# How Effective are State Space Models for Machine Translation?

#### **Anonymous ACL submission**

#### Abstract

Transformers are the current architecture of choice for NLP, but their attention layers do not 004 scale well to long contexts. Recent works propose to replace attention with linear recurrent layers-this is the case for state space models, which enjoy efficient training and inference. However, it remains unclear whether these models are competitive with transformers in machine translation (MT). In this paper, we provide a rigorous and comprehensive experimental comparison between transformers and linear recurrent models for MT. Concretely, we 013 experiment with RetNet, Mamba, and hybrid versions of Mamba which incorporate attention mechanisms. Our findings demonstrate that 017 Mamba is highly competitive with transformers on sentence and paragraph-level datasets, where in the latter both models benefit from shifting the training distribution towards longer sequences. Further analysis show that integrating attention into Mamba improves translation quality, robustness to sequence length extrapolation, and the ability to recall named entities.

#### 1 Introduction

035

037

041

The inherent design of attention—the underlying mechanism of transformers—leads to quadratic computational costs and challenges in length generalization (Varis and Bojar, 2021). As an alternative, recent works propose to replace attention with linear recurrent approaches, which enjoy efficient training and inference, and obtain competitive results in language modeling tasks (Katharopoulos et al., 2020; Gu et al., 2022; Peng et al., 2023; Sun et al., 2023a; Gu and Dao, 2023).

In machine translation (MT), there is an increasing demand for supporting longer context lengths, such as paragraphs or entire documents (Fernandes et al., 2021; Wang et al., 2023; Kocmi et al., 2023). Given this trend, it has become increasingly important to design models capable of efficiently handling longer sequences. Previous research indicates that models like state space models (SSMs), exemplified by S4 (Gu et al., 2022), still lag behind transformers in MT (Vardasbi et al., 2023). However, it remains unclear whether these findings hold true for recent, more expressive variations of linear recurrent models, such as RetNet (Sun et al., 2023a) and Mamba (Gu and Dao, 2023), especially on settings that involve the use of pretrained models and long context datasets. 042

In this paper, we provide a rigorous and comprehensive experimental comparison between transformers, RetNet, Mamba, as well as hybrid versions of Mamba that incorporate attention mechanisms (§4). We also compare with pretrained Mamba and Pythia (Biderman et al., 2023) at two parameter scales, ~400M and 1.4B. Building on existing literature that explores the capabilities of linear recurrent models in language modeling (Arora et al., 2023; Jelassi et al., 2024), we further investigate the performance of models trained from scratch in recalling context tokens during the translation process (§4.2). Moreover, we extend our analysis by investigating the models' ability to handle long contexts, on paragraph-level datasets (§5), along with measuring their sensitivity to different sequence lengths ( $\S5.2$ ) and inference cost ( $\S5.3$ ). Overall, our main findings are:<sup>1</sup>

- For sentence-level experiments, we show that Mamba exhibits competitive performance compared to transformers, for both trained-fromscratch and pretrained models.
- At the paragraph level, we find that Mamba is sensitive to the training distribution's sequence length and struggles with longer inputs. However, shifting the distribution towards longer sequence lengths helps to close the gap with transformers.

<sup>&</sup>lt;sup>1</sup>Our code will be released upon acceptance.

• We observe that integrating attention and state space models creates a strong model in terms of translation quality, robustness to sequence length extrapolation, and ability to recall named entities.

# 2 Background

In this section, we present an overview of transformers, and the foundation of the linear recurrent models covered in this paper: linear attention (Ret-Net) and state space models (Mamba).

# 2.1 Transformers

The key component in the transformer architecture is the attention mechanism, which is responsible for contextualizing information within and across input sequences. Concretely, given query  $Q \in \mathbb{R}^{n \times d}$ , key  $K \in \mathbb{R}^{n \times d}$ , and value  $V \in \mathbb{R}^{n \times d}$  matrices as input, where *n* is the sequence length and *d* the hidden size, the single head *self-attention mechanism* is defined as follows (Vaswani et al., 2017):

$$oldsymbol{Y} = ext{softmax}igg(rac{oldsymbol{Q}oldsymbol{K}^ op}{\sqrt{d}}igg)oldsymbol{V} \in \mathbb{R}^{n imes d}.$$
 (1)

For decoder-only models, a causal mask is used to ignore future tokens. Notably, the  $QK^{\top}$  operation leads to a  $\mathcal{O}(n^2)$  cost during training, and  $\mathcal{O}(n)$  during inference with caching and causal masking.

# 2.2 Linear Attention

Denote by  $q_i, k_i, v_i, y_i \in \mathbb{R}^d$  respectively the (column) vectors corresponding to the *i*<sup>th</sup> rows of the matrices Q, K, V, Y defined above. Katharopoulos et al. (2020) reformulate the attention mechanism by casting the role of the softmax as a similarity function sim  $(q, k) = \exp(q^{\top}k/\sqrt{d})$ :

$$\boldsymbol{y}_{i} = \frac{\sum_{j=1}^{n} \operatorname{sim}(\boldsymbol{q}_{i}, \boldsymbol{k}_{j}) \boldsymbol{v}_{j}}{\sum_{j=1}^{n} \operatorname{sim}(\boldsymbol{q}_{i}, \boldsymbol{k}_{j})}.$$
 (2)

110However, any kernel  $k(\boldsymbol{x}, \boldsymbol{y}) : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$ 111is a suitable candidate for the similarity func-112tion (Smola and Schölkopf, 1998; Tsai et al., 2019).113In particular, a kernel  $k(\boldsymbol{x}, \boldsymbol{y}) = \boldsymbol{\phi}(\boldsymbol{x})^{\top} \boldsymbol{\phi}(\boldsymbol{y})$ ,114where  $\boldsymbol{\phi} : \mathbb{R}^d \to \mathbb{R}^r$  is a feature map, leads to:

115  

$$y_{i} = \frac{\sum_{j=1}^{n} \phi(q_{i})^{\top} \phi(k_{j}) v_{j}}{\sum_{j=1}^{n} \phi(q_{i})^{\top} \phi(k_{j})}$$

$$= \frac{\sum_{j=1}^{n} v_{j} \phi(k_{j})^{\top} \phi(q_{i})}{\sum_{j=1}^{n} \phi(k_{j})^{\top} \phi(q_{i})}$$

$$\mathbf{S}^{\top} \phi(q_{i})$$

117 
$$= \frac{S^{\top}\phi(q_i)}{z^{\top}\phi(q_i)},$$
 (3)

where  $S = \sum_{j=1}^{n} \phi(k_j) v_j^{\top} \in \mathbb{R}^{r \times d}$  and  $z = \sum_{j=1}^{n} \phi(k_j) \in \mathbb{R}^r$ . Notably, if initial states are initialized as  $S_0 = \mathbf{0}_{r \times d}$  and  $z_0 = \mathbf{0}_r$ , intermediate states can be computed in a recurrent fashion:

$$oldsymbol{S}_i = oldsymbol{S}_{i-1} + oldsymbol{\phi}(oldsymbol{k}_i)oldsymbol{v}_i^ op,$$

118

147

148

149

150

151

$$\boldsymbol{z}_i = \boldsymbol{z}_{i-1} + \boldsymbol{\phi}(\boldsymbol{k}_i).$$
 (4)

Since we can reuse the same  $S_i$  and  $z_i$  for all queries, this recurrent variant offers a O(n) complexity during training and enjoys a O(1) complexity for inference.<sup>2</sup>

**Retentive Networks (RetNet).** Sun et al. (2023a) set  $\phi$  as the identity function, i.e.,  $k(q, k) = q^{\top}k$ , ignore the normalizer in Equation 2, and introduce an exponential decay mask  $\gamma$ , leading to:

$$oldsymbol{S}_i = \gamma oldsymbol{S}_{i-1} + oldsymbol{k}_i oldsymbol{v}_i^ op,$$
 132

$$\boldsymbol{y}_i = \boldsymbol{S}_i^\top \boldsymbol{q}_i. \tag{5}$$

This formulation effectively biases the attention mechanism to focus on closer token interactions. RetNet also uses XPos (Sun et al., 2023b), a relative positional encoding method, to improve its context extrapolation abilities.

# 2.3 State Space Models (SSMs)

SSMs (Gu et al., 2020) provide an alternative sequence mixing layer by processing sequences  $x_1, ..., x_n$ , where each  $x_i \in \mathbb{R}^d$ , through a linear recurrence. Letting  $H_i \in \mathbb{R}^{r \times d}$  denote the "state" at the *i*<sup>th</sup> time step, a discrete SSM is defined as follows:<sup>3</sup>

$$H_i = AH_{i-1} + bx_i^{\top},$$
  

$$y_i = H_i^{\top}c,$$
 (6)

where  $A \in \mathbb{R}^{r \times r}$ ,  $b \in \mathbb{R}^{r}$ , and  $c \in \mathbb{R}^{r}$  are (discrete) parameters.<sup>4</sup> Since the same parameters are used for both relevant and irrelevant inputs, this model is deemed *input-independent*, which, in turn,

for each input dimension  $j \in [d]$  as

$$h_i^{(j)} = Ah_{i-1}^{(j)} + bx_i^{(j)}, \quad y_i^{(j)} = c^{\top}h_i^{(j)},$$

with A, b, and c shared across input dimensions. This is equivalent to (6), where the  $j^{\text{th}}$ -column of  $H_i$  equals  $h_i^{(j)}$ .

<sup>&</sup>lt;sup>2</sup>In practice, however, this recurrent view is not parallelizable, leading to chunkwise-recurrent variations for training (Hua et al., 2022; Sun et al., 2023a; Yang et al., 2024).

<sup>&</sup>lt;sup>3</sup>A discretization step is needed in order to obtain discrete parameters. For example, a possible method for this step is the zero-order hold rule, used by Mamba (Gu and Dao, 2023). <sup>4</sup>The SSM equations are commonly written independenty

makes the model unable to reset or overwrite its 152 hidden states. S4 (Gu et al., 2022) is an instance of 153 this model, which enjoys a  $\mathcal{O}(n \log n)$  time com-154 plexity during training, and  $\mathcal{O}(1)$  during inference. 155 Vardasbi et al. (2023) shows that S4 still under-156 performs transformers for MT. Finally, note the 157 similarity between Eq. 5 and Eq. 6: RetNets can 158 be seen as state space models with  $A = \gamma I$  and 159 data-dependent b and c. 160

**Mamba.** To make the SSM parameters *data-dependent*, Mamba (Gu and Dao, 2023) introduces a selection mechanism that uses learnable linear projections over x prior to the discretization step, effectively making all parameters dependent on the  $i^{\text{th}}$  input. This leads to:

$$egin{aligned} m{H}_i &= m{A}_i \odot m{H}_{i-1} + m{B}_i \odot m{X}_i, \ m{y}_i &= m{H}_i^\top m{c}_i, \end{aligned}$$

where  $X_i = \mathbf{1}_r \boldsymbol{x}_i^{\top} \in \mathbb{R}^{r \times d}$  is an *r*-sized stack of the input,  $A_i \in \mathbb{R}^{r \times d}$  represents *d* diagonal matrices of size  $r \times r$ ,  $B_i \in \mathbb{R}^{r \times d}$ ,  $c_i \in \mathbb{R}^r$ , and  $\odot$  is the Hadamard product. Note that, unlike S4, where the same *A* and *B* parameters are shared across all hidden dimensions  $1 \leq h \leq d$ , Mamba defines  $A_i$  and  $B_i$  with a shape of  $(\dots, d)$ , allowing for unique parameters in each hidden dimension. While this formulation makes Mamba more expressive, it disrupts the convolutional approach used for training in S4. To address this, Gu and Dao (2023) propose an efficient IO-aware and parallelizable associative scan algorithm for training (Smith et al., 2023). Nonetheless, the recurrent view can still be used for inference with a  $\mathcal{O}(1)$  time complexity.

#### **3** Experimental Setup

We conduct experiments with transformers, RetNet, and Mamba for MT in §4 and §5. In this section, we detail the sentence and paragraph-level datasets used in our experiments, along with the settings for our models, which are trained in two distinct regimes: from scratch, or finetuned from a pretrained checkpoint.

#### 3.1 Datasets

For sentence-level experiments, we focus on WMT14 DE $\rightarrow$ EN and WMT16 RO $\rightarrow$ EN for consistency with previous works (Vardasbi et al., 2023), using the standard training, validation and test splits. For paragraph level, we use the more recent WMT23 dataset (Kocmi et al., 2023),

DATASET	# SAMPLES	# Tokens
$\begin{array}{l} IWSLT17 (\text{de} \leftrightarrow \text{en}) \\ WMT16 (\text{ro} \leftrightarrow \text{en}) \\ WMT14 (\text{de} \leftrightarrow \text{en}) \\ WMT23-6M (\text{de} \leftrightarrow \text{en}) \end{array}$	200K 610K 4.5M 6M	$\begin{array}{c} 45.2 \pm 29.5 \\ 58.9 \pm 31.1 \\ 62.1 \pm 45.6 \\ 58.4 \pm 32.9 \end{array}$
WMT23-CAT-5 ( $DE \leftrightarrow EN$ ) WMT23-CAT-10 ( $DE \leftrightarrow EN$ )	2M 1M	$\begin{array}{c} 171.3 \pm {\scriptstyle 134.9} \\ 312.4 \pm {\scriptstyle 282.3} \end{array}$
Ted Talks Val. (DE↔EN) WMT23 Test (DE→EN) WMT23 Test (EN→DE)	995 549 557	$\begin{array}{c} 268.5 \pm 189.6 \\ 135.1 \pm 147.7 \\ 185.2 \pm 188.2 \end{array}$

Table 1: Sentence and paragraph-level datasets statistics.

which contains  $\sim$ 300M training samples and  $\sim$ 1K test samples incorporating multi-sentence passages. In order to obtain a small high-quality subset for training, we exclude ParaCrawl and CommonCrawl samples from the original dataset and clean the remaining data. Our cleaning process includes three steps. First, we identify and remove samples in incorrect languages via langdetect<sup>5</sup>. Second, we eliminate duplicates. Third, we rank the samples using COMETKIWI-22 (Rei et al., 2022b) a state-of-the-art translation quality estimator, and keep only the top 6M samples. We call the refined dataset WMT23-6M. Datasets statistics are shown in Table 1.

#### 3.2 Models

We make a broad selection of models spanning both trained-from-scratch and finetuned versions. In the first setting, we compare standard transformers, linear recurrent models, and also hybrid approaches that integrate attention into Mamba. For finetuned models, we experiment with released Pythia and Mamba checkpoints. We describe each model next.

#### 3.2.1 Standard Models

**Transformers.** We select two variants of the transformer model as baselines: a base encoder-decoder formulation and a modern decoder-only version. The **Transformer Enc-Dec.** model, as described in the original paper (Vaswani et al., 2017), has 77M parameters, and uses sinusoidal positional embeddings and standard ReLU activations. The second variant, **Transformer++**, is a decoder-only formulation incorporating recent advancements, such as rotary positional embeddings (Su et al., 2023) and the SwiGLU layer (Shazeer, 2020). Specifically, we use the LLaMA architecture (Touvron et al., 2023), adjusting the embedding dimension to match the parameter count of

233

234

<sup>&</sup>lt;sup>5</sup>https://github.com/Mimino666/langdetect

the base transformer (79M), consistent with the version employed in (Gu and Dao, 2023).

Linear recurrent models. We select two representative recurrent models, **RetNet** (Sun et al., 2023a) and **Mamba** (Gu and Dao, 2023). Both models are tested with 77M parameters to approximately match the number of parameters in the transformer models.

### 3.2.2 Hybrid Models

276

Previous work has shown that incorporating attention into linear recurrent models leads to strong performance in language modeling (Fu et al., 2023; Arora et al., 2024; De et al., 2024). Therefore, we aim to examine if this is also the case for MT by exploring three hybrid variants, detailed next.

Mamba-MHA. The simplest hybrid formulation involves replacing some of the Mamba layers with attention. Some natural questions then arise: how many attention layers are needed, and where to place them? After careful ablations, detailed in Appendix B, we use two attention layers placed at the middle and at the output of the network, resembling the hybrid version of H3 (Fu et al., 2023).

Mamba-Local. While aiming to achieve robust performance, the introduction of full attention to Mamba disrupts its efficiency gains. Thus, we consider local attention variants such as sliding window attention (Beltagy et al., 2020; Child et al., 2019), employed in recent hybrid models (Arora et al., 2024; De et al., 2024). We use a window size of 64 based on the average sequence length shown in Table 1 and ablations in Appendix B.

**Mamba Enc-Dec.** Lastly, inspired by the S4based encoder-decoder model from Vardasbi et al. (2023), we replace the self-attention mechanism in transformers with a Mamba block and keep the cross-attention component intact. In terms of complexity, since this variant computes attention over the source sentence, it incurs an additional  $\mathcal{O}(n^2)$ cost for training and  $\mathcal{O}(n)$  for inference.

# 3.2.3 Pretrained Models

In order to fairly evaluate the relative performance between pretrained models, we need to ensure consistency between their pretraining data. Taking this into account, we consider two strong models pretrained on The Pile (Gao et al., 2020): Pythia (Biderman et al., 2023), a modern transformer, and Mamba, a modern SSM. Note, however, that Pythia was pretrained on more tokens than Mamba (see Table 6), hence the comparison might be slightly unfavorable to Mamba. We experiment with two model scales, *small* (S) and *medium* (M). Concretely, we experiment with Pythia 410M and 1.4B, and with Mamba 370M and 1.4B.

# 3.3 Training and Evaluation

For models trained from scratch, we follow the settings proposed in (Vardasbi et al., 2023), whereas for pretrained models, we follow the finetuning settings used by Mamba (Gu and Dao, 2023). For decoder-only models, we pass a concatenation of the source and target sequences separated by a special token as input. We evaluate all models with BLEU (Post, 2018)<sup>6</sup> and COMET (Rei et al., 2022a).<sup>7</sup> We base our analysis on the latter, given its strong correlation with human judgments on sentence and paragraph-level data (Freitag et al., 2022, 2023). More training details can be found in §A.

# 4 Sentence-level Translation

We start by evaluating our standard, hybrid, and finetuned models on the sentence-level WMT16  $RO \leftrightarrow EN$  and WMT14  $DE \leftrightarrow EN$  datasets. Results can be found in Table 2 in terms of BLEU and COMET. Next, we discuss the key findings.

#### 4.1 Discussion

Mamba is competitive when trained from scratch. Mamba, a decoder-only model, not only outperforms a decoder-only transformer (Transformer++) across the board, but also an encoderdecoder transformer (Transf. Enc-Dec) in the larger WMT14 for both DE $\leftrightarrow$ EN language pairs. This creates a contrast with the S4 results obtained by Vardasbi et al. (2023). We hypothesize that Mamba's good results are due to its data-dependent state updates (Eq. 7), which allows for more precise information retention in its hidden state. On the other hand, RetNet's performance is generally subpar compared to other models, likely due to its strong locality bias (induced by  $\gamma$  in Eq. 5), which may hinder performance in MT, a task where the source input servers as a prefix to the translation, and it requires "focused attention" during decoding.

Attention benefits Mamba. By including attention layers in Mamba's architecture, we find that Mamba-MHA, which employs only two attention

Table 2: Sentence-level results in terms of BLEU and COMET for models trained from scratch (top) and models finetuned from a pretrained checkpoint (bottom). **Bold** represents top results; <u>underline</u> represents second-best.

layers, is able to outperform both transformers
and Mamba for almost all language pairs. While
Mamba-Local retains constant inference complexity via windowed attention, it is not as strong as
the full attention variant. Finally, Mamba EncDec's performance is also competitive, falling just
short of Mamba-MHA and echoing the S4 encoderdecoder findings of Vardasbi et al. (2023).

**Pretraining improves all models.** We note a large COMET gap, roughly 4-8 COMET points, between the finetuned models and those trained from scratch for all language pairs. This is expected, since not only are these models bigger, but they also have strong data-driven priors, which are beneficial in downstream tasks (Amos et al., 2024).

340

341

342

344

Larger models achieve top results. For small 345 models, Mamba outperforms Pythia for RO \leftrightarrow EN in 346 terms of COMET and BLEU. However, Pythia is 347 superior on the larger  $DE \leftrightarrow EN$  datasets. Moving to larger models, we note that Mamba improves 349 COMET scores by  $\sim 1$  point on EN $\leftrightarrow$ DE while dropping only 0.1-0.2 on  $EN \leftrightarrow RO$  datasets. On the other hand, Pythia improves results consistently for 353 all language pairs with a larger model size, outperforming or matching the results of other models. 354 On average, we find that both their gaps decrease when moving from smaller to medium-sized models but Pythia benefits more in terms of COMET. It 357

is worth noting that Mamba is pretrained on fewer samples than Pythia (see Table 6) and that the impact of pretraining data quality can also play a role in downstream task performance.

#### 4.2 Recall of Named Entities

Following our discussion of sentence-level translation, we now focus on how well these models recall context tokens during translation. Inspired by prior studies investigating the recall of context tokens in language modeling with state space models (Arora et al., 2023; Jelassi et al., 2024), we conduct a similar experiment for MT. Unlike language modeling, where token patterns often recur within a near context, MT presents a challenge due to the distinct spelling of words across languages. Therefore, we focus on the recall of named entities (NEs) that appear verbatim in both source and target sentences, using NLTK for NE recognition (Bird, 2006).

We assess the models' ability to recall NEs from the WMT16 RO $\rightarrow$ EN dataset according to their frequency in the training set, as illustrated in Figure 1. The results reveal a clear correlation between NE frequency and their chance to be recalled in the translation process, as more frequent NEs are recalled more often. Notably, we note a disparity in performance with unseen entities, which provides a more illustrative view of recall ability. In this respect, transformers and Mamba perform on par,

while RetNet shows inferior results. As before, the hybrid models are promising, with Mamba-MHA outperforming all models, followed closely by Mamba Enc-Dec.

While Mamba shows competitive performance with transformers on sentence-level datasets (see Table 2), it was originally designed to handle long sequences. Thus, we now turn our attention to paragraph-level datasets. This allows us to study the models' sensitivity to long sequence lengths along with their robustness in handling sequences that are longer than the ones seen during training.<sup>8</sup>

To this end we focus on the WMT23-6M dataset (\$3.1), from which the training and test sets are composed of sentence and paragraph-level passages, respectively. In order to see the impact of training on long sequences, we propose to artificially construct multi-sentence datasets, which we call WMT23-CAT-N. Our procedure is as follows:

- 1. We first retain the original training samples from WMT23-6M with a probability of 50%.
- 2. Next, for the remaining part, we concatenate *N* random training samples.

This approach ensures that we consistently main-410 tain a 50% ratio between single-sentence and multi-411 sentence samples. For validation, we sample 412 1-to-10-sentence passages from the TED Talks 413 dataset (Cettolo et al., 2012). Statistics for CAT-N414 datasets can be found in Table 1. COMET scores on 415 the WMT23 EN $\leftrightarrow$ DE test sets are shown in Table 3. 416 We provide additional BLEU scores in Table 8 in 417 Appendix D. Next, we discuss our key findings. 418

#### 5.1 Discussion

**Concatenation helps.** Our strategy of concatenating sentences proves beneficial for almost all models, as COMET scores tipically improve with the CAT-5 and CAT-10 datasets, whether models are trained from scratch or finetuned. Among models trained from scratch, Transformer Enc-Dec, Mamba-MHA, and Mamba Enc-Dec show substantial improvements, with Mamba Enc-Dec achieving the best overall results. For finetuned models, concatenation benefits larger models; Mamba-M outperforms Pythia-M in  $DE \rightarrow EN$  but underperforms in  $EN \rightarrow DE$ . Interestingly, for both training regimes, the concatenation strategy can lead to COMET gains of up to 5 points.

**Finetuning outperforms training from scratch.** Finetuned models consistently achieve higher COMET scores, with larger models attaining the top results overall. Similar to sentence-level experiments, Pythia outperforms Mamba when trained on the original, WMT23-6M dataset. However, both Pythia and Mamba benefit from our concatenation strategy. While these results indicate that our concatenation strategy helps in translating long inputs, it remains unclear whether performance on short inputs is compromised or if the models can handle longer inputs than those seen during training. We investigate these issues next.

#### 5.2 Sensitivity to Input Length

Based on the previous observations, we notice that performance between models varies considerably after being exposed to different sequence lengths during training. In this subsection, we investigate how robust each model is to length distribution shifts between training and test. Results are shown in Figure 2 for both training regimes on the WMT23 DE $\rightarrow$ EN dataset. Results are consistent for EN $\rightarrow$ DE, shown in Figure 4, Appendix C.

<sup>&</sup>lt;sup>8</sup>We dropped RetNet and Mamba-Local as they already achieve poor results on long *sentence-level* inputs (see Fig. 3).

		DE→EN			EN→DE		
Model	Size	ORIG.	CAT5	CAT10	ORIG.	CAT5	CAT10
Trained from scratch							
Transf. Enc-Dec	77M	72.4	74.6	69.6	65.2	<u>70.3</u>	<u>70.3</u>
Transformer++	79M	70.7	73.6	72.8	64.8	69.1	68.8
Mamba	77M	70.0	73.3	72.3	63.3	67.5	67.8

Mamba-M	1.4B	74.6	79.6	<u>79.5</u>	73.4	77.5	77.3

Table 3: Paragraph-level results in terms of COMET for models trained from scratch (top) and models finetuned from a pretrained checkpoint (bottom) on WMT23 EN↔DE test set, according to the training dataset: original WMT23-6M, WMT23-CAT-5 and WMT23-CAT-10. **Bold** represents top results; <u>underline</u> represents second-best.

Figure 2: Sensitivity to input length, measured by the number of sources tokens, on the WMT23  $DE \rightarrow EN$  datset, for models trained from scratch (top) and finetuned from a pretrained checkpoint (bottom).

**Discussion.** When training on WMT23-6M, we observe a decline in performance for all models on long sequences, affecting both trained-from-scratch and finetuned variants. Interestingly, this degradation is evident in Mamba, as expected due to its finite hidden state capacity. However, it is also challenging for transformers despite their relative positional embeddings. Moreover, both finetuned and hybrid models exhibit more consistent performance across different sequence lengths, even on the original sentence-level dataset, suggesting a more robust capability for dealing with long-context inputs.

Overall, our concatenation approach has largely mitigated the performance issues with long inputs present in models trained on WMT23-6M, as models trained on CAT datasets produce higherquality translations for longer sequences. This improvement is uniform across all models, with CAT-10 yielding consistently better translations in the longest bin (257+ tokens). However, the CAT-10 dataset seems to reduce translation quality for shorter samples in some models, though this effect is minimal or absent in hybrid and finetuned models. We further examine the ability to extrap-

In §2 we covered the theoretical time complexity of our models in training and inference time. Here, we examine the wallclock time and memory usage of Pythia and Mamba in a realistic setting where inputs are WMT23 DE $\rightarrow$ EN test samples, and outputs continue to be generated until they reach exactly  $L \in \{512, 1024\}$  tokens. Table 4 shows that Mamba's memory usage is significantly lower than Pythia's, with gaps of ~ 3-5x overall. The wallclock time difference is not as notable but still substantial, especially for larger models, where Mamba-M is 2x faster than Pythia-M for L = 1024. In other words, Mamba-M throughputs ~806 tokens/s while Pythia-M outputs ~405 tokens/s, aligning with (Gu and Dao, 2023).<sup>9</sup>

#### 6 Related Works

Linear recurrent models for MT. Our work is closely related to (Vardasbi et al., 2023), which compares SSMs and transformers. Furthermore, they also experiment with hybrid architectures composed of S4 and attention layers, an approach that has since become common (Arora et al., 2024; De et al., 2024; Glorioso et al., 2024). In this work, we experiment with more recent linear recurrent models and their respective hybrid versions while also including larger and pretrained variants. Our analysis further includes investigating each model's ability to recall named entities, along with measuring translation performance across different sequence lengths on paragraph-level datasets. In contrast to Vardasbi et al. (2023)'s results showing that S4 lags behind transformer baselines in MT tasks, we observe that Mamba, a modern SSM, is competitive

Linear recurrent models' limitations. Recent works show that Mamba struggles in tasks that involve recalling context tokens (Arora et al., 2023; Jelassi et al., 2024), such as the synthetic Multi-Query Associative Recall task. In MT, however, context tokens (source and translation prefix) are not often replicated in the output (translation). In this work, we study this phenomenon with named entities and analyze the recall ability of transformers and linear recurrent models in §4.2.

**Sentence concatenation** Kondo et al. (2022); Varis and Bojar (2021) analyze transformers' generalization towards sequence length. They show that transformers are susceptible to the training distribution of context length and that concatenating multiple sentences can improve the translation of longer sentences. Specifically, Kondo et al. (2022) augment the original data with samples containing concatenations of two random sentences, while Varis and Bojar (2021) concatenate up to six sentences. While these studies focused on sentencelevel translation with sequence lengths up to 120 tokens, in this work, we extend the analysis to much longer sequences and test on paragraph-level data from the WMT2023 dataset.

### 7 Conclusion

We set out to evaluate recent linear recurrent models, particularly RetNet and Mamba, in MT tasks while thoroughly comparing them to transformer baselines and hybrid models, which combine Mamba and attention. We find that Mamba models are competitive with transformers, both when they are trained from scratch and when they are finetuned from a pretrained checkpoint; however, the performance delta is smaller in the latter regime. Our paragraph-level experiments reveal that models are hindered by the mismatch in the training and test length distributions; however, a simple concatenation approach helps to mitigate the issue. We find that hybrid models are only slightly affected by this issue while also being competitive or outperforming transformers. Finally, we note that Mamba models also exhibit a faster runtime and consume less memory than transformers.

with transformers on sentence and paragraph-level datasets, whether trained from scratch or fine-tuned from a pretrained checkpoint, especially in the first setting when equipped with attention mechanisms.

We point out some limitations of the presented 568 study. First, one limitation is that we refrain from 569 pretraining the hybrid models due to the high as-570 sociated compute costs. To this effect, while our 571 trained-from-scratch results are promising, validating them with a larger scale and strong language 573 priors would strengthen our claim of their good performance. Secondly, our experiments ((C.3)) 575 appear to indicate larger models are more robust to sequence length issues. Nonetheless, we limited our study to models with parameter scales between 578 370M and 1.4B since, in preliminary sentence-level experiments, translation quality gains plateaued at 580 the latter scale. 581

In another direction, we mainly rely on automated metrics for evaluating translation quality, which might not fully capture the accuracy of the translation. We alleviate this fault by considering the recollection of NEs in translations (§4.2). Furthermore, our experiments in §5.2 do not have a notion of translation difficulty, which might help explain the differences between models and associated datasets in different length buckets (albeit sentence length and difficulty may be connected).

# Potential Risks

Translation biases and error modes inherent in transformed-based LLMs could also be manifested in the linear recurrent models studied in this paper. Careful evaluation and mitigation strategies, such as detecting and overcoming hallucinations (Guerreiro et al., 2023; Dale et al., 2023), can alleviate these risks and ensure models' responsible use. It should also be noted that although SSMs are potentially more energy efficient than transformerbased models, they still pose energy consumption concerns, particularly due to the large size of the models.

#### A Implementation and Training Details

All experiments were carried on Nvidia RTX A6000 GPUS with 48GB VRAM, and the training framework is constructed around PyTorch Lightning.<sup>10</sup> To train and generate translations in batches, we use a left-padding strategy. However, for Mamba, additional functionality is required to avoid processing padding tokens. To address this, we zero out inputs before and after convolution at the positions of the padding tokens and sacrifice some efficiency by using the slow path in Mamba<sup>11</sup>. Notably, during inference, the slow path affects only the initial processing of the prompt and does not impact the actual generation. Moreover, we added Dropout (Srivastava et al., 2014) to Mamba blocks, which was missing in the original implementation. Specifically, dropout is applied after the last linear projection of the Mamba block. Additionally, following the findings in (Vardasbi et al., 2023), we calculate cross-entropy loss only for target tokens. During training, we use greedy decoding and select the top model using BLEU as the validation metric, as it is faster to compute in comparison to COMET. For inference, we use beam search with a beam size of 5. Due to the time-consuming nature of our experiments, we report the results of a single run for all experiments. The overall model structure and hyperparameters across both training regimes, from-scratch (§A.1) and finetuning (§A.2), are shown in Table 5. Furthermore, all models were trained with bfloat16 precision.

#### A.1 Training from Scratch

Regarding tokenization, we leverage the Hugging-Face *tokenizers* library<sup>12</sup> and construct a separate BPE tokenizer (Sennrich et al., 2016) per dataset. The total vocabulary size is 32000 tokens. We carried out a hyperparameter search to select appropriate dropout values, learning rates and architectural decisions, with the latter two detailed in Table 5. We employ a dropout of 0.3 and 0.1 for both WMT14 and the different variations of WMT23. Other hyperparameters were kept intact. Concretely, we use the Inverse Square Root learning rate scheduler (Vaswani et al., 2017) with 4000 warmup steps and a weight decay of 0.001.

MODEL	Size	LR	L	Н	D	FFN		
Trained from scratch								
Transf. Enc-Dec	77M	4e-4	6-6	8	512	2048

Mamba-MHA	78M	7e-4	24	8	624	-		
Mamba-Local	78M	7e-4	24	8	624	-		
Mamba Enc-Dec	82M	7e-4	8-6	8	512	2048		
Finetuned								
Pythia-S	410M	1e-5	24	16	1024	4096		
Mamba-S	370M	3e-4	24	-	1024	-		
Pythia-M	1.4B	1e-5	24	16	2048	8192		
Mamba-M	1.4B	3e-4	24	-	2048	-		

Table 5: Detailing the full set of hyperparameters for the different models. Encoder-Decoder models have their number of layers separated by each module. LR represents the Learning Rate; L represents the number of layers; H is the number of Attention Heads; D is the model dimension; FFN is the size of the inner feedforward network.

MODEL	Size	TRAINING TOKENS	Context tokens
Pythia-S	410M	300B	2048
Pythia-M	1.4B	300B	2048
Mamba-S	370M	7B	2048
Mamba-M	1.4B	26B	2048

Table 6: Pre-training details. All models were pretrained on The Pile (Gao et al., 2020).

#### A.2 Finetuning Pretrained Checkpoints

We employ pretrained models and corresponding tokenizers from the Huggingface library. Table 6 shows the number of tokens and the size of the context window used during pretraining. For finetuning, in all experiments, we use a dropout of 0.1 with the exception of WMT16 EN $\leftrightarrow$ RO, where dropout varies from 0.1 to 0.3. Moreover, we use weight decay only in Mamba-M, with a value of  $2 \cdot 10^{-4}$ . Additionally, learning rates and models' attributes are shown in Table 5.

## A.3 Inference Cost

For the inference cost experiments, we measure overall wallclock time using cuda events and cuda synchronization from torch.cuda module. The overall time includes the entire generation pipeline. Moreover, we use torch.cuda.max\_memory\_allocated to measure memory usage. 937

Building on the shortcomings of linear models (Akyürek et al., 2024; Arora et al., 2023; Jelassi et al., 2024), we designed hybrid models to complement SSMs with attention mechanisms. In this section, we ablate the design choices leading to the construction of our hybrid models. These experiments were conducted using the IWSLT17 DE $\leftrightarrow$ EN dataset (Cettolo et al., 2017). Results are shown in Table 7.

Since our Mamba-MHA model replaces a set of Mamba layers with attention modules, we ablated various configurations to determine the optimal number and placement of attention layers. Our analysis of COMET scores indicated that incorporating two attention layers significantly boosted performance, aligning with findings in previous studies (Fu et al., 2023). The placement of these layers had a minimal effect, leading us to select the configuration with layers at positions N/2 and N for further experiments due to its consistently higher COMET scores.

In the case of Mamba-Local, which uses a sliding window attention, we explored various window sizes. Our experiments revealed that performance generally improved with window size in a linear way. Ultimately, a 128-token window nearly matched full attention performance, and two layers of 64-token windowed attention provided a good balance between performance and efficiency for our experiments.

Before experimenting with paragraph-level data, we analyze how our trained-from-scratch models perform on different sequence lengths. To this end, we study their sensitivity to input length when trained and tested on WMT14 DE $\rightarrow$ EN. The results are shown in Figure 3. While all models show a deterioration in performance as sequence length increases, this effect is more pronounced for Transformer++, RetNet, and Mamba-Local, with a significant drop in performance for samples longer than 64 tokens.

#### C.2 Sensitivity to Input Length

Following the discussion in §5.2, we further investigate the sensitivity of our models to input length using the WMT23 EN $\rightarrow$ DE test set, with results shown in Figure 4. Notably, our takeaways remain broadly the same: concatenating samples in the training data is indeed helpful when handling longer sequences, and models trained on the WMT23-CAT-10 dataset are much better in the longer bin (257+) with minimal translation quality degradation in shorter samples. However, when considering each of the training datasets' histograms in Figure 5, we can observe that models have been exposed to the longest samples during training, even if in low quantities. This implies that the previous experiments do not represent an extrapolation setting, where inference is done on longer sequence lengths than those seen during training. We cover extrapolation to longer sequences next.

#### C.3 Extrapolation to Longer Sequences

Following the previous discussion, to further explore the impact of sequence length on our models,

Figure 4: Sensitivity to input length, measured by the number of sources tokens, on the WMT23 EN $\rightarrow$ DE datset, for models trained from scratch (top) and finetuned from a pretrained checkpoint (bottom).

we create a new test set sampled from TED Talks DE $\rightarrow$ EN passages that is much larger (2200 samples) and contains much longer sequences. The source length distribution can be seen in Figure 5 (bottom right). After evaluating our models in this dataset, we plot COMET scores per sentence length in Figure 6. Note that the dashed vertical line rep-1028 resents the bin containing the longest sentences the model has been exposed to during training.

Discussion. We observe some interesting behav-1031 ior: when training from scratch, the translation 1032 quality of Transformer++, Mamba, and Mamba-1033 MHA falls sharply when handling 769+ tokens, 1034 whereas Mamba Enc-Dec excels even in pure ex-1035 trapolation settings on the longest inputs. With the finetuned models, we also see decreasing translation quality over longer sequences, consistent 1038 with previous experiments. Nonetheless, Mamba 1039 models show a more robust trend. In particular, Mamba-M extrapolates well to longer sequences when trained on CAT-10. For example, for models 1042 trained on CAT-10, the best COMET score for in-1043 puts longer than 1024 tokens for Pythia-M is  $\sim 68$ , 1044 1045 while Mamba-M is able to achieve a score of  $\sim$ 75. The gap increases and reaches almost 20 points as we increase the sequence length. 1047

#### **Full Paragraph-Level Results** D 1048

For completeness, we report paragraph-level results in terms of BLEU and COMET for all language pairs and models in Table 8.
