DIG-MILP: a Deep Instance Generator for Mixed-Integer Linear Programming with Feasibility Guarantee

Anonymous authors
Paper under double-blind review

Abstract

Mixed-integer linear programming (MILP) stands as a notable NP-hard problem pivotal to numerous crucial industrial applications. The development of effective algorithms, the tuning of solvers, and the training of machine learning models for MILP resolution all hinge on access to extensive, diverse, and representative data. Yet compared to the abundant naturally occurring data in image and text realms, MILP is markedly data deficient, underscoring the vital role of synthetic MILP generation. We present DIG-MILP, a deep generative framework adept at extracting deep-level structural features from highly limited MILP data and producing instances that closely mirror the target data. Notably, by leveraging the MILP duality, DIG-MILP guarantees a correct and complete generation space as well as ensures the boundedness and feasibility of the generated instances. Our empirical study highlights the novelty and quality of the instances generated by DIG-MILP through two distinct downstream tasks: (S1) We identify Data Sharing, which involves MILP solver tuning without directly sharing the original data. Experiments show that solver solution time on instances generated by Dig-MILP correlate highly positively with the original data, offering a potential solution direction.; (S2) Data Augmentation, wherein the DIG-MILP-generated instances bolster the generalization performance of machine learning models tasked with resolving MILP problems.

1 Introduction

Mixed integer linear programming (MILP) is a prominent problem central to operations research (OR) (Achterberg & Wunderling, 2013; Wolsey, 2020). It forms the basis for modeling numerous crucial industrial applications, including but not limited to supply chain management (Hugos, 2018), production scheduling (Branke et al., 2015), financial portfolio optimization (Mansini et al., 2015), and network design (Al-Falahy & Alani, 2017; Radosavovic et al., 2020). This article aims to answer the question: *How can one produce a series of high-quality MILP instances?* The motivation behind this inquiry is illustrated through the subsequent scenarios, where the definition of "high-quality" varies based on the specific requirements of each context.

(Scenario I). In industry, clients from real-world business seek specialized companies to develop or fine-tune intricate solver systems (Cplex, 2009; Bestuzheva et al., 2021; Gurobi, 2023) for solving MILP problems. The empirical success of the systems heavily depends on well-tuned hyper-parameters for the solvers, which demands ample and representative testing cases that accurately reflect the actual cases. However, real data is often scarce during the early stages of a business. In addition, clients are typically reluctant to publish data that might encompass some specific information (e.g., schedules or contract stipulations for flight arrangement (Richards & How, 2002; Roling et al., 2008), platform costs or audience data for ad placements (Rodríguez et al., 2016)). In this scenario, the goal is to generate new instances randomly, without sensitive information, but with similar solution times across different settings. By sharing these synthetic instances with solver developers, they can refine algorithms or configurations based on these instances, thereby gaining valuable insights and potentially applying these improvements directly to real-world cases.

(Scenario II). Beyond the development and testing of MILP algorithms by domain experts (Lawler & Wood, 1966; Gamrath et al., 2015), recent efforts have explored machine learning (ML) to derive heuristic

algorithms directly from data (Khalil et al., 2016; 2017; Nair et al., 2020). The effectiveness of ML-driven methods heavily relies on the availability of extensive and representative training data (Lu et al., 2022). Given the scarcity of MILP instances compared to other data types like images or texts, there arises a necessity for instance generation. In this scenario, the objective is to augment the training data to improve the generalization performance of ML models on MILP tasks.

Both scenarios underscore the motivation to synthetically generate novel instances that resemble the limited existing MILP data. Compared with some existing methods tailored to specific problems (e.g., knapsack (Hill et al., 2011) and quadratic assignment (Drugan, 2013)), our approach focuses on a more **general framework** for MILP generation. We aim for our proposed method to be capable of generating instances for a variety of problems, as long as they can be formulated as MILPs. This general-purpose MILP generator potentially has wider applications compared to more specialized solutions.

A major challenge in synthetic MILP generation is ensuring **representativeness**. This demands that the generated instances should closely mirror the original data in terms of scale, modeling logic (the structure of the objective and constraints), and key mathematical properties such as feasibility and boundedness.

In this paper, we are particularly interested in generating **feasible and bounded** MILP instances. In many applications, practitioners are required to formulate feasible and bounded MILPs; otherwise, adjustments to the formulas or numerical values are necessary. Take, for instance, the Unit Commitment problem in power grid systems. The goal is to determine which power generation units should be turned on or off to meet energy demands at the lowest cost, adhering to operational constraints like minimum downtime and startup times. The problem must be feasible to ensure there is always enough generation capacity online to meet demand. An infeasible solution means that there is no possible combination of on/off statuses for generation units that meet the required demand. Unfortunately, a randomly generated MILP with naive approaches is likely to be infeasible or unbounded. [1] Given that determining the feasibility of an MILP is NP-Complete (Conforti et al., 2014; Hartmanis, 1982), methods that simply generate and then discard infeasible instances are inefficient. Thus, there is a clear need for generating MILPs with guaranteed feasibility and boundedness.

Existing methods for MILP generation fall short of fulfilling the criteria above. Some approaches generate new instances in an embedding space with handcraft statistics (Smith-Miles & Bowly, 2015; Bowly, 2019). These methods model MILPs' coefficients with simple distributions such as Gaussian, generating instances with very limited structural characters that may not be representative enough. A concurrent paper (Geng et al., 2024) with our work learn the MILP distribution over instance space with neural networks (NNs). The generated instances from Geng et al. (2024) do not enjoy feasibility-boundedness guarantee.

By employing deep neural networks (NNs) to extract the in-depth structural information, our proposed method DIG-MILP generates "representative" data that resembles the original samples without expert knowledge. Additionally, DIG-MILP leverages the MILP duality theories to ensure the feasibility and boundedness of each generated instance by controlling its primal format and the dual format of its linear relaxation having at least a feasible solution, which achieves the "feasibility-boundedness" of the generated data. Moreover, any feasible-bounded MILP is inside the generation space of DIG-MILP, meeting the demand for "generality". An illustration of DIG-MILP's generation strategy is shown in Figure. 1. Recognizing the limited original data along with the requirements on scalability and numerical precision in MILP generation, instead of generating

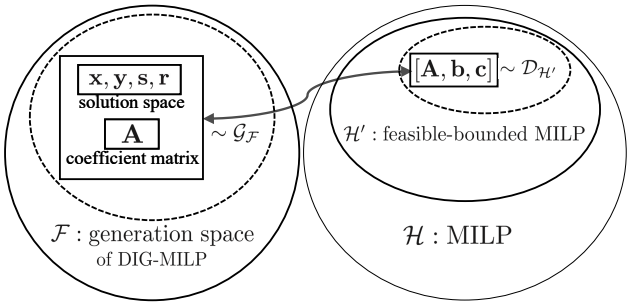

Figure 1: DIG-MILP generates feasible-bounded instances that resemble the target MILP data from distribution $\mathcal{D}_{\mathcal{H}'}$ by learning to sample the coefficient matrix along with a set of feasible solutions for both the primal format and dual format of the linear relaxation from the corresponding distribution $\mathcal{G}_{\mathcal{F}}$. See detailed explanations in Section. 3.

[1] As noted in Section 4.1 of (Bowly et al., 2020), only 37.5% of the LP instances generated by naive methods are feasible and bounded, and this proportion decreases further when integer constraints are involved.

from scratch, DIG-MILP iteratively modifies parts of existing MILPs, allowing control on the degree of structural similarity towards the original data.

We conduct two downstream tasks to validate the quality and novelty of DIG-MILP-generated instances, corresponding to the motivation of data generation in industry and in academia respectively. The first task is to measure whether the examples generated by DIG-MILP show a positive correlation in terms of the time required to solve them on the solver with the same hyper-parameters, compared to the original examples. Across four problems, the solution time of solver SCIP (Bestuzheva et al., 2021) exhibits a highly positive correlation between the DIG-MILP-generated instances and the original data w.r.t. different hyper-parameter sets. The experiments can be viewed as a preliminary attempt to address the issue from **(scenario I)** using deep generative models and provide a potentially promising research direction. To completely solve the problem would require further research effort. The other task is envisioned as data augmentation, where the generated instances are used to enhance the performance of an important proxy task for exploring how neural networks (NN) solve MILP problems. Specifically, it helps assist in training NNs to predict the optimal objective values for MILP problems (Chen et al., 2023). Models trained on datasets augmented with DIG-MILP-generated instances demonstrate enhanced generalization capabilities.

2 Related Work

In the following, we discuss works on MILP generation and works on generative models.

In light of Hooker's proposals (Hooker, 1994; 1995), research on MILP generation diverges into two paths. The first focuses on leveraging expert domain knowledge to create generators for specific problems such as set covering (Balas & Ho, 1980), traveling sales person (Pilcher & Rardin, 1992; Vander Wiel & Sahinidis, 1995), graph colouring (Culberson, 2002), knapsack (Hill et al., 2011), and quadratic assignment (Drugan, 2013). This specificity causes poor generalization across different problems and thus fails to meet the generality criterion. In contrast, the second path aims at generating general MILPs. Asahiro et al. (1996) propose to generate completely random instances, which is inadequate for producing instances with specific distributional features (Hill & Reilly, 2000). Bowly (2019); Bowly et al. (2020) attempt to sample feasible instances similar to target data by manually controlling distributions in an embedding space. Its manual feature extraction and statistic control by simple distributions leads to instances with limited structural characteristics. A concurrent work Geng et al. (2024) adopts NNs to further improve the expressive capability of the instance generator in Bowly (2019) and thus achieves more similar instances, yet the framework does not produce instances with boundedness-feasibility guarantees. Inspired by Bowly (2019), DIG-MILP generates instances from the solution space and uses DNNs to dig out more details, aiming to delineate the structural attributes more precisely and generate feasible-bounded instances.

Recent years have witnessed the fast development of generative models, such as GAN Creswell et al. (2018), VAE Kipf & Welling (2016), and diffusion models Ho et al. (2020); Song & Ermon (2019). Considering the training complexity, and the strongly-structured MILP instances, we adopt VAE as the generative backbone in this paper, and we leave the utilization of more advanced generative models with potentially higher training computational cost as a feature direction to explore.

3 Methodology

We start by providing a preliminary background on MILP generation. Subsequently, we discuss the theoretical foundation based on which DIG-MILP's generation strategy ensures the feasibility and boundedness of its generated instances. Finally, we delve into the training and inference process of DIG-MILP along with its neural network architecture.

3.1 Preliminaries

Given a triplet of coefficient matrix $\boldsymbol{A} \in \mathbb{R}^{m \times n}$, right-hand side constant $\boldsymbol{b} \in \mathbb{R}^m$, and objective coefficient $\boldsymbol{c} \in \mathbb{R}^n$, an MILP is defined as:

$$\mathbf{MILP}(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}): \quad \max_{\boldsymbol{x}} \boldsymbol{c}^\top \boldsymbol{x}, \quad \text{s.t. } \boldsymbol{A}\,\boldsymbol{x} \leq \boldsymbol{b},\ \boldsymbol{x} \in \mathbb{Z}^n_{\geq 0}. \tag{1}$$

To solve MILP is to identify a set of non-negative integer variables that maximize the objective function while satisfying a series of linear constraints, which is NP-hard (Bulut & Ralphs, 2021). Within the entire MILP space $\mathcal{H} = \{[\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}] : \boldsymbol{A} \in \mathbb{R}^{m\times n}, \boldsymbol{b} \in \mathbb{R}^m, \boldsymbol{c} \in \mathbb{R}^n\}$, many of MILP problems are infeasible (no $\boldsymbol{x}$ satisfies all the constraints in (1)) or unbounded (the value of $\boldsymbol{c}^\top \boldsymbol{x}$ can grow indefinitely while still satisfying all the constraints). However, *In real-world scenarios, MILPs derived from practical issues are often either naturally or modified to be feasible, bounded, and yield an optimal solution*[2], as discussed in Section 1. Therefore, we are particularly interested in generating feasible-bounded MILPs from the space $\mathcal{H}'$ as follows: [3]

$$\mathcal{H}' := \{[\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}] : \boldsymbol{A} \in \mathbb{Q}^{m\times n}, \boldsymbol{b} \in \mathbb{Q}^m, \boldsymbol{c} \in \mathbb{Q}^n \text{ and MILP}(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}) \text{ is feasible and bounded.}\}.$$

It's important to note that merely telling the feasibility of such a problem is NP-Complete (Conforti et al., 2014; Hartmanis, 1982), and its special case (the binary case) is listed in one of the Karp's 21 problems (Karp, 2010). Thus, the task of reliably generating MILPs from $\mathcal{H}'$ is far from trivial.

Suppose a target MILP dataset D that models a particular business scenario is sampled from a distribution $\mathcal{D}_{\mathcal{H}'}(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ defined on $\mathcal{H}'$, the task of MILP instance generation is to approximate the distribution $\mathcal{D}_{\mathcal{H}'}$ and sample novel MILP instances from it.

3.2 DIG-MILP with Feasibility Guarantee

An intuitive idea for MILP generation is to directly sample $[\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}]$ from $\mathcal{D}_{\mathcal{H}'}$, which is practically hard to implement as it's hard to guarantee the generated instance to be feasible-bounded.

According to MILP duality theories, we observe that as long as DIG-MILP ensure that a generated instance's primal format MILP$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ and the dual format of its linear relaxation DualLP$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ (as defined in Equation. 2) both have at least one set of feasible solutions, then the newly generated instance will be guaranteed to be feasible-bounded (as proved in Proposition. 1).

$$\textbf{DualLP}(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}): \quad \min_{\boldsymbol{y}} \boldsymbol{b}^\top \boldsymbol{y}, \quad \text{s.t.} \quad \boldsymbol{A}^\top \boldsymbol{y} \geq \boldsymbol{c}, \ \boldsymbol{y} \geq 0, \tag{2}$$

To guarantee the existence of feasible solutions to both problems, inspired by (Bowly, 2019), we propose to sample the instances from another space $\mathcal{F}$, where

$$\mathcal{F} := \{[\boldsymbol{A}, \boldsymbol{x}, \boldsymbol{y}, \boldsymbol{s}, \boldsymbol{r}] : \boldsymbol{A} \in \mathbb{Q}^{m\times n}, \boldsymbol{x} \in \mathbb{Z}^n_{\geq 0}, \boldsymbol{y} \in \mathbb{Q}^m_{\geq 0}, \boldsymbol{s} \in \mathbb{Q}^n_{\geq 0}, \boldsymbol{r} \in \mathbb{Q}^m_{\geq 0}\}. \tag{3}$$

$\mathcal{F}$ defines an alternative space to represent feasible-bounded MILPs, with each element $[\boldsymbol{A}, \boldsymbol{x}, \boldsymbol{y}, \boldsymbol{s}, \boldsymbol{r}]$ consisting of the coefficient matrix $\boldsymbol{A}$ along with a set of feasible solutions $\boldsymbol{x}, \boldsymbol{y}$ to MILP$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ and DualLP$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$, respectively, where $\boldsymbol{b}, \boldsymbol{c}$ are determined by the corresponding slacks $\boldsymbol{s}, \boldsymbol{r}$ via the equalities defined in Equation. 4. By leveraging this idea, DIG-MILP aims to learn a distribution $\mathcal{G}_{\mathcal{F}}$ over the space of $\mathcal{F}$ to sample $[\boldsymbol{A}, \boldsymbol{x}, \boldsymbol{y}, \boldsymbol{s}, \boldsymbol{r}]$, which can be further transformed into $[\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}]$ that defines an MILP problem based on Equation. 4.

$$\textbf{Slack Variables:} \quad \boldsymbol{A}\boldsymbol{x} + \boldsymbol{r} = \boldsymbol{b}, \boldsymbol{A}^\top \boldsymbol{y} - \boldsymbol{s} = \boldsymbol{c}, \quad \text{where } \boldsymbol{r} \in \mathbb{Q}^m_{\geq 0}, \boldsymbol{s} \in \mathbb{Q}^n_{\geq 0} \tag{4}$$

Such a generation strategy offers theoretical guarantees on the boundedness and feasibility of the generated instances, ensuring the "feasibility-boundedness" of the produced data. Moreover, all the feasible and bounded MILPs in $\mathcal{H}'$ correspond to at least a tuple $[\boldsymbol{A}, \boldsymbol{x}, \boldsymbol{y}, \boldsymbol{s}, \boldsymbol{r}]$. In other words, generating tuples in the form of $[\boldsymbol{A}, \boldsymbol{x}, \boldsymbol{y}, \boldsymbol{s}, \boldsymbol{r}]$ instead of generating $[\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}]$ directly is a general approach for producing feasible and bounded instances. This is formally stated in Proposition. 1. See detailed proof in A.1 in the appendix.

Proposition 1 (**Boundedness and Feasibility Guarantee of DIG-MILP**). *Denote $\mathcal{H}''$ as the DIG-MILP-generating space:*

$$\mathcal{H}'' := \left\{[\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}] : \boldsymbol{b} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{r}, \boldsymbol{c} = \boldsymbol{A}^\top \boldsymbol{y} - \boldsymbol{s}, [\boldsymbol{A}, \boldsymbol{x}, \boldsymbol{y}, \boldsymbol{s}, \boldsymbol{r}] \in \mathcal{F}\right\}.$$

It holds that this generating space is exactly equal to $\mathcal{H}'$: $\mathcal{H}'' = \mathcal{H}'$.

[2] Definitions of boundedness, feasibility, and optimal solution of MILP in Definition. 1 2 3 in the appendix.

[3] Narrowing from the real domain to the rational domain is common in MILP studies to avoid cases where an MILP is feasible and bounded but lacks an optimal solution Schrijver (1998). For example, $\min \sqrt{3}x_1 - x_2$, s.t. $\sqrt{3}x_1 - x_2 \geq 0, x_1 \geq 1, \boldsymbol{x} \in \mathbb{Z}^2_{\geq 0}$. No feasible solution has objective equal to zero, but there are feasible solutions with objective arbitrarily close to zero.

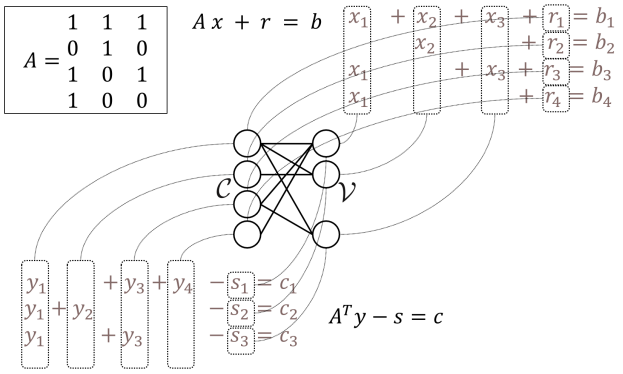

Figure 2: An example of bipartite graph representation with 4 nodes in set $\mathcal{C}$ and 3 nodes in set $\mathcal{V}$.

3.3 Generation Process and Architecture

Having shown the equivalence between spaces $\mathcal{F}$ and $\mathcal{H}'$, we then present how DIG-MILP learns a distribution $\mathcal{G}_{\mathcal{F}}$ to sample $[\boldsymbol{A}, \boldsymbol{x}, \boldsymbol{y}, \boldsymbol{x}, \boldsymbol{r}]$ from. The key concept is as follows: We first conceptualize $[\boldsymbol{A}, \boldsymbol{x}, \boldsymbol{y}, \boldsymbol{x}, \boldsymbol{r}]$ as a bipartite graph, thus transforming the generation of these elements into a *graph generation* problem. To train a model capable of generating such graphs, we employ an autoregressive method: iteratively removing a node from the graph, and then using a neural network to predict and restore the removed node's edges and attributes. During inference, we randomly select and remove a node from the current graph, and then use the trained neural network to reconstruct it. This process is repeated to generate a new graph.

Graph Representation. Here, we detail the representation of $[\boldsymbol{A}, \boldsymbol{x}, \boldsymbol{y}, \boldsymbol{s}, \boldsymbol{r}]$ as a bipartite graph within a variable-constraint (VC) framework, denoted as graph $G(\mathcal{V}, \mathcal{C}, \mathcal{E})$. Inspired by (Gasse et al., 2019), we treat each MILP variable as a node in $\mathcal{V}$, labeled v_j, where $j = 1, 2, \cdots, n$. The j-th element in $\boldsymbol{x}$ and $\boldsymbol{s}$, x_j and s_j, are attributes associated with node v_j. Similarly, each MILP constraint is represented as a node in $\mathcal{C}$, denoted by c_i, with $i = 1, 2, \cdots, m$. The elements y_i and r_i are attributes linked to node c_i. An edge $e_{i,j}$ in $\mathcal{E}$ connects a variable node v_j in $\mathcal{V}$ to a constraint node c_i in $\mathcal{C}$ if the coefficient $a_{i,j}$ in the matrix $\boldsymbol{A}$ is non-zero, indicating that the j-th variable contributes to the i-th constraint of the system $\boldsymbol{A}\boldsymbol{x} \leq \boldsymbol{b}$ in MILP (1). Therefore, $\boldsymbol{A}$ can be considered as the adjacency matrix of graph G. Figure 2 illustrates this graph representation with a 4×3 example. The attributes of nodes and edges are detailed in Table. 1. With this graph representation, we transform the MILP generation problem into a graph generation task.

Generation pipeline. We display the training and inference pipeline in Figure. 3. As illustrated in Algorithm. 1, on each training step of DIG-MILP, we randomly select and remove a constraint node c_i (corresponding to the i-th constraint) from the bipartite graph, along with all its connected edges $\mathcal{E}_G(c_i)$. Concurrently, we erase the features of the solution space $\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{s}, \boldsymbol{r}$ on all the nodes, resulting in an incomplete graph $G'(\mathcal{C} \backslash c_{i\_\boldsymbol{y},\boldsymbol{s}}; \mathcal{V}_{-\boldsymbol{x},\boldsymbol{r}}; \mathcal{E} \backslash \mathcal{E}_G(c_i))$. The training objective is to learn DIG-MILP to reconstruct G from the given G' by maximizing the log likelihood:

$$\arg\max_{\theta,\phi} \mathbb{E}_{G \sim D} \mathbb{E}_{G' \sim p(G'|G)} \log \mathbb{P}(G|G'; \theta, \phi), \tag{5}$$

where $p(G'|G)$ denotes the aforementioned process of randomly removing a node and it's connected edges to obtain the incomplete graph. We adhere to standard VAEs (Kingma & Welling, 2013; Kipf & Welling, 2016) and introduce latent variable $\boldsymbol{z} = [z_1, ..., z_{m+n}]$ with the assumption that $\boldsymbol{z}$ is independent with G'. Utilizing ELBO, we endeavor to maximize the training objective through the optimization of the following loss function:

$$\min_{\theta,\phi} \mathcal{L}_{\theta,\phi} = \mathbb{E}_{G \sim D} \mathbb{E}_{G' \sim p(G'|G)} \left[\alpha \mathbb{E}_{\boldsymbol{z} \sim q_\phi(\boldsymbol{z}|G)} [-\log p_\theta(G|G', \boldsymbol{z})] + \mathcal{D}_{KL}[q_\phi(\boldsymbol{z}|G) \| \mathcal{N}(0, I)] \right], \tag{6}$$

where the decoder p adeptly reconstructs graph G based on $\boldsymbol{z}$ and the incomplete graph G'; the encoder q is to depict the posterior distribution of $\boldsymbol{z}$. The hyper-parameter α functions as a balancing factor. See

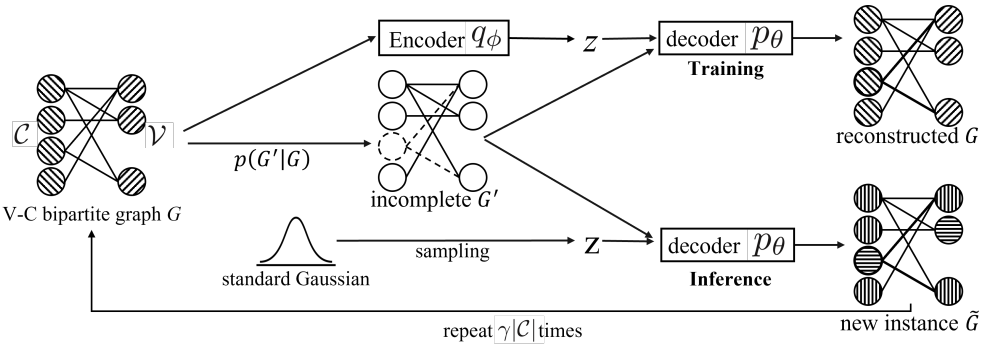

Figure 3: The training and inference pipeline of DIG-MILP. In each training step, DIG-MILP removes a random constraint node, its connected edges, along with the solution and slack features on all the nodes, resulting in an incomplete graph G'. The training objective of DIG-MILP is to reconstruct G from G' and $\boldsymbol{z}$ sampled by the encoder q_ϕ. As to inference, DIG-MILP employs an auto-regressive approach, generating new instances by iteratively modifying the existing MILPs.

detailed derivation in A.2 in the appendix. During training, DIG-MILP modifies one constraint of an instance at a time. During inference, the graph rebuilt after removing a constraint can be fed back as input, allowing iterative modifications to the original data. The number of iterations controls the degree of structural similarity to the original problem. The inference procedure is shown in Algorithm. 2, where $\gamma|\mathcal{C}$ denotes the number of iterations to remove a constraint.

Algorithm 1 DIG-MILP Training

Require: : dataset D, epoch N, batch size B

Solve MILPs for $\{[\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{s}, \boldsymbol{r}]\}$ over D
Encode MILPs into graphs $\{G(\mathcal{V}, \mathcal{C}, \mathcal{E})\}$
for epoch=1,...,N **do**
  Allocate empty batch $\mathcal{B} \leftarrow \emptyset$
  for idx=1,...,B **do**
    $G \sim D$; $G' \sim p(G'|G)$
    $\mathcal{B} \leftarrow \mathcal{B} \cup \{(G, G')\}$
    Encode $\boldsymbol{z} \sim q_\phi(\boldsymbol{z}|G)$
    Decode $G \sim p_\theta(G|G', \boldsymbol{z})$
    Calculate $\mathcal{L}_{\theta,\phi}(G, G')$
  end for
  $\mathcal{L}_{\theta,\phi} \leftarrow \frac{1}{B} \sum_{(G,G') \in \mathcal{B}} \mathcal{L}_{\theta,\phi}(G, G')$
  Update ϕ, θ by minimizing $\mathcal{L}_{\theta,\phi}$
end for
return θ, ϕ

Algorithm 2 DIG-MILP Inference

Require: : dataset D, batch size B, constraint replace rate γ

Solve MILPs for $\{[\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{s}, \boldsymbol{r}]\}$ over D
Encode MILPs into graphs $\{G(\mathcal{V}, \mathcal{C}, \mathcal{E})\}$
Allocate empty batch $\mathcal{B} \leftarrow \emptyset$
for id=1,...,B **do**
  $G \sim D$
  for t=1,...,$\gamma|\mathcal{C}|$ **do**
    $G' \sim p(G'|G)$
    $\boldsymbol{z} \sim \mathcal{N}(0, I)$
    Decode $\tilde{G} \sim p_\theta(\tilde{G}|G', \boldsymbol{z})$
    $G \leftarrow \tilde{G}$
  end for
  $\mathcal{B} \leftarrow \mathcal{B} \cup G$
end for
return new instance batch $\mathcal{B}$

Neural Network Architecture For both the encoder and decoder, we employ the same bipartite graph neural networks (GNN) as the backbone. The encoder is as follows:

$$q_\phi(\boldsymbol{z}|G) = \prod_{u \in \mathcal{C} \cup \mathcal{V}} q_\phi(\boldsymbol{z}_u|G), \qquad q_\phi(\boldsymbol{z}_u|G) = \mathcal{N}(\mu_\phi(\boldsymbol{h}_u^G), \Sigma_\phi(\boldsymbol{h}_u^G)), \tag{7}$$

where $\boldsymbol{z}_u$ is conditionally independent with each other on G, $\boldsymbol{h}^G = \mathrm{GNN}_\phi(G)$ denotes the node embeddings of G outputted by the encoder backbone, μ_ϕ and Σ_ϕ are two MLP layers that produce the mean and variance for the distribution of $\boldsymbol{z}$. The decoder connects seven parts conditionally independent on the latent variable

and node representations, with detailed structure as follows:

$$p_\theta(G|G', \boldsymbol{z}) = p_\theta(d_{c_i}|\boldsymbol{h}_{c_i}^{G'}, \boldsymbol{z}_{c_i}) \cdot \prod_{u\in\mathcal{V}} p_\theta(e(c_i,u)|\boldsymbol{h}_{\mathcal{V}}^{G'}, \boldsymbol{z}_{\mathcal{V}}) \cdot \prod_{u\in\mathcal{V}:e(c_i,u)=1} p_\theta(w_{c_i}|\boldsymbol{h}_{\mathcal{V}}^{G'}, \boldsymbol{z}_{\mathcal{V}}) \cdot \prod_{u\in\mathcal{C}} p_\theta(\boldsymbol{y}_u|\boldsymbol{h}_{\mathcal{C}}^{G'}, \boldsymbol{z}_{\mathcal{C}}) p_\theta(\boldsymbol{r}_u|\boldsymbol{h}_{\mathcal{C}}^{G'}, \boldsymbol{z}_{\mathcal{C}}) \cdot \prod_{u\in\mathcal{V}} p_\theta(\boldsymbol{x}_u|\boldsymbol{h}_{\mathcal{V}}^{G'}, \boldsymbol{z}_{\mathcal{V}}) p_\theta(\boldsymbol{s}_u|\boldsymbol{h}_{\mathcal{V}}^{G'}, \boldsymbol{z}_{\mathcal{V}}), \tag{8}$$

where $\boldsymbol{z}_{\mathcal{C}}, \boldsymbol{h}_{\mathcal{C}}^{G'}$ denotes the latent variable and node representations on side $\mathcal{C}$, while $\boldsymbol{z}_{\mathcal{V}}, \boldsymbol{h}_{\mathcal{V}}^{G'}$ signifies those on side $\mathcal{V}$; d_{c_i} predicts the degree of the deleted node c_i; $e(c_i, \cdot)$ denotes the probability of an edge between c_i and a node on side $\mathcal{V}$; w_{c_i} is the edge weights connected with c_i; $\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{s}, \boldsymbol{r}$ are value of the solution and slacks. We use separate MLPs to model each part's prediction as a regression task. We optimize each part of the decoder with the Huber Loss (Huber, 1992). See Section. B.2 in the appendix for more details.

4 Numerical Evaluations

In this section, we first delineate the experimental setup. Then we calculate the structural statistical similarity between generated and original instances. Subsequently, we evaluate DIG-MILP with two downstream tasks: *(i)* MILP data sharing for solver tuning and *(ii)* MILP data augmentation for ML model training.

4.1 Settings

Datasets: We perform DIG-MILP on four MILP datasets, encompassing scenarios involving simple and complex instances, a mix of small and large problem scales, varying instance quantities, and generation/collection from both synthetic and real-world sources. Specifically, we include two manually generated datasets, namely the set covering (SC) and the combinatorial auctions (CA), following the generation methodologies outlined in (Gasse et al., 2019). The remaining two datasets, namely CVS and IIS, are from the MIPLIB2017 benchmark (Gleixner et al., 2021)[4], which comprises challenging instances from a large pool of problem-solving contexts. CVS pertains to the capacitated vertex separator problem on hypergraphs, while IIS mirrors real-world scenarios and resembles the set covering problems. Details are elaborated in Table. 2. It's worth emphasizing that for CVS and IIS, we exclusively employ the 'training' data during the training of DIG-MILP and all downstream models. The 'testing' data is used only for downstream task evaluation.

Table 2: Datasets Meta-data. For CVS and IIS, 'training' (non-bold) instances are for DIG-MILP or downstream model training, 'testing' (bold) instances are used in downstream testing only.

	SC	CA	CVS					IIS	
# data	1000	1000	training			testing		training	testing

Downstream Tasks: We devise two downstream applications, tailored to address distinct motivations. One motivation pertains to generating and sharing data that can substitute target instances. The other motivation involves data augmentation for better training ML models.

(S1): Generating New Data for Solver Configuration Tuning Through this part of experiment, we offer clients a potential approach and feasible research direction for attempting to utilize deep generative models to generate new instances and hand them over to companies specializing in MILP solver tuning. In particular, we calculate the Pearson positive correlation of the solution times required by the SCIP (Bestuzheva et al., 2021) solver between the generated examples and the original testing data across various hyper-parameter configurations. Should the solution time consistently demonstrate a positive correlation between the original and generated problems across varied parameter settings, it implies a consistent level of the effectiveness on the original and new instances under the same parameter configuration, which facilitates sharing data for parameter tuning.

Figure 4: The solution time (second) of SCIP on CVS with 45 different hyper-parameter sets.

(S2): Optimal Value Prediction via ML We train GNNs to express the optimum of the objective function in an MILP (Chen et al., 2023; 2024), which serves as an important proxy task to test NN's ability in solving MILP instances. We follow exactly the experiment settings of Chen et al. (2023; 2024). The only difference is that instead of picking synthetic MILP problems as in Chen et al. (2023), we formulate more complicated and challenging datasets into MILP problems. We use the instances generated by DIG-MILPas data augmentation. For more detailed implementation, see B.6 in the appendix.

Solvers and Baselines: We use the open source solver SCIP (Bestuzheva et al., 2021) with its Python interface, namely PySCIPOpt (Maher et al., 2016b) for all the experiments. We consider two approaches as our baselines. The first, named 'Bowly', aligns with Bowly (2019) that generates MILP instances from scratch by sampling in an embedding space based on manually designed distributions, which to the best of our knowledge, is the only existing methods that work for generating novel MILP instances. The second baseline 'random' randomizes the network's outputs, further validating the importance and efficacy of model training. For more implementation details of the baselines, please refer to B.3 in the appendix.

4.2 Results and Analysis

It's shown that the instances generated by DIG-MILP share higher similarity with the original instance structures compared to baselines, for the statistical structural evaluation between the generated instances and the original instances, please refer to Appendix. B.4 for implementation details and C.1 for results.

4.2.1 downstream task #1: Generating New Data for Solver Configuration Tuning

We conduct experiments across all the four datasets. SCIP boasts an extensive array of parameters, rendering a tuning across the entire range impractical. Therefore, we adopt the reduced parameter space consistent with mainstream research on SCIP solver tuning (Hutter et al., 2011; Lindauer & Hutter, 2018; Lindauer et al., 2022). See Table. 11 in the appendix for detailed parameter space selection. We employ random seed $0 - 44$ to generate 45 distinct parameter configurations. To validate the impact of randomness on SCIP, we initiate two independent trials on the same original testing data and compare the Pearson score of solution time. As illustrated in the diagonal of Table. 3, it clearly demonstrates a very high positive correlation for two independent trials on the same data. For subsequent experiments, each is run three times independently, with results averaged to mitigate randomness effects. We then compare the correlation of solution time on the original data across different datasets, as presented in the upper triangle of Table. 3. We observe a certain degree of positive correlation between synthetic datasets SC and CA, as well as between MIPLIB datasets CVS and IIS, which reveals that the effectiveness of parameters may naturally exhibit some degree of generalization across similar problems. However, the correlation between synthetic and MIPLIB datasets

Table 3: The Pearson correlation coefficient ('r') and the significance value ('p') of the SCIP solution time under 45 different hyper-parameters on dataset-pairs.

tends to be much lower, underscoring the necessity of generating new instances for solver tuning on specific problems. Finally, we compare the positive correlation of solution time between the generated instances and the original testing instances of the same datasets, as shown in Table. 4. Across all four datasets, the DIG-MILP-generated instances, exhibit the highest correlation with the testing data compared to the baselines, with the lowest p-value of significance. The correlation between solution times for real and synthetic instances was lower for the CVS and IIS datasets compared to CA and SC. This difference primarily stems from the availability of training data: CA and SC each had substantial training data, with 1000 instances for each task, while CVS and IIS, which are derived from MIPLIB, had significantly fewer instances (CVS had only 3 and IIS had just 1 for training). Generating synthetic instances from the given data requires capturing the underlying distribution information, which is typically more challenging when working with limited samples.

We visualize the correlation of solution time between the original testing data and the generated data on the CVS in Figure. 4. More detailed implementation and the visualization of the other datasets can be found in B.5 and Figure. 5-8 in the appendix.

4.2.2 downstream task #2: Optimal Value Prediction via machine learning

We conduct experiments for the second downstream task on all four datasets. It is important to note that the dataset used to train the DIG-MILP model for generating new samples is the same dataset used to train the neural network for optimal value prediction without data augmentation. This ensures that the DIG-MILP model is not exposed to any additional data beyond what the neural network receives, thereby maintaining the fairness of the experiment.

Set Covering (SC) We select 'density' as a metric of the SC instance distribution, which represents the number of sets to be covered within a constraint. We only include densities ranging from 0.15 to 0.35 in the training set (for both DIG-MILP and the downstream predictor). We present in-distribution test set (0.15 to 0.35) as well as out-of-distribution test sets with densities falling within the unexplored range of 0.03 to 0.10, to reflect the predictor's ability to generalize across distribution shift. The relative mean squared error (MSE) values of the models' predictions are presented in Table. 5. In the upper rows (Datasets #1-#8), we fix the size of training set as 1000. Dataset #1 consist of 1000 original data, dataset #2 consists 500 original with 500 instances generated via the 'Bowly', #3 uses the 'random' baseline. Datasets #4-#8 comprise a combination of 500 original instances and 500 DIG-MILP-generated instances, with various constraint node replacement ratios γ ranging from 0.01 to 0.50. Models trained exclusively on in-distribution data exhibit superior fitting and predictive accuracy within the in-distribution test sets. However, models trained on a combination of

Table 5: The relative mean square error (MSE) of the optimal objective value task on the set covering (SC) problem. The 500 original instances in training dataset $\#2 - \#14$ are identical.

original and DIG-MILP-generated instances display significantly enhanced prediction accuracy on out-of-distribution testing data. We attribute this phenomenon to the increased structural and label diversity in the newly generated instances, mitigating over-fitting on in-distribution data and consequently bolstering the model's cross-distribution capabilities. It's worth noting that 'Bowly' or 'random' neither enhances the model's in-distribution nor out-of-distribution performance. We believe this is due to the less precise representation of the target distribution by the manually-designed 'Bowly' baseline and the excessively high randomness in 'random', causing the generated instances to deviate substantially from the original problems in both solution space and structure. In the lower rows (Datasets #9-#14), we investigate the impact of progressively incorporating DIG-MILP-generated instances into the dataset, initially starting with 500 original instances. We observe a consistent improvement in model performance with the gradual inclusion of additional newly generated instances, with peak performance achieved when augmenting the dataset with 500 newly generated instances.

Combinatorial Auctions (CA) We set the number of bid/item pairs that determines the quantity of variables and constraints as the parameter for distribution shift. Our training set only comprises examples with bid/item values ranging from 40/200 to 80/400, our testing set also introduces instances with bid/item values ranging from 40/200 to 160/800. The relative mean squared error (MSE) of the model's predictions is provided in Table. 6. The experiments are also divided into two parts. The upper rows (Datasets #1-#8) yields similar conclusions, where models trained solely on original data excel in fitting within in-distribution test sets, models trained on a mixture of half original and half DIG-MILP-generated instances perform better on test sets at scales never encountered during training (bid/item ranging from 100/500 to 160/800). This observation is attributed to the diversity introduced by the generated instances, in terms of both the problem structure and optimal objective labels, that prevents the models from over-fitting and thereby enhance their generalization across scales. Consistent with the SC, the second part demonstrates the impact of gradually increasing the new instances as training data and also achieves the peak performance with 500 newly generated instances.

CVS and IIS Experiments on CVS and IIS show similar insights, see Appendix. C.2 for details.

5 Conclusion

This paper introduces DIG-MILP, a deep generative framework for MILP. Contrasting with conventional MILP generation techniques, DIG-MILP does not rely on domain-specific expertise. Instead, it employs DNNs to extract profound structural information from limited MILP data, generating "representative" instances. Notably, DIG-MILP guarantees the feasibility and boundedness of generated data, ensuring the data's "autheticity". The generation space of DIG-MILP encompasses any feasible-bounded MILP, making it a general framework for generating feasible-bounded MILPs. Experiment evaluations highlights DIG-MILP's potential in (S1) MILP data sharing for solver hyper-parameter tuning without publishing the original data and (S2) data augmentation to enhance the generalization capacity of ML models tasked with

Table 6: The relative mean square error (MSE) of the optimal objective value task on the combinatorial auction (CA) problem. The 500 original instances in training dataset $\#2 - \#14$ are identical.

solving MILPs. As infeasible or unbounded problems are also important, particularly in testing the robustness of MILP solvers. Therefore, exploring the generation of these types of instances represents a promising direction for future research.

A supplementary theoretical results

A.1 Proof of Proposition 1

To validate Proposition 1, we follow the methodology outlined in Bowly (2019). Before the proof of Proposition 1, we first give the definition of boundedness, feasibility and optimal solutions of MILP, then we discuss the existence of optimal solutions of LP and MILP.

Definition 1 (Feasibility of MILP)**.** *An MILP*$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ *is feasible if there exists an* $\boldsymbol{x}$ *such that all the constraints are satisfied:* $\boldsymbol{x} \in \mathbb{Z}^n_{\geq 0}, \boldsymbol{A}\boldsymbol{x} \leq \boldsymbol{b}$*. Such an* $\boldsymbol{x}$ *is named a feasible solution.*

Definition 2 (Boundedness of MILP)**.** *An MILP*$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ *is bounded if there's an upper bound on* $\boldsymbol{c}^\top \boldsymbol{x}$ *across all feasible solutions.*

Definition 3 (Optimal Solution for MILP)**.** *A vector* $\boldsymbol{x}^\star$ *is recognized as an optimal solution if it's a feasible solution and it is no worse than all other feasible solutions:* $\boldsymbol{c}^\top \boldsymbol{x}^\star \geq \boldsymbol{c}^\top \boldsymbol{x}$*, given* $\boldsymbol{x}$ *is feasible.*

All LPs must fall into one of the following cases Bertsimas & Tsitsiklis (1997):

- Infeasible.
- Feasible but unbounded.
- Feasible and bounded. Only in this case, the LP yields an optimal solution.

However, general MILP will be much more complicated. Consider a simple example: $\min \sqrt{3}x_1 - x_2$, s.t. $\sqrt{3}x_1 - x_2 \geq 0, x_1 \geq 1, \boldsymbol{x} \in \mathbb{Z}^2_{\geq 0}$. No feasible solution has objective equal to zero, but there are feasible solutions with objective arbitrarily close to zero. In other words, *an MILP might be bounded but with no optimal solutions.* Such a pathological phenomenon is caused by the irrational number $\sqrt{3}$ in the coefficient. Therefore, we only consider MILP with rational data:

$$\boldsymbol{A} \in \mathbb{Q}^{m \times n}, \boldsymbol{b} \in \mathbb{Q}^m, \boldsymbol{c} \in \mathbb{Q}^m.$$

Such an assumption is regularly adopted in the research of MILP.

Without requiring $\boldsymbol{x}$ to be integral, equation 1 will be relaxed to an LP, named its *LP relaxation*:

$$\mathbf{LP}(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}): \quad \max_{\boldsymbol{x}} \boldsymbol{c}^\top \boldsymbol{x}, \quad \text{s.t. } \boldsymbol{A}\ \boldsymbol{x} \leq \boldsymbol{b},\ \boldsymbol{x} \geq 0.$$

The feasibility, boundedness, and existence of optimal solutions, along with the relationship with its LP relaxation, are summarized in the following lemma.

Lemma 1. *Given* $\boldsymbol{A} \in \mathbb{Q}^{m \times n}, \boldsymbol{b} \in \mathbb{Q}^m, \boldsymbol{c} \in \mathbb{Q}^m$*, it holds that*

- *(I) If LP*$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ *is infeasible, MILP*$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ *must be infeasible.*
- *(II) If LP*$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ *is feasible but unbounded, then MILP*$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ *must be either infeasible or unbounded.*
- *(III) If LP*$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ *is feasible and bounded, MILP*$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ *might be infeasible or feasible. If we further assume MILP*$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ *is feasible, it must yield an optimal solution.*

Proof. Conclusion (I) is trivial. Conclusion (II) is exactly (Byrd et al., 1987, Theorem 1). Conclusion (III) is a corollary of (Meyer, 1974, Theorem 2.1). To obtain (III), we first write MILP$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ into the following form:

$$\max_{\boldsymbol{x}, \boldsymbol{r}} \boldsymbol{c}^\top \boldsymbol{x} \quad \text{s.t. } \boldsymbol{A}\boldsymbol{x} + \boldsymbol{r} = \boldsymbol{b},\ \boldsymbol{x} \geq \boldsymbol{0},\ \boldsymbol{r} \geq \boldsymbol{0},\ \boldsymbol{x} \text{ is integral}$$

Then the condition (v) in (Meyer, 1974, Theorem 2.1) can be directly applied. Therefore, the feasibility and boundedness of MILP$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ imply the existence of optimal solutions, which concludes the proof. □

With Lemma 1, we could prove Proposition 1 now.

Proof of Proposition 1. At the beginning, we define the space of $[\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}]$ generated based on $\mathcal{F}$ as $\mathcal{H}''$ for simplicity.

$$\mathcal{H}'' := \left\{ [\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}] : \boldsymbol{b} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{r}, \boldsymbol{c} = \boldsymbol{A}^\top \boldsymbol{y} - \boldsymbol{s}, [\boldsymbol{A}, \boldsymbol{x}, \boldsymbol{y}, \boldsymbol{s}, \boldsymbol{r}] \in \mathcal{F} \right\}$$

Then it's enough to show that $\mathcal{H}' \subset \mathcal{H}''$ and $\mathcal{H}'' \subset \mathcal{H}'$.

We first show $\mathcal{H}'' \subset \mathcal{H}'$: For any $[\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}] \in \mathcal{H}''$, it holds that $[\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}] \in \mathcal{H}'$. In another word, we have to show MILP$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ to be feasible and bounded for all $[\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c}] \in \mathcal{H}''$. The feasibility can be easily verified. The boundedness can be proved by "weak duality." For the sake of completeness, we provide a detailed proof here. Define the Lagrangian as

$$\mathcal{L}(\boldsymbol{x}, \boldsymbol{y}) := \boldsymbol{c}^\top \boldsymbol{x} + \boldsymbol{y}^\top (\boldsymbol{b} - \boldsymbol{A}\boldsymbol{x})$$

Inequalities $\boldsymbol{A}\boldsymbol{x} \leq \boldsymbol{b}$ and $\boldsymbol{y} \geq \boldsymbol{0}$ imply

$$\mathcal{L}(\boldsymbol{x}, \boldsymbol{y}) \geq \boldsymbol{c}^\top \boldsymbol{x}$$

Inequalities $\boldsymbol{A}^\top \boldsymbol{y} \geq \boldsymbol{c}$ and $\boldsymbol{x} \geq \boldsymbol{0}$ imply

$$\mathcal{L}(\boldsymbol{x}, \boldsymbol{y}) \leq \boldsymbol{b}^\top \boldsymbol{y}$$

Since $\boldsymbol{x} \in \mathbb{Q}^n_{\geq 0}$ and $\boldsymbol{y} \in \mathbb{Q}^m_{\geq 0}$, it holds that

$$-\infty < \boldsymbol{c}^\top \boldsymbol{x} \leq \boldsymbol{b}^\top \boldsymbol{y} < +\infty$$

which concludes the boundedness of MILP$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$.

We then show $\mathcal{H}' \subset \mathcal{H}''$: For any MILP$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ that is feasible and bounded, there must be $[\boldsymbol{A}, \boldsymbol{x}, \boldsymbol{y}, \boldsymbol{s}, \boldsymbol{r}] \in \mathcal{F}$ such that

$$\boldsymbol{b} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{r}, \tag{9}$$

$$\boldsymbol{c} = \boldsymbol{A}^\top \boldsymbol{y} - \boldsymbol{s}. \tag{10}$$

The existence of $\boldsymbol{x}, \boldsymbol{r}$, along with equation 9, is a direct conclusion of the feasibility of MILP$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$. Now let's prove the existence of rational vectors $\boldsymbol{y}, \boldsymbol{s}$, along with equation 10. Since MILP$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ is feasible and bounded, according to Lemma 1, LP$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ must be feasible and bounded. Thanks to the weak duality discussed above, we conclude that DualLP$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ must be feasible and bounded. As long as DualLP$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ has an optimal solution $\boldsymbol{y}^\star$ that is rational, one can obtain equation 10 by regarding $[\boldsymbol{y}^\star, \boldsymbol{A}^\top \boldsymbol{y}^\star - \boldsymbol{c}]$ as $[\boldsymbol{y}, \boldsymbol{s}]$. Therefore, it's enough to show DualLP$(\boldsymbol{A}, \boldsymbol{b}, \boldsymbol{c})$ has a rational optimal solution.

Define:

$$\begin{aligned} \boldsymbol{A}' &= [\boldsymbol{A}^\top, -\boldsymbol{I}] \\ \boldsymbol{y}' &= [\boldsymbol{y}^\top, \boldsymbol{s}^\top]^\top \\ \boldsymbol{b}' &= [\boldsymbol{b}^\top, \boldsymbol{0}^\top] \end{aligned}$$

Then DualLP can be written as a standard-form LP:

$$\min_{\boldsymbol{y}'} (\boldsymbol{b}')^\top \boldsymbol{y}' \quad \text{s.t. } \boldsymbol{A}'\boldsymbol{y}' = \boldsymbol{c},\ \boldsymbol{y}' \geq \boldsymbol{0} \tag{11}$$

As long as an LP has an optimal solution, it must have a basic optimal solution Bertsimas & Tsitsiklis (1997). Specifically, we can split $\boldsymbol{A}'$ in column-based fashion as $\boldsymbol{A}' = [\boldsymbol{B}', \boldsymbol{N}']$ and split $\boldsymbol{y}'$ as $\boldsymbol{y}' = [\boldsymbol{y}_B^\top, \boldsymbol{y}_N^\top]^\top$, where $\boldsymbol{y}_N = \boldsymbol{0}$. Such a $\boldsymbol{y}'$ is termed a *basic optimal solution* to the LP presented in equation 11. Therefore,

$$\boldsymbol{A}'\boldsymbol{y}' = \boldsymbol{B}'\boldsymbol{y}_B + \boldsymbol{N}'\boldsymbol{y}_N = \boldsymbol{B}'\boldsymbol{y}_B = \boldsymbol{c} \implies \boldsymbol{y}_B = (\boldsymbol{B}')^{-1}\boldsymbol{c}$$

Since $\boldsymbol{B}'$ is a sub-matrix of $\boldsymbol{A}'$, $\boldsymbol{B}'$ is rational. Therefore, $(\boldsymbol{B}')^{-1}$ and $\boldsymbol{y}_B$ are rational, which implies $\boldsymbol{y}'$ is rational. This concludes the existence of rational optimal solutions of DualLP, which finishes the entire proof. □

A.2 Derivation of the loss function

Here we show the derivation from the training objective in Equation. 5 towards the loss function in Equation. 6.

$$
\begin{aligned}
\log \mathbb{P}(G|G';\theta,\phi) &= \mathbb{E}_{\boldsymbol{z}\sim q_\phi(\boldsymbol{z}|G)} \log \mathbb{P}(G|G';\theta,\phi) \\
&= \mathbb{E}_{\boldsymbol{z}\sim q_\phi(\boldsymbol{z}|G)}[\log \frac{p_\theta(G|G',\boldsymbol{z})p(\boldsymbol{z})}{q_\phi(\boldsymbol{z}|G)} \frac{q_\phi(\boldsymbol{z}|G)}{p(\boldsymbol{z}|G)}] \\
&= \mathbb{E}_{\boldsymbol{z}\sim q_\phi(\boldsymbol{z}|G)} \log \frac{p_\theta(G|G',\boldsymbol{z})p(\boldsymbol{z})}{q_\phi(\boldsymbol{z}|G)} + \mathbb{E}_{\boldsymbol{z}\sim q_\phi(\boldsymbol{z}|G)}[\log \frac{q_\phi(\boldsymbol{z}|G)}{p(\boldsymbol{z}|G)}] \\
&= \mathbb{E}_{\boldsymbol{z}\sim q_\phi(\boldsymbol{z}|G)}[\log p_\theta(G|\boldsymbol{z},G')] - \mathcal{D}_{KL}[q_\phi(\boldsymbol{z}|G)||p(\boldsymbol{z})] + \mathcal{D}_{KL}[q_\phi(\boldsymbol{z}|G)||p(\boldsymbol{z}|G)] \\
&\geq \mathbb{E}_{\boldsymbol{z}\sim q_\phi(\boldsymbol{z}|G)}[\log p_\theta(G|G',\boldsymbol{z})] - \mathcal{D}_{KL}[q_\phi(\boldsymbol{z}|G)||\mathcal{N}(0,I)]
\end{aligned}
\quad , \tag{12}
$$

and thus we have

$$
\mathbb{E}_{G\sim\mathcal{G}}\mathbb{E}_{G'\sim p_{G'|G)}} \log \mathbb{P}(G|G';\theta,\phi) \geq -\mathcal{L}_{\theta,\phi} \tag{13}
$$

B supplementary implementation details

B.1 Hardware, Software and Platforms

At the hardware level, we employ an Intel Xeon Gold 6248R CPU and a Nvidia quadro RTX 6000 GPU. For tasks that exclusively run on the CPU, we utilize a single core, for tasks that run on the GPU, we set the upper limit to 10 cores. On the software side, we utilize PyTorch version 2.0.0+cu117 (Paszke et al., 2019) and PyTorch Geometric version 2.0.3 (Fey & Lenssen, 2019). We utilize PySCIPOpt solver version 3.5.0 (Maher et al., 2016a) for optimization purposes with default configurations.

B.2 Implementation of DIG-MILP

For both the encoder and the decoder, we adopt the bipartite GNN exactly the same as that in Gasse et al. (2019) as their backbones, the original codes for the backbone is publicly available[5].

Encoder To obtain the latent variable samples, we feed the encoder with G encoded as per the method in Table. 1, we then incorporate two distinct multi-layer perceptron (MLP) layers following the backbone to output the mean and log variance of the latent variable $\boldsymbol{z}$. During the training process, we use the reparametrization trick (Bengio et al., 2013; Maddison et al., 2016; Jang et al., 2016) to render the process of sampling $\boldsymbol{z}$ from the mean and variance differentiable. During inference, we directly sample $\boldsymbol{z} \sim \mathcal{N}(0, I)$.

Table 7: The last layer design of decoder.

prediction	embeddings
$d, e, w, \boldsymbol{x}, \boldsymbol{r}$	$\boldsymbol{h}_v, \boldsymbol{z}_v, v \in \mathcal{V}$
$\boldsymbol{y}, \boldsymbol{s}$	$\boldsymbol{h}_c, \boldsymbol{z}_c, c \in \mathcal{C}$

Decoder We feed the backbone of the decoder with the incomplete graph G' to obtain the latent node representations $\boldsymbol{h}^{G'} = \{\boldsymbol{h}_c^{G'}, \boldsymbol{h}_v^{G'}\}$. The backbone is then followed by seven distinct heads conditionally independent on $\boldsymbol{h}$ and $\boldsymbol{z}$, each corresponding to the prediction of: 1) the degree of the removed node d_{c_i}, 2) the edges $e(c_i, u)$ between the constraint node c_i and the nodes in the other side, 3) the edge weights w_{c_i}, and 4) - 7) the value of $\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{r}, \boldsymbol{s}$ of the new graph $\tilde{G}$. Each head is composed of layers of MLP, and takes different combinations $\boldsymbol{h}^{G'}, \boldsymbol{z}^{G'}$ as inputs, which is illustrated in Table. 7. We perform min-max normalization on all the variables to predict according to their maximum and minimum value occurred in the training dataset. Each part is modeled as a regression task, where we use the Huber Loss Huber (1992) as the criterion for each part and add them together as the total loss for decoder.

For the case of binary MILP problems, their primal, dual and slack variables could be written in the form as Equation. 14 15 16:

[5] https://github.com/ds4dm/learn2branch/blob/master/models/baseline/model.py

Primal (Binary)

$$\begin{aligned} \max_{\boldsymbol{x}} \quad & \boldsymbol{c}^\top \boldsymbol{x} \\ \text{s.t.} \quad & \mathbf{A}\boldsymbol{x} \leq \boldsymbol{b} \\ & \boldsymbol{x} \leq 1 \\ & \boldsymbol{x} \geq 0 \\ & \boldsymbol{x} \in \mathbb{Z} \end{aligned} \tag{14}$$

Dual (Binary) (Linear Relaxation)

$$\begin{aligned} \max_{y} \quad & [\boldsymbol{b}^\top, 1^\top]\boldsymbol{y} \\ \text{s.t.} \quad & [\mathbf{A}^\top, I]\boldsymbol{y} \geq \boldsymbol{c} \\ & \boldsymbol{y} \geq 0 \end{aligned} \tag{15}$$

Slack (Binary)

$$\begin{aligned} \mathbf{A}\boldsymbol{x} + \boldsymbol{r} &= \boldsymbol{b} \\ [\mathbf{A}^\top, I]\boldsymbol{y} - \boldsymbol{s} &= \boldsymbol{c} \\ \boldsymbol{r} &\geq 0 \\ \boldsymbol{s} &\geq 0 \end{aligned} \tag{16}$$

Considering the inherent structure of binary MILP, we can further decompose the dual solution $\boldsymbol{y}$ into two parts: $\boldsymbol{y}_1$ (corresponding to regular constraints $\boldsymbol{A}\boldsymbol{x} \leq \boldsymbol{b}$) and $\boldsymbol{y}_2$ (corresponding to constraints $\boldsymbol{x} \leq 1$). The encoding of binary MILP problem into a bipartite VC graph is illustrated in Table. 8. And the decoder could be models as Equation. 17.

$$\begin{aligned} p_\theta(G|G', \boldsymbol{z}) = p_\theta(d_{c_i}|\boldsymbol{h}_{c_i}^{G'}, \boldsymbol{z}_{c_i}) \cdot \prod_{u\in\mathcal{V}} p_\theta(e(c_i,u)|\boldsymbol{h}_{\mathcal{V}}^{G'}, \boldsymbol{z}_{\mathcal{V}}) \cdot \prod_{u\in\mathcal{V}:e(c_i,u)=1} p_\theta(w_{c_i}|\boldsymbol{h}_{\mathcal{V}}^{G'}, \boldsymbol{z}_{\mathcal{V}}) \\ \cdot \prod_{u\in\mathcal{C}} p_\theta(\boldsymbol{y}_{1u}|\boldsymbol{h}_{\mathcal{C}}^{G'}, \boldsymbol{z}_{\mathcal{C}}) p_\theta(\boldsymbol{r}_u|\boldsymbol{h}_{\mathcal{C}}^{G'}, \boldsymbol{z}_{\mathcal{C}}) \cdot \prod_{u\in\mathcal{V}} p_\theta(\boldsymbol{x}_u|\boldsymbol{h}_{\mathcal{V}}^{G'}, \boldsymbol{z}_{\mathcal{V}}) p_\theta(\boldsymbol{s}_u|\boldsymbol{h}_{\mathcal{V}}^{G'}, \boldsymbol{z}_{\mathcal{V}}) p_\theta(\boldsymbol{y}_{2u}|\boldsymbol{h}_{\mathcal{V}}^{G'}, \boldsymbol{z}_{\mathcal{V}}), \end{aligned} \tag{17}$$

where the decoder of DIG-MILP specifically designed for binary MILP partitions the predicted dual solution $\boldsymbol{y}$ into two segments $\boldsymbol{y}_1, \boldsymbol{y}_2$ and predict each segment separately.

Table 8: V-C encoding for binary MILP.

object	feature
constraint node $\mathcal{C} = \{c_1...c_m\}$	all 0's $\boldsymbol{y}_1 = \{\boldsymbol{y}_{11}...\boldsymbol{y}_{1m}\}$ $\boldsymbol{r} = \{\boldsymbol{s}_1...\boldsymbol{s}_m\}$
variable node $\mathcal{V} = \{v_1...v_n\}$	all 1's $\boldsymbol{x} = \{\boldsymbol{x}_1...\boldsymbol{x}_n\}$ $\boldsymbol{s} = \{\boldsymbol{r}_1...\boldsymbol{r}_n\}$ $\boldsymbol{y}_2 = \{\boldsymbol{y}_{21}...\boldsymbol{y}_{2n}\}$
edge $\mathcal{E}$	non-zero weights in $\boldsymbol{A}$

Hyper-parameters Across the four datasets, we set the same learning rate for DIG-MILP as $1e-3$. We use the Adam optimizer (Kingma & Ba, 2014). For the SC, we set the α in $\mathcal{L}_{\theta,\phi}$ as 5, for the CA, the CVS, and the IIS, we set α as 150. We use the random seed as 123 for DIG-MILP training across all the four datasets.

B.3 Implementation of baseline

'Bowly' Here we show the implementation of generating instances from scratch with the baseline Bowly (Bowly, 2019). The generation of matrix $\mathbf{A}$ is illustrated in the algorithm. 3. With the generated adjacency matrix $\mathbf{A}$, where we manipulate the hyper-parameters during the generation process to ensure that the statistical properties of $\mathbf{A}$ align as closely as possible with the original dataset. Specifically, we keep the size of graph (m, n) the same as the original dataset and uniformly sample p_v, p_c from $[0, 1]$ for all the four datasets. For the other hyper-parameter settings, see Tables. 9.

Then we uniformly sample the solution space $\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{s}, \boldsymbol{r}$ with intervals defined by their corresponding maximum and minimum from the training dataset. Then we deduce $\boldsymbol{b}, \boldsymbol{c}$ to get the new MILP instances.

'Random' We use exactly the same network architecture and generation process as DIG-MILP. The key difference is that instead of utilizing the trained NN, we uniformly sample the variables $d_{c_i}, e(c_i, u), w_{c_i}, \boldsymbol{y}_1, \boldsymbol{s}, \boldsymbol{x}, \boldsymbol{r}, \boldsymbol{y}_2$ required for decoder prediction within intervals delineated by the maximum

Algorithm 3 Bowly - generation of matrix $\mathbf{A}$

Require: $n \in [1, \infty), m \in [1, \infty), \rho \in (0, 1], p_v \in [0, 1], p_c \in [0, 1], \mu_A \in (-\infty, \infty), \sigma_A \in (0, \infty)$
Ensure: Constraint matrix$\mathbf{A} \in \mathbb{Q}^{m \times n}$

Set target variable degree $d_(u_i) = 1$ for randomly selected i,0 for all others
Set target constraint degree $d_(u_i) = 1$ for randomly selected i,0 for all others
$e \leftarrow 1$
while $e < \rho mn$ **do**
    $s \leftarrow$ draw n values from $U(0, 1)$
    $t \leftarrow$ draw m values from $U(0, 1)$
    Increment the degree of variable node i with maximum $p_v \frac{d(u_i)}{e} + s_i$
    Increment the degree of constraint node j with maximum $p_c \frac{d(v_j)}{e} + t_j$
    $e \leftarrow e + 1$
end while
for $i = 1, ..., n$ **do**
    for $j = 1, ..., m$ **do**
        $r \leftarrow$ draw from $U(0, 1)$
        if $r < \frac{d(u_i)d(v_j)}{e}$ **then**
            Add edge (i, j) to VC
        end if
    end for
end for
while $\min((d(u_i), d(v_j)) = 0$ **do**
    Choose i from $\{i | d(u_i) = 0\}$, or randomly if all $d(u_i) > 0$
    Choose j from $\{j | d(v_j) = 0\}$, or randomly if all $d(v_j) > 0$
    Add edge (i, j) to VC
end while
for $(i, j) \in E(VC)$ **do**
    $a_{ij} = \mathcal{N}(\mu_{\mathbf{A}}, \sigma_{\mathbf{A}})$
end for
return A

Table 9: The hyper-parameter selection of the Bowly baseline.

	density	$\mu_{\mathbf{A}}$	$\sigma_{\mathbf{A}}$
SC	$\mathcal{U}\{0.15, 0.20, 0.25, 0.30, 0.35\}$	-1	0
CA	0.05	1	$\mathcal{U}(0.1, 0.3)$
CVS	0.0013	0.2739	0.961
IIS	0.0488	-1	0

and minimum values of each variable from the training set, simulating the random parameters of an untrained neural network.

B.4 Implementation of the structural statistical characteristics

The explanation of various statistical metrics used for comparing the structural similarity of MILP problem instances is detailed as shown in Table. 10. Specific numerical values for different metrics for the SC and CA problems can be found in Table. 13 and Table. 14, respectively.

Table 10: Explanation of the statistic metrics of the MILP instances

name	explanation
density mean	the average number of non zero values in the constraint matrix
cons degree mean	the average number of constraint node degree
cons degree std	the standard variance of constraint node degree
var degree mean	the average number of variable node degree
var degree std	the standard variance of variable node degree
$\boldsymbol{b}$ mean	the average $\boldsymbol{b}$ value
$\boldsymbol{b}$ std	the standard variance of $\boldsymbol{b}$ value
$\boldsymbol{c}$ mean	the average value of $\boldsymbol{c}$
$\boldsymbol{c}$ std	the standard variance of $\boldsymbol{c}$ value

For each statistic metric i shown in Table. 10, we begin by collecting lists of the values from four data sources: the original dataset, the data generated by the 'Bowly' baseline, the data generated by the 'random' baseline, and data generated by DIG-MILP. Each data source contains 1000 instances. We then employ the lists from the four data sources to approximate four categorical distributions. Utilizing the *numpy.histogram* function, we set the number of bins to the default value of 10, with the min and max values derived from the collective minimum and maximum of a given metric across the four data sources, respectively. Next, we employ Jensen-Shannon (JS) divergence D_{js}^i via the function *scipy.spatial.distance.jensenshannon* (Virtanen et al., 2020) to quantify the divergence between the original samples and the rest three data sources, resulting in score_i for each statistical metric.

$$\text{score}_i = (\max(D_{js}) - D_{js}^i)/(\max(D_{js}) - \min(D_{js})), \tag{18}$$

where $\max(D_{js}), \min(D_{js})$ are the maximum and minimum of JS divergence across all the metrics.

Then we average the score for each statistic metric to obtain the final similarity score, as is shown in Table. 12:

$$\text{score} = \frac{1}{9}\sum_{i=1}^{9} \text{score}_i. \tag{19}$$

B.5 Implementation of Data Sharing for Solver Configuration Tuning

Below are the hyper-parameters that we randomly sample to test the positive-correlation of different dataset pairs. We adhere to the configuration established in mainstream solver tuning literature to select the pa-

rameters requiring adjustment Hutter et al. (2011); Lindauer & Hutter (2018); Lindauer et al. (2022), . For a detailed explanation of each parameter, please refer to the SCIP documentation[6].

Table 11: The selected SCIP hyper-parameters and the range to randomly select from.

params	whole range/choice	default	our range/choice
branching/scorefunc	s, p, q	s	s, p, q
branching/scorefac	[0, 1]	0.167	[0, 1]

B.6 Implementation of Optimal Value Prediction via ML

Neural Network Architecture In this downstream task, We also use the bipartite GNN backbone which is exactly the same as that in Gasse et al. (2019). We use an MLP layer and global mean pooling to produce the optimal objective value prediction. The learning rate is set as $1e-3$.

C Supplementary Experiment Results

C.1 statistical characteristics of the generated instances

Table 12: The similarity score ↑ between the original and generated data .

constraint	replace rates γ	-	0.01	0.05	0.10	0.20	0.50
SC	Bowly	0.337	-	-	-	-	-
	random	-	0.701	0.604	0.498	0.380	0.337
	ours	-	**0.856**	**0.839**	**0.773**	**0.652**	**0.570**
CA	Bowly	0.386	-	-	-	-	-
	random	-	0.630	0.566	0.508	0.432	0.306
	ours	-	**0.775**	**0.775**	**0.768**	**0.733**	**0.630**

We compare the statistical metrics between the generated instances and the original instances on the SC and CA datasets. We do not calculate the statistics on the CVS and IIS due to their limited size that prevents meaningful statistical comparisons. We count nine statistic metrics in total, see Table. B.4 in the appendix for details. The similarity score is derived from the Jensen-Shannon (JS) divergence (the lower the better) between each metric of the generated and original data, as shown in Table. 12. 'Bowly' shows the least similarity. As the the constraint replacement ratio γ increases from 0.01 to 0.50, the table shows a decreasing similarity between new and original instances for both DIG-MILP and 'random', aligning with our expectation of controlling structural similarity by adjusting the number of constraint nodes to replace. Instances generated by DIG-MILP more closely mirror the target data in structural statistical metrics across all γ. For detailed calculations of the similarity score and the specific values of each statistic

metric, see B.4 and C.1 in the appendix. The detailed dynamic ranges of CA and SC could be found in `https://miplib.zib.de/tag_collection.html`.

C.2 Data Sharing for Solver configuration Tuning

CVS and IIS There are five total instances in CVS, comprising three for training DIG-MILP and the downstream predictor and two for testing. The IIS has two instances, one for training and one for testing (with allocation based on alphabetical order). Please refer to Table. 15 for the model's performance. 'ground truth' corresponds to the true values of the optimal objectives for each problem. Models trained exclusively on the 'original' training set exhibit superior fitting and more accurate predictions on the training set itself. However, models trained on the datasets where we introduce 20 additional newly generated instances by DIG-MILP with varying constraint replacement ratio γ not only demonstrate minimal gap in prediction on the training set towards the models trained solely on the original data compared with the baselines, but also showcase improved predictive performance on previously unseen test sets. This underscores the notion that the DIG-MILP-generated data can indeed increase structural and solution label diversity to a certain extent, thereby enhancing the generalization capability and overall performance of the models. Again, similar to the previous two experiments, 'Bowly' degrades the predictive performance of the model, 'random' results in marginal improvement in out-of-distribution prediction accuracy.

Table 15: The predicted value and relative mean square error (MSE) of the optimal objective value on the CVS and the IIS problem. In the CVS, 'cvs08r139-94','cvs16r70-62','cvs16r89-60' are used as training data, 'cvs16r106-72','cvs16r128-89' are used as testing data. In the IIS, 'iis-glass-cov' is used as the training data, 'iis-hc-cov' is used as the testing data. 'original' shows the performance of the model trained merely on the three (CVS) or single (IIS) original training instances.
