\top \mathbf{w})_g \leq m_g M. \end{aligned} \quad (12)$$

780  
781

782 Due to Lagrange dual method (Boţ et al., 2008), we can still convert the problem as:

783  
784

$$\min_{\lambda} \max_{\mathbf{w}} -\mathbf{1}^\top (\hat{\mathbf{A}}^\top \mathbf{w}) + \lambda (\max_{g \in \mathcal{G}} \frac{(\hat{\mathbf{A}}^\top \mathbf{w})_g}{m_g} - M). \quad (13)$$

785

786 Therefore, we can always find a  $\lambda \geq 0$  ( $\lambda$  value relates to the value of  $M$ ), such that we can directly  
787 optimize

788  
789

$$\min \mathbf{1}^\top \hat{\mathbf{A}}^\top \mathbf{w} + \lambda \max_{g \in \mathcal{G}} \frac{(\hat{\mathbf{A}}^\top \mathbf{w})_g}{m_g}. \quad (14)$$

790

791 Let  $\gamma \in \mathbb{R}^{|\mathcal{G}|}$  be the vector  $[1/m_1, 1/m_2, \dots, 1/m_{|\mathcal{G}|}]$ , then the equation can be written as:

792  
793

$$\min \mathbf{1}^\top \hat{\mathbf{A}}^\top \mathbf{w} + \lambda \max_{g \in \mathcal{G}} \gamma_g (\hat{\mathbf{A}}^\top \mathbf{w})_g. \quad (15)$$

794

795 Furthermore, the minimum function  $\max(\cdot)$  can be viewed as the infinite norm function:

796  
797

$$\max \mathbf{x} = \lim_{t \rightarrow \infty} (\mathbf{1}^\top \mathbf{x}^t)^{1/t}.$$

798

799 Then we consider the following function:

800  
801

$$g(\mathbf{x}; \mathbf{k}; s) = (\mathbf{k}^\top \mathbf{x}^{1+s})^{\frac{1}{1+s}},$$

802 where  $\mathbf{0} \leq \mathbf{x} \leq M\mathbf{1}$ . Therefore, Equation (15) can be regarded as a linear trade-off between two  
803 points with the  $\lambda \geq 0$  as the trade-off coefficient:

804  
805

$$\min_{\mathbf{w} \in \mathcal{W}} g(\hat{\mathbf{A}}^\top \mathbf{w}; \mathbf{1}; 0) + \lambda g(\hat{\mathbf{A}}^\top \mathbf{w}; \gamma; \infty).$$

806 Since  $g(\mathbf{x}; t)$  is continuous *w.r.t.*  $t$  and the feasible region of  $\mathbf{x}$  is convex and continuous (because  
807  $\mathbf{w} \in \mathcal{W}$  is the linear transformation over a simplex space (Lindenstrauss et al., 1978)), there exists a  
808 constant number  $t \geq 0$  and  $\mathbf{b} \in \mathbb{R}^{|\mathcal{G}|}$ , s.t. Equation (1) can be optimized as:

809

$$\mathcal{L} = \min \mathbf{b}^\top (\hat{\mathbf{A}}^\top \mathbf{w})^{1+t}.$$

This is because  $t$  is a constant number and  $\mathbf{k}$  for optimizing  $g(\mathbf{x}; \mathbf{k}; s)$  is linear w.r.t. to  $x^{(1+s)}$  (Since the  $x$  is the variable and  $s$  is constant).

Note that the specific value of  $t$  is an implicit function and cannot be solved explicitly in closed form. This is because according to the fact that the function  $g$  is continuous with respect to  $s$  over its entire domain and based on the intermediate value theorem for continuous functions, there must exist a  $t$  such that the linear combination of the linear functions at the two endpoints equals.

Nonetheless, we emphasize that the subsequent methods and proof strategies are independent of the explicit solution for  $t$ . As long as there exists a  $t \neq 0$ , the Jansen gap exists, and as  $\lambda$  increases,  $t$  will also increase.

□

## B LEMMA 1

**Lemma 1.** When  $t \geq 0$ , let

$$f(x) = x^{t+1}$$

where  $x > 0$ . And

$$\begin{aligned} e(i) &= \sum_{l=1}^i f(y_l) \\ \text{s.t. } \sum_{l=1}^i y_l &\leq c, \quad y_l \geq 0 \end{aligned} \tag{16}$$

where  $c$  is a constant number. Then we have when  $j \geq i$ : we have  $\min_{y_j} e(j) \leq \min_{y_i} e(i)$ .

*Proof.* According to the Lagrange dual method, we have

$$\min e(i) = \min_{\lambda \geq 0} \max \sum_{l=1}^i f(y_l) + \lambda \left( \sum_{l=1}^i y_l \right) - \lambda c,$$

then according to the condition of the first derivative equaling zero, we have

$$\frac{\partial e(i)}{\partial y_l} = y_l^t + \lambda = 0, \quad \frac{\partial e(i)}{\partial \lambda} = \sum_{l=1}^i y_l - c = 0.$$

Taking these two condition together, we have:

$$y_k = y_m = \frac{c}{i}, \quad \forall k, m = [1, 2, \dots, i].$$

Therefore, we have

$$\begin{aligned} \min_{y_j} e(j) - \min_{y_i} e(i) &= \min_{y_j} \sum_j f(y_j) - \min_{y_i} \sum_i f(y_i) \\ &= \left(\frac{c}{j}\right)^{1+t} - \left(\frac{c}{i}\right)^{1+t} \end{aligned}$$

Then we can see function  $\frac{1}{x^{1+t}}$  is a decreasing function function, therefore,  $\min_{y_j} e(j) \leq \min_{y_i} e(i)$ .

□

---

## 864 C PROOF OF THEOREM 2

865  
866 *Proof.* Under mini-batch sample strategies, we partition the user set  $\mathcal{U}$  into  $|\mathcal{U}|/B$  subsets and  
867 perform optimization on each subset. For each batch, the optimization becomes

$$868 \mathcal{L}^B = \min \sum_{j=1}^{|\mathcal{U}|/B} \mathbf{b}^\top (\hat{\mathbf{A}}^\top \mathbf{w}_j)^{1+t} \tag{17}$$

$$869 \text{ s.t. } \mathbf{w}_{j,i} = - \sum_{u \in \mathcal{U}_j} c_{u,i} \log(\hat{c}_{u,i}), \forall i \in \mathcal{I}, j \in [1, 2, \dots, |\mathcal{U}|/B],$$

870 where  $\mathcal{U}_b$  is the  $b$ -th partition of the user set  $\mathcal{U}$ .

871 Since the function  $f(x) = x^{1+t}$  is not a linear function, we have

$$872 \sum_{j=1}^{|\mathcal{U}|/B} \mathbf{b}^\top (\mathbf{A}^\top \mathbf{w}_j)^{1+t} \neq \mathbf{b}^\top (\mathbf{A}^\top \mathbf{w})^{1+t}.$$

873 and we can get the Jensen gap

$$874 J(B) = |\mathcal{L}^B - \mathcal{L}| \neq 0.$$

875 Then we will observe how  $e(B)$  changes *w.r.t.* the mini-batch size  $B$ .

876 Let  $\mathbf{e} = \hat{\mathbf{A}}^\top \mathbf{w}$ , where each element  $e_g$  represents the utility (sum of user-item scores) of group  $g$ .  
877 According to the recommendation constraint, we have  $e_g \leq L$ , meaning that the utility of group  $g$  is  
878 at least as high as when all items belonging to group  $g$  are recommended to the users.

879 Therefore, taking  $f(e_g) = e_g^{1+t}$  into Lemma 1, without loss of generality, when batch size  $B_2 \leq B_1$ ,  
880 we have:  $|\mathcal{U}|/B_2 \geq |\mathcal{U}|/B_1$ , we can easily have:

$$881 \min \sum_{j=1}^{|\mathcal{U}|/B_2} (\mathbf{A}^\top \mathbf{w}_j)_g^{1+t} \leq \min \sum_{j=1}^{|\mathcal{U}|/B_1} (\mathbf{A}^\top \mathbf{w}_j)_g^{1+t} \leq \min \mathbf{e}_g^{1+t}.$$

882 Therefore, we have

$$883 \min \sum_{j=1}^{|\mathcal{U}|/B_2} \mathbf{b}^\top (\mathbf{A}^\top \mathbf{w}_j)^{1+t} \leq \min \sum_{j=1}^{|\mathcal{U}|/B_1} \mathbf{b}^\top (\mathbf{A}^\top \mathbf{w}_j)^{1+t} \leq \min \mathbf{b}^\top \mathbf{e}^{1+t}.$$

884 In other words, the mini-batch size becomes smaller, and we are more likely to underestimate the  
885 original loss function that trades off MMF and recommendation accuracy. The recommendation loss  
886 underestimation will result in the Jensen gap when optimizing the loss function constraint with MMF.

887  $\square$

## 904 D LEMMA 2

905  
906 **Lemma 2.** Considering the following function, for  $\lambda > 0, L > 0$  and for the  $d$ -th dimension variable  
907  $\boldsymbol{\mu} \in \mathbb{R}^d$ , when  $\boldsymbol{\mu} \in \mathcal{M}$ :

$$908 r(\boldsymbol{\mu}) = \max_{\mathbf{x} \leq \mathbf{m}} (\min \mathbf{x}/\mathbf{m} + \boldsymbol{\mu}^\top \mathbf{x}/\lambda), \tag{18}$$

909 where

$$910 \mathcal{M} = \left\{ \boldsymbol{\mu} \left| \sum_{i \in [d]} \mu_i m_i \geq -\lambda, \forall [d] \in \mathcal{S} \right. \right\},$$

911 where  $\mathcal{S}$  is power set of  $[1, 2, \dots, d]$ , i.e., the set of all subsets of  $[1, 2, \dots, d]$ .

912 When  $\boldsymbol{\mu} \in \mathcal{M}$ , the optimization function  $r(\cdot)$  has a closed form:  $r(\boldsymbol{\mu}) = \mathbf{m}^\top \boldsymbol{\mu}/\lambda + 1$ , and  
913  $\mathbf{m} = \arg \max_{\mathbf{x} \leq \mathbf{m}} (\min \mathbf{x}/\mathbf{m} + \boldsymbol{\mu}^\top \mathbf{x}/\lambda)$ .

914 When  $\boldsymbol{\mu} \notin \mathcal{M}$ , the function  $r(\cdot)$  will diverge to  $\infty$ .

918 *Proof.* Let the variable  $\mathbf{z} = \mathbf{x}/\mathbf{m} - \mathbf{1}$ . Then we have:

$$919 \quad r(\boldsymbol{\mu}) = \max_{\mathbf{x} \leq \mathbf{m}} [\min \mathbf{x}/\mathbf{m} + \boldsymbol{\mu}^\top \mathbf{x}/\lambda]$$

$$920 \quad = \boldsymbol{\mu}^\top \mathbf{m}/\lambda + 1 + \max_{\mathbf{z} \leq \mathbf{0}} \left[ \min_i \mathbf{z}_i + (1/\lambda) \boldsymbol{\mu}^\top (\mathbf{z} \odot \mathbf{m}) \right],$$

921 where  $\odot$  is the Hadamard product.

922 Let

$$923 \quad \mathbf{v} = \mathbf{m} \odot \boldsymbol{\mu}/\lambda,$$

924 then we define

$$925 \quad s(\mathbf{v}) = \max_{\mathbf{z} \leq \mathbf{0}} \left( \min_i \mathbf{z}_i + \mathbf{z}^\top \mathbf{v} \right).$$

926 From the definition of the region  $\mathcal{M}$ , we can re-wright  $\mathcal{M}$  as

$$927 \quad \mathcal{M} = \{ \mathbf{v} \mid \sum_{i \in [d]} \mathbf{v}_i \geq -1, \forall [d] \in \mathcal{S} \}.$$

928 Suppose that there exists a subset  $\mathcal{S} \in [1, 2, \dots, d]$  such that  $\sum_{i \in \mathcal{S}} \mathbf{v}_i < -1$ . For any  $\epsilon/|\mathcal{S}| > 1$ , we can get a feasible solution:

$$929 \quad \mathbf{v}_i = \begin{cases} -\epsilon/|\mathcal{S}|, & i \in \mathcal{S} \\ 0, & \text{otherwise.} \end{cases}$$

930 Then, because such solution is feasible and  $\min_i \mathbf{z}_i = -\epsilon$ , and  $|\mathcal{S}| \geq 1$ , we obtain that

$$931 \quad s(\mathbf{v}) \geq \min_i \mathbf{z}_i - (\epsilon/|\mathcal{S}|) \left( \sum_{i \in \mathcal{S}} \mathbf{v}_i \right) = -\epsilon \left( \sum_{i \in \mathcal{S}} \mathbf{v}_i + 1/|\mathcal{S}| \right)$$

$$932 \quad \geq \epsilon \left( \sum_{i \in \mathcal{S}} \mathbf{v}_i + 1 \right).$$

933 Let  $\epsilon \rightarrow \infty$ , we have  $s(\mathbf{v}) \rightarrow \infty$ .

934 Then we show that  $s(\boldsymbol{\mu}) = 0$  for  $\mathbf{v} \in \mathcal{M}$ . Note that  $\mathbf{z} = 0$  is feasible. Therefore, we have

$$935 \quad \min_i \mathbf{v}_i \geq s(0) = 0.$$

936 Then we have  $\mathbf{z} \leq 0$  and without loss of generality, that the vector  $\mathbf{z}$  is sorted in increasing order, i.e.,  $\mathbf{z}_1 \leq \mathbf{z}_2, \dots, \leq \mathbf{z}_d$ . The objective value is

$$937 \quad s(\mathbf{v}) = \mathbf{z}_1 + \mathbf{v}^\top \mathbf{z}$$

$$938 \quad = \sum_{j=1}^d (\mathbf{z}_j - \mathbf{z}_{j+1}) \left( 1 + \sum_{i=1}^j \mathbf{v}_i \right) \leq 0.$$

939 Thus we can have  $s(\boldsymbol{\mu}) = 0$  for  $\mathbf{v} \in \mathcal{M}$ . Finally, we can have  $\arg \max_{\mathbf{x} \leq \mathbf{m}} (\min_g \mathbf{x}_g/\mathbf{m}_g + \boldsymbol{\mu}^\top \mathbf{x}/\lambda) = \mathbf{m}$ .

940 □

## 941 E LEMMA 3

942 **Lemma 3.** *The feasible space  $\mathcal{M}$  of dual variable  $\boldsymbol{\mu}$  is convex.*

943 *Proof.* Suppose  $\boldsymbol{\mu} \in \mathcal{M}$ , from Lemma 2, we have

$$944 \quad r(\boldsymbol{\mu}) = \max_{\mathbf{x} \leq \boldsymbol{\gamma}} (\min \mathbf{x}/\boldsymbol{\gamma} + \boldsymbol{\mu}^\top \mathbf{x}/\lambda) < \infty,$$

945 therefore, for any  $\mathbf{b} \in \mathbb{R}_+^{|\mathcal{G}|}$  and  $c > 0$ , we have

$$946 \quad r(\boldsymbol{\mu} + c\mathbf{b}) = \max_{\mathbf{x} \leq \boldsymbol{\gamma}} (\min \mathbf{x}/\boldsymbol{\gamma} + (\boldsymbol{\mu} + c\mathbf{b})^\top \mathbf{x}/\lambda)$$

$$947 \quad = r(\boldsymbol{\mu}) + Lc\mathbf{b}^\top \mathbf{1} < \infty.$$

948 Therefore,  $\boldsymbol{\mu} + c\mathbf{b} \in \mathcal{M}$ . □

972 F PROOF OF THEOREM 3

973  
974 *Proof.* Let  $\mathbf{e} = \mathbf{A}\mathbf{w}$ , where each element  $e_g$  measures the ranking score accumulated among group  
975  $g$ . Let  $L$  be the maximum ranking score for each group, i.e.,  $\mathbf{e} \leq L\mathbf{1}$ .

976 According to the proof in Theorem 1, we can see the Equation (1) can be written as:  
977

$$\begin{aligned} & \min \sum_{u \in \mathcal{U}} \sum_{i \in \mathcal{I}} c_{u,i} \log(\hat{c}_{u,i}) + \lambda (\max_{g \in \mathcal{G}} \mathbf{e}_g / m_g) \\ \text{s.t. } & \mathbf{e}_g = -\frac{\mathbb{I}(i \in \mathcal{I}_g)}{n_i} c_{u,i} \log(\hat{c}_{u,i}), \forall g \in \mathcal{G}. \end{aligned}$$

983 Then the equation can be re-written as:

$$\begin{aligned} & \max_{\hat{c}_{u,i}} \sum_{u \in \mathcal{U}} \sum_{i \in \mathcal{I}} c_{u,i} \log(\hat{c}_{u,i}) + \lambda (\min_{g \in \mathcal{G}} \mathbf{e}_g / m_g) \\ \text{s.t. } & \mathbf{e}_g = \sum_{u \in \mathcal{U}} \sum_{i \in \mathcal{I}} \mathbb{I}(i \in \mathcal{I}_g) c_{u,i} \log(\hat{c}_{u,i}), \forall g \in \mathcal{G}. \end{aligned} \quad (19)$$

989 Then e can utilize the Lagrangian condition (Balseiro et al., 2021) to decompose the relation between  
990  $\mathbf{e}$  and model prediction  $\hat{c}_{u,i}$  in Equation (19):  
991

$$\begin{aligned} & \max_{\hat{c}_{u,i}} \min_{\boldsymbol{\mu}} \sum_{u \in \mathcal{U}} \sum_{i \in \mathcal{I}} c_{u,i} \log(\hat{c}_{u,i}) + \lambda (\min_{g \in \mathcal{G}} \mathbf{e}_g / m_g) - \sum_{g \in \mathcal{G}} \boldsymbol{\mu}_g \left( \mathbf{e}_g - \sum_{u \in \mathcal{U}} \sum_{i \in \mathcal{I}} \mathbb{I}(i \in \mathcal{I}_g) c_{u,i} \log(\hat{c}_{u,i}) \right) \\ & \leq \min_{\boldsymbol{\mu}} \max_{\hat{c}_{u,i}} \sum_{u \in \mathcal{U}} \sum_{i \in \mathcal{I}} c_{u,i} \log(\hat{c}_{u,i}) + \lambda (\min_{g \in \mathcal{G}} \mathbf{e}_g / m_g) + \sum_{g \in \mathcal{G}} \boldsymbol{\mu}_g \left( \mathbf{e}_g - \sum_{u \in \mathcal{U}} \sum_{i \in \mathcal{I}} \mathbb{I}(i \in \mathcal{I}_g) c_{u,i} \log(\hat{c}_{u,i}) \right) \\ & = \min_{\boldsymbol{\mu}} \max_{\hat{c}_{u,i}} \left( \sum_{u \in \mathcal{U}} \sum_{i \in \mathcal{I}} (1 - \sum_{g \in \mathcal{G}} \boldsymbol{\mu}_g \mathbb{I}(i \in \mathcal{I}_g)) c_{u,i} \log(\hat{c}_{u,i}) \right) + \lambda \min_g \mathbf{e}_g / m_g + \boldsymbol{\mu}^\top \mathbf{e} \\ & = \min_{\boldsymbol{\mu}} \max_{\hat{c}_{u,i}} \left( \sum_{u \in \mathcal{U}} \sum_{g \in \mathcal{G}} (1 - \boldsymbol{\mu}_g) \sum_{i \in \mathcal{I}_g} c_{u,i} \log(\hat{c}_{u,i}) \right) + \lambda \min_g \mathbf{e}_g / m_g + \boldsymbol{\mu}^\top \mathbf{e}. \end{aligned} \quad (20)$$

1005 From the Equation (20), we can observe that the recommendation task constrained by max-min  
1006 fairness can be viewed as a re-weighting approach across different groups on the original loss function  
1007 solely optimized for accuracy:  
1008

$$\mathcal{L} = \min - \sum_{u \in \mathcal{U}} \sum_{g \in \mathcal{G}} \mathbf{s}_g \sum_{i \in \mathcal{I}_g} c_{u,i} \log(\hat{c}_{u,i}),$$

1011 where the fairness weight  $\boldsymbol{\mu}$  is determined by

$$\begin{aligned} \boldsymbol{\mu} &= \arg \min_{\boldsymbol{\mu} \in \mathcal{M}} \left( \max_{u \in \mathcal{U}} \sum_{g \in \mathcal{G}} \mathbf{s}_g \sum_{i \in \mathcal{I}_g} c_{u,i} \log(\hat{c}_{u,i}) + \lambda r^*(\boldsymbol{\mu}) \right), \\ r^*(\boldsymbol{\mu}) &= \max_{\mathbf{w} \leq \mathbf{m}} \left( \min_g (\mathbf{A}\mathbf{w})_g m_g + \mathbf{A}^\top \mathbf{w} \boldsymbol{\mu} / \lambda \right) = \mathbf{m}^\top \boldsymbol{\mu} / \lambda + 1. \end{aligned}$$

1019 To make sure the functions do not diverge, we need to ensure  $r^*(\boldsymbol{\mu}) < \infty$ . Taking the  $r^*(\boldsymbol{\mu})$  into  
1020 Lemma 2, we show  $\boldsymbol{\mu} \in \mathcal{M}$ , where

$$\mathcal{M} = \left\{ \boldsymbol{\mu} \mid \sum_{g \in \mathcal{S}} \boldsymbol{\mu}_g m_g \geq -\lambda, \forall \mathcal{S} \in \mathcal{G}_s \right\},$$

1024 where  $\mathcal{G}_s$  is power set of  $\mathcal{G}$ , i.e., the set of all subsets of  $\mathcal{G}$ .  
1025

□

---

## 1026 G PROOF OF THEOREM 4

1027  
1028 *Proof.* We first bound the performance on the primal space.

1029  
1030 Let  $N = \frac{|\mathcal{U}|}{B}$  be the total batch number. Considering the  $j$ -th batch, we have the accuracy loss  
1031 function without fairness at  $j$ -th batch as:

$$1032 \mathcal{L}^j(\text{ACC}) = (\mathbf{s}^j + \mathbf{A}^j \boldsymbol{\mu}^j)^\top \mathbf{l}^j = \mathbf{1}^\top \mathbf{l}^j,$$

1033  
1034 and the max-min fairness loss function will become:

$$1035 \mathcal{L}^j(\text{Fair}) = r^*(\boldsymbol{\mu}) - (\boldsymbol{\mu}^j)^\top \mathbf{e} / \lambda,$$

1036  
1037 therefore, the overall loss across  $\mathcal{L}^B$  on the primal space utilizing batch training will become:

$$1038 N\mathbb{E}_j[\mathcal{L}^j] = N\mathbb{E}_j[\mathcal{L}^j(\text{ACC}) + \lambda\mathcal{L}^j(\text{Fair})]  
1039 = N\mathbb{E}_j[(\mathbf{s}^j + \mathbf{A}^j \boldsymbol{\mu}^j)^\top \mathbf{l}^j + \lambda r^*(\boldsymbol{\mu}) - (\boldsymbol{\mu}^j)^\top \mathbf{e}]  
1040 = \mathcal{L}'^B - N\mathbb{E}_j[(\boldsymbol{\mu}^j)^\top (\mathbf{e} - (\mathbf{A}^j)^\top \mathbf{l}^j)].$$

1041  
1042  
1043 The term

$$1044 w(\boldsymbol{\mu}^j) = (\boldsymbol{\mu}^j)^\top (\mathbf{e} - (\mathbf{A}^j)^\top \mathbf{l}^j)$$

1045 is considered as the complementary slackness in dual theory (Churchman et al., 1957), which captures  
1046 error from the dual transformation. And  $\mathcal{L}'^B$  is the same in Equation (5). Therefore, the original loss  
1047 can be viewed as the dual form augmented with a complementary slackness form.

1048  
1049 **Then we utilize the online gradient descent to bound the complementary slackness.**

1050 Let  $\boldsymbol{\mu} = \sum_{j=1}^N \boldsymbol{\mu}^j$ , then the loss without dividing the full dataset into batches can be represented as:

$$1051 \mathcal{L} = \mathcal{L}' - w(\boldsymbol{\mu}).$$

1052  
1053  
1054 After observing the dual form of  $\mathcal{L}'$ , we can see the  $\mathcal{L}'$  is linear *w.r.t.* dual variable  $\boldsymbol{\mu}$ , therefore, we  
1055 have

$$1056 \mathcal{L}' = \mathcal{L}'^B,$$

1057 and the Jensen gap

$$1058 J(B) = \left| \sum_{j=1}^N w(\boldsymbol{\mu}^j) - w(\boldsymbol{\mu}) \right|.$$

1059  
1060  
1061 Given  $\|\tilde{\mathbf{g}}^j\|_2 \leq G$ , for all  $j$ , we have:

$$1062 \|\mathbf{g}^j\|_2 = \|(1 - \alpha) \sum_{s=1}^j \alpha^{j-s} (\tilde{\mathbf{g}}^s)\|_2 \leq G.$$

1063  
1064  
1065 Next, we will bound the value of  $G$ . Firstly, according to the dual gradient descent, we have:

$$1066 \tilde{\mathbf{g}}^j = \partial(\mathbf{s}^j \mathcal{L}^j + \lambda r^*(\boldsymbol{\mu}^j)) = -(\mathbf{A}^j)^\top \tilde{\mathbf{w}} + \boldsymbol{\gamma}_j.$$

1067 where  $\boldsymbol{\gamma}_j$  is the remain maximum loss column at  $j$ -th updating batch.

1068 Therefore, we have the each element of  $\tilde{\mathbf{w}}_b$  has the bound of

$$1069 \tilde{\mathbf{w}}_b \leq K,$$

1070 since each user can obtain a maximum ranking score of 1 for each preferred item in the ranking  
1071 list with a size of  $K$ . Typically, the group size is smaller than batch size ( $|\mathcal{G}| < B$ ) and there exists  
1072  $c = \max_g m_g$  (typically,  $m_g$  is proportional to the group size  $|\mathcal{G}|$ ). Then we get

$$1073 \|\tilde{\mathbf{g}}^j\|_2^2 \leq |\mathcal{G}|(c + K)^2 \leq L|\mathcal{G}|^2,$$

1074  
1075 where  $L > 0$ .

1080 According to the Theorem 2 in Balseiro et al. (2021), we have

$$\begin{aligned} 1081 J(B) &= \left| \sum_{j=1}^N w(\boldsymbol{\mu}^j) - w_t(\boldsymbol{\mu}) \right| \leq \frac{H}{\eta} + \frac{G^2}{(1-\alpha)\sigma} \eta \frac{|\mathcal{U}|}{B} + \frac{G^2}{2(1-\alpha)^2\sigma\eta} \\ 1082 &= \frac{H}{\eta} + \frac{|\mathcal{U}|L|\mathcal{G}|^2}{B(1-\alpha)\sigma} \eta + \frac{L|\mathcal{G}|^2}{2(1-\alpha)^2\sigma\eta} \end{aligned}$$

1083 where function  $\|\cdot\|_2^2$  is  $\sigma$ -strongly convex. When setting learning rate  $\eta = O(B^{-1/2})$ , the Jensen  
1084 Bound is comparable with  $O(B^{-1/2})$ .

1085 □

## 1092 H GENERALIZABILITY TO OTHER FORMS OF FAIRNESS

1093 In fact, our method can be easily generalized to the user group level by replacing the adjacency matrix  
1094 with a user-side equivalent while keeping the rest unchanged. For the two-sided form, it simply  
1095 requires introducing two coefficients,  $\lambda_1$  and  $\lambda_2$ , and applying two independent dual gradient descent  
1096 updates as described in our algorithm.

1097 In Theorem 1, we demonstrate that our optimization objective is equivalent to the power-family  
1098 fairness framework, which encompasses mainstream fairness definitions such as Entropy Fairness,  
1099  $\alpha$ -Fairness, and Theil Index Lan and Chiang (2011). Consequently, our method is highly adaptable  
1100 and can be generalized to various fairness objectives within this framework.

## 1103 I DETAILS OF EXPERIMENTAL SETTINGS

1104 Here we will provide the details of experimental settings.

### 1105 Detailed Implementation Details.

- 1106 • Environment: our experiments were implemented using Python 3.9 and PyTorch  
1107 2.0.1+cu117 (Paszke et al., 2017). All experiments were conducted on a server with an  
1108 NVIDIA A5000 running Ubuntu 18.04. We implement FairDual with the cvxpy (Diamond  
1109 and Boyd, 2016) for optimization.
- 1110 • Hyper-parameter settings: the learning rate  $\eta \in [1e^{-2}, 1e^{-4}]$  (results shown in Figure 5),  
1111 and trade-off factor  $\lambda \in [0, 10]$  (results shown in Figure 3). We set the  $m_g$  as the group  
1112 size  $m_g = |\mathcal{I}_g|$ . We also tune sample number  $Q \in [50, 400]$  (results shown in the Table 4),  
1113 historical length  $H \in [3, 7]$  (results shown in Table 3), freeze parameter updating gap  
1114  $\beta \in [128, 3840]$  (results shown in Figure 4).
- 1115 • LLMs settings: To mitigate the impact of randomness, we set the temperature coefficient to  
1116 0.2 for the LLM and ran each model three times, taking the average of the results. Other  
1117 LLMs settings are: the penalty for frequency is 0.0, and the penalty for presence is 0.0, the  
1118 maximum generated token number to 1024.
- 1119 • Used toolkit: For the Non-LLMs-RS backbones, we mainly reference the RecBole toolkit<sup>3</sup>.  
1120 For the LLMs tuning, we reference the BigRec pipelines<sup>4</sup>. And we have also included our  
1121 code in the supplementary materials to ensure reproducibility.

1122 **Datasets.** The experiments are conducted on the commonly used two widely used and publicly  
1123 available recommendation datasets, including:

- 1124 • MIND (Wu et al., 2020)<sup>5</sup>: it is constructed from user news click behavior logs on the  
1125 Microsoft News platform. we utilize the major topic category of the news to group the items.  
1126 The dataset contains 94,057 users, 18,801 items, 124,154 interactions, and 17 groups.

1132 <sup>3</sup><https://github.com/RUCAIBox/RecBole>

1133 <sup>4</sup><https://github.com/SAI990323/BIGRec>

<sup>5</sup><https://microsoftnews.msn.com>

- 
- 1134
- 1135 • Amazon-Book <sup>6</sup>: The Amazon dataset from the book domain (He and McAuley, 2016) with  
1136 item grouping based on the "categories" field. As part of the preprocessing (Xu et al., 2024),  
1137 groups containing fewer than 50 items are amalgamated into a single group, referred to as  
1138 the "infrequent group". The dataset contains 15,362,619 users, 1,175,085 items, 1,051,862  
1139 interactions, and 25 groups.
  - 1140 • Amazon-Electronic <sup>7</sup>: The Amazon dataset from the electronic products (He and McAuley,  
1141 2016) with item grouping based on the "categories" field. As part of the preprocessing (Xu  
1142 et al., 2024), groups containing fewer than 50 items are amalgamated into a single group,  
1143 referred to as the "infrequent group". The dataset contains 728,719 users, 160,052 items,  
6,739,590 interactions, and 19 groups.

1144 **Backbones.** For the backbone, we first select three large-scale recommender models:  
1145

- 1146 • **NRMS** (Wu et al., 2019) with 110M parameters utilizes BERT (Devlin et al., 2018) as the  
1147 feature extractor.
- 1148 • **RecFormer** (Li et al., 2023) with 150M parameters utilizes LongFormer (Beltagy et al.,  
1149 2020) to learn text-based representation from items
- 1150 • **BigRec** (Bao et al., 2023a) utilizes Lora techniques (Hu et al., 2021) to fine-tune Llama  
1151 2 (Touvron et al., 2023) (with 7B parameters). Note that BigRec only utilizes 1024 samples  
1152 to train due to large computational cost.

1153  
1154 Meanwhile, we also cover three traditional recommender models:

- 1155 • **BPR** Rendle et al. (2012) utilized a pair-wise loss function to train a matrix factorization  
1156 model for recommendation.
- 1157 • **GRU4Rec** Hidasi et al. (2015) utilized gated recurrent unit network to learn the historical  
1158 behaviors of users.
- 1159 • **SASRec** Kang and McAuley (2018a) utilized attention network to learn the historical  
1160 behaviors of users.

1161  
1162 **Baselines.**

1163 For the baselines, we choose several fair-aware re-weight baselines that aim to improve group MMF:  
1164

- 1165 • **UNI**: each sample has the same weight during training.
- 1166 • **DRO** (Hashimoto et al., 2018): every step, the model only optimizes the worst-off groups to  
1167 enhance group MMF.
- 1168 • **S-DRO** (Wen et al., 2022): improves DRO with the distributional shift to optimize group  
1169 MMF.
- 1170 • **Prop** (Hu et al., 2023) assigns higher group weight to the samples closer to the decision  
1171 boundary in each group.
- 1172 • **IFairLRS** (Jiang et al., 2024) employs the reciprocal of the sum popularity of items within  
1173 the group as the weight assigned to that group.
- 1174 • **Maxmin Sample** (Abernethy et al., 2022) applies optimizing techniques to dynamically  
1175 sample groups.

1176  
1177 Meanwhile, we also choose three fair-aware non-LLMs recommender models that aim to improve  
1178 group fairness:  
1179

- 1180 • **FOCF** (Yao and Huang, 2017) applies a fair-aware regularization loss of different groups  
1181 into non-LLMs RS.
- 1182 • **Reg** (Kamishima and Akaho, 2017) penalizes the squared difference between the average  
1183 scores of two groups for all positive user-item pairs into non-LLMs RS.
- 1184 • **FairNeg** (Chen et al., 2023a) proposed a negative sampling way for pair-wise recommenda-  
1185 tion into non-LLMs RS.

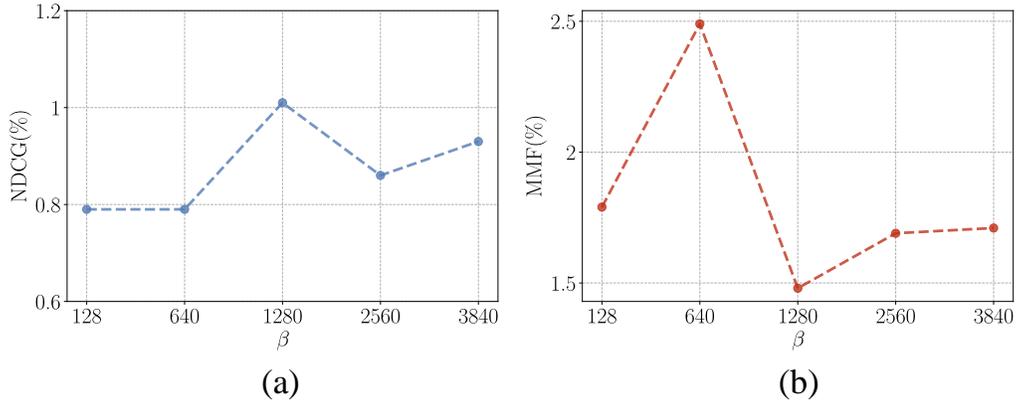

Figure 4: Sub-figure (a) and (b) describe the NDCG and MMF changes *w.r.t.* freeze parameter updating gap  $\beta$ .

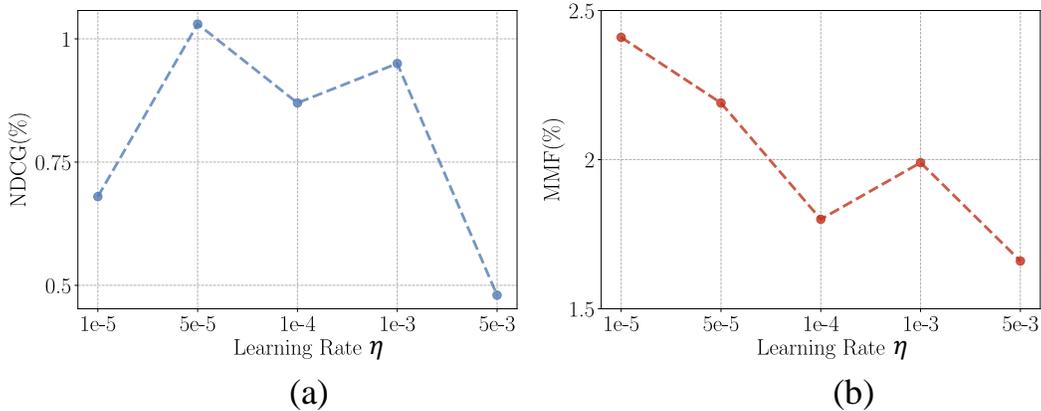

Figure 5: Sub-figure (a) and (b) describe the NDCG and MMF changes *w.r.t.* dual learning rate  $\eta$ .

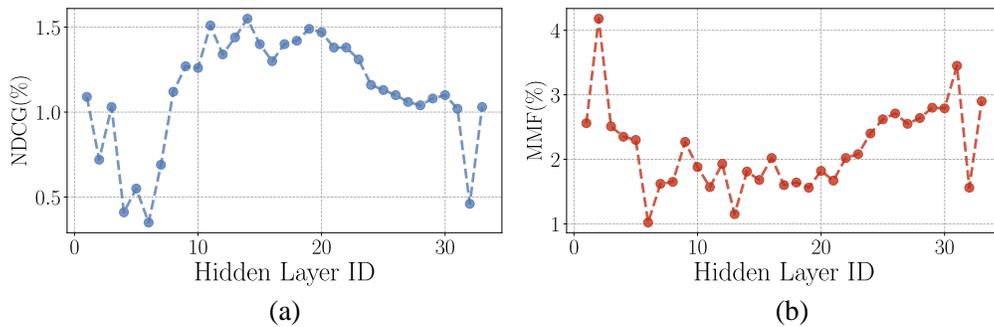

Figure 6: Sub-figure (a) illustrates the density distribution of embeddings for each hidden layer of Llama2. Sub-figures (b) and (c) depict the changes in NDCG and MMF metrics when different hidden layers are utilized to represent user or item embeddings.

Table 3: We conduct empirical experiments to show the effect of the length of item-clicked sequences. The experiments are conducted on the MIND dataset under BigRec backbones. All the numbers with “%” omitted.

History length $H$	NDCG@5	MMF@5	NDCG@ 10	MMF@10	NDCG@20	MMF@20
3	0.79	1.88	1.35	2.79	1.85	3.23
4	0.81	1.63	1.36	2.65	1.99	3.21
5	1.15	2.82	1.69	2.99	2.28	3.39
6	1.04	2.57	1.64	2.66	2.26	3.29
7	1.02	3.27	1.40	3.5	2.16	4.29

Table 4: We conduct empirical experiments to show the effect of the sample size  $Q$ . The experiments are conducted on the MIND dataset under BigRec backbones.

sample size $Q$	50	100	200	300	400	full (unbiased)
NDCG(%)	1.08	1.08	1.15	1.19	1.19	1.29
MMF(%)	1.2	1.28	2.18	2.10	2.29	2.31

## J ANALYSIS FOR HYPER-PARAMETERS

We also conduct analysis for other important hyper-parameters of FairDual on MIND dataset under BigRec base models.

**Inference on Updating Gap  $\beta$ .** We first will investigate the impacts of freeze parameter updating gap  $\beta$ . As shown in Figure 4, we can observe that the accuracy degree (NDCG) increases when  $\beta \in [128, 1280]$  and then drops slightly when  $\beta \in [1280, 3840]$ . Similarly, we can observe that the fairness degree (MMF) increases when  $\beta \in [128, 640]$  and then drops with a large margin when  $\beta \in [640, 3840]$ . The results align with our expectations: excessively frequent updates can lead to instability during training, while infrequent updates may cause the model to miss new ranking patterns, ultimately affecting performance negatively.

**Inference on dual learning rate  $\eta$ .** We then investigate the impacts of dual learning rate  $\eta$ . As shown in Figure 5, we can observe that the accuracy degree (NDCG) increases when  $\eta \in [1e^{-5}, 5e^{-5}]$  and then drops when  $\eta \in [5e^{-5}, 5e^{-3}]$ . On the other hand, the fairness performance drops with  $\eta$  goes larger. The results demonstrate that the learning rate  $\eta$  serves as a trade-off factor: excessively large values detrimentally affect both accuracy and fairness, whereas excessively small values improve fairness at the expense of accuracy in recommendation system models.

**Performances under Different Hidden Layers.** In this experiment, we aim to analyze the FairDual performance under different hidden layers in Llama2. We test the NDCG and MMF performance when we utilize different hidden layers to represent user or item embeddings. From Figure 6 (a) and (b), it is evident that the accuracy (NDCG) and fairness (MMF) trends exhibit distinct patterns: accuracy performance initially ascends, peaking in the middle layer before gradually declining, whereas fairness performance initially descends, hitting a nadir before steadily increasing.

This phenomenon can be interpreted as follows: in the initial layers, which are not yet fully trained, the recommendation system tends to suggest more random items, resulting in lower accuracy but higher fairness. As the layers deepen, the accuracy increases, but it also tends to recommend more unipolar items. Eventually, as the layers approach the last layer, our FairDual model emphasizes fairness more by adjusting the weights for the weaker groups. This will also help us to better understand the mechanisms of FairDual.

**Performances under different lengths  $H$  of item-clicked sequences.** In Table 3, we conduct the empirical experiments to show the effect for the length of item-clicked sequences. The experiments are conducted on MIND dataset under BigRec backbones.

From the experiments, we can observe that the length of history is a trade-off factor for the methods: initially, increasing the length improves accuracy and fairness, but once it reaches a peak, performance begins to drop. We analyze the reason as follows: the length of history sequences indeed influences

Table 5: The convergence time (performance stabilizing within 50 steps) of our method compared to other baselines under BigRec backbones on the MIND dataset.

Model	DRO	Prop	S-DRO	IFairLRS	<b>FairDual(ours)</b>	Improvement
Convergence time	10.1h	11.7h	7.9h	7.1h	<b>5h</b>	28.5%

Table 6: Performances of other fairness metric Gini Index.

Models	GINI@5	GINI@10	GINI@20
Prop	0.488	0.488	0.472
DRO	0.511	0.476	0.487
SDRO	0.503	0.478	0.453
IFairLRS	0.458	0.454	0.448
<b>FairDual(ours)</b>	<b>0.444</b>	<b>0.450</b>	<b>0.441</b>

performance. Sequences that are too short make it difficult to learn user preferences, while sequences that are too long increase computational costs and risk hitting the prompt limit of LLMs.

**Performances under different sample sizes  $Q$ .** Intuitively, a larger  $Q$  provides a more accurate gradient estimation but also incurs higher computational costs. We have conducted experiments to evaluate the impact of  $Q$  and will present the results. The results were conducted under the same settings as the analysis section. The experiments were conducted under BigRec on MIND dataset with ranking size  $K = 5$ .

From the results in Table 4, we observe that increasing the sample value  $Q$  leads to improvements in both accuracy and fairness performance. However, in LLM-based recommender systems, a larger  $Q$  significantly increases training time (with each item requiring an additional 1.5 seconds) and storage space. Different applications should select appropriate  $Q$  values based on their specific accuracy, fairness requirements, and computational constraints.

## K COMPUTATIONAL AND STORAGE COSTS

In Table 5, we measured the convergence time (performance stabilizing within 50 steps) of our method compared to other baselines under BigRec backbones on MIND dataset.

Firstly, we all have parameters of the same magnitude (i.e., group size parameters (hundred level), which are in the range of hundreds and negligible compared to the backbone (million level)). Our method only requires additional space for  $Q$  item embeddings and extra training time ( $1.5Q$ s). Applications can trade off  $Q$  based on available resources (as discussed in a previous response).

Secondly, as observed in Table 5 of the original paper, although there is an additional time overhead per round, our convergence speed accelerates by 30% compared to the best baseline. This 30% improvement in convergence speed is highly significant for industrial applications, along with enhanced performance.

## L PERFORMANCES ON OTHER FAIRNESS METRICS

We test the performances of another fairness metric Gini Index (Do and Usunier, 2022) Compared to the baselines (Table 6) on MIND datasets. Note that a smaller Gini Index means more fairness. From the results, we can observe that our model can still perform well on other fairness metrics. We believe our paper can help other researchers explore its applicability to various loss functions, and other fairness metrics, which is also our contribution to the communities.

1350 Table 7: Popularity bias effect utilizing Inverse Propensity Score (IPS)-based Xu et al. (2022)  
 1351 reweighting method.

$\lambda$	0.1	1	2	5
NDCG(%)				
IPS	0.58	0.58	0.58	0.58
FairDual	0.53	0.60	0.57	0.67
FairDual+IPS	0.59	0.56	0.56	0.58
MMF(%)				
IPS	12.63	12.63	12.63	12.63
FairDual	4.50	11.98	13.46	13.76
FairDual+IPS	10.90	12.40	12.40	14.36

## 1365 M EFFECT OF POPULARITY BIAS

1367 Since the popularity bias will influence the accuracy estimation in real dataset shown in Figure 3, we  
 1368 conduct the experiments on a relatively light transformer-based SASRec (Kang and McAuley, 2018a)  
 1369 backbones and MIND datasets. We apply the Inverse Propensity Score (IPS)-based Xu et al. (2022)  
 1370 to our method to see whether it can improve our methods.

1371 Table 7 shows the results on  $K = 5$  results. From the results, we can observe that when the  $\lambda$  is  
 1372 small, adding the IPS will increase the accuracy and fairness with a large margin due to the popularity  
 1373 bias. However, when  $\lambda$  is large, the FairDual+IPS will not perform very well. This is because IPS  
 1374 will break the convergence condition of FairDual. Therefore, when  $\lambda$  is large, it is preferable not to  
 1375 involve IPS. We will include the related experiments and discussion in the Appendix of the revised  
 1376 paper.
