
Exponential Quantum Communication Advantage in Distributed Inference and Learning

Anonymous Authors¹

Abstract

Training and inference with large machine learning models that far exceed the memory capacity of individual devices necessitates the design of distributed architectures, forcing one to contend with communication constraints. We present a framework for distributed computation over a quantum network in which data is encoded into specialized quantum states. We prove that for models within this framework, inference and training using gradient descent can be performed with exponentially less communication compared to their classical analogs, and with relatively modest overhead relative to standard gradient-based methods. We show that certain graph neural networks are particularly amenable to implementation within this framework, and moreover present empirical evidence that they perform well on standard benchmarks. To our knowledge, this is the first example of exponential quantum advantage for a generic class of machine learning problems that hold regardless of the data encoding cost. Moreover, we show that models in this class can encode highly nonlinear features of their inputs, and their expressivity increases exponentially with model depth. We also delineate the space of models for which exponential communication advantages hold by showing that they cannot hold for linear classification. Our results can be combined with natural privacy advantages in the communicated quantum states that limit the amount of information that can be extracted from them about the data and model parameters. Taken as a whole, these findings form a promising foundation for distributed machine learning over quantum networks.

Preliminary work. Under review by the International Conference on Machine Learning (ICML). Do not distribute.

1. Introduction

As the scale of the datasets and parameterized models used to perform computation over data continues to grow (Kaplan et al., 2020; Hoffmann et al., 2022), distributing workloads across multiple devices becomes essential for enabling progress. The choice of architecture for large-scale training and inference must not only make the best use of computational and memory resources, but also contend with the fact that communication may become a bottleneck (Pope et al., 2022). This is particularly pertinent as models grow so large that they cannot rely on high-bandwidth interconnects within datacenters (Barroso et al., 2013), but are instead trained across multiple datacenters (Team et al., 2023). When using modern optical interconnects, classical computers exchange bits represented by light. This however does not fully utilize the potential of the physical substrate; given suitable computational capabilities and algorithms, the *quantum* nature of light can be harnessed as a powerful communication resource. Here we show that for a broad class of parameterized models, if quantum bits (*qubits*) are communicated instead of classical bits, an exponential reduction in the communication required to perform inference and gradient-based training can be achieved. This protocol additionally guarantees improved privacy of both the user data and model parameters through natural features of quantum mechanics, without the need for additional cryptographic or privacy protocols. To our knowledge, this is the first example of generic, exponential quantum advantage on problems that occur naturally in the training and deployment of large machine learning models. These types of communication advantages help scope the future roles and interplay between quantum and classical communication for distributed machine learning.

Quantum computers promise dramatic speedups across a number of computational tasks, with perhaps the most prominent example being the ability revolutionize our understanding of nature by enabling the simulation of quantum systems, owing to the natural similarity between quantum computers and the world (Feynman, 1982; Lloyd, 1996). However, much of the data that one would like to compute with in practice seems to come from an emergent classical world rather than directly exhibiting quantum properties.

While there are some well-known examples of exponential quantum speedups for classical problems, most famously factoring (Shor, 1994) and related hidden subgroup problems (Childs & van Dam, 2008), these tend to be isolated and at times difficult to relate to practical applications that involve learning from data. In addition, even though significant speedups are known for certain ubiquitous problems in machine learning such as matrix inversion (Harrow et al., 2009) and principal component analysis (Lloyd et al., 2014), the advantage is often lost when including the cost of loading classical data into the quantum computer or of reading out the result into classical memory. This is because the complexity of loading dense classical data into the amplitudes of a quantum state (which is typically the encoding needed to obtain an exponential runtime advantage) and of reading out the amplitudes from a quantum state into classical memory, are both polynomial in the number of amplitudes (Aaronson, 2015). In applications where an efficient data access model avoids the above pitfalls, the complexity of quantum algorithms tends to depend on condition numbers of matrices which scale with system size in a way that reduces or even eliminates any quantum advantage (Montanaro & Pallister, 2015). It is worth noting that much of the discussion about the impact of quantum technology on machine learning has focused on computational advantage. However quantum resources are not only useful in reducing computational complexity — they can also provide an advantage in communication complexity, enabling exponential reductions in communication for some problems (Raz, 1999; Bar-Yossef et al., 2008). Inspired by these results, we study a setting where quantum advantage in communication is possible across a wide class of machine learning models. This advantage holds without requiring any sparsity assumptions or elaborate data access models such as QRAM (Giovannetti et al., 2008).

We focus on compositional distributed learning, known as *pipelining* (Huang et al., 2018; Barham et al., 2022). While there are a number of strategies for distributing machine learning workloads that are influenced by the requirements of different applications and hardware constraints (Xu et al., 2021; Jouppi et al., 2023), splitting up a computational graph in a compositional fashion (Figure 2) is a common approach. We describe distributed, parameterized quantum circuits that can be used to perform inference over data when distributed in this way, and can be trained using gradient methods. The ideas we present can also be used to optimize models that use certain forms of data parallelism (Appendix D). In principle, such circuits could be implemented on quantum computers that are able to communicate quantum states.

We show the following:

- Even for simple distributed quantum circuits, there is an exponential quantum advantage in communication

for the problem of estimating the loss and the gradients of the loss with respect to the parameters (Section 2). This additionally implies a privacy advantage from Holevo’s bound (Appendix L). We also show that this is advantage is not a trivial consequence of the data encoding used, since it does not hold for certain problems like linear classification (Appendix I).

- We study a class of models that can efficiently approximate certain graph neural networks (Section 3), and show that they both maintain the exponential communication advantage and achieve performance comparable to standard classical models on common node and graph classification benchmarks (Section 4).
- For certain distributed circuits, there is an exponential advantage in communication for the entire training process, and not just for a single round of gradient estimation. This includes circuits for fine-tuning using pre-trained features. The proof is based on convergence rates for stochastic gradient descent under convexity assumptions (Appendix H).
- The ability to interleave multiple unitaries encoding nonlinear features of data enables expressivity to grow exponentially with depth, and universal function approximation in some settings. This implies that these models are highly expressive in contrast to popular belief about linear restrictions in quantum neural networks (Appendix J).

2. Distributed learning with quantum resources

For a preliminary discussion on the types of distributed computation we consider and related work, see Appendix B. We focus on parameterized models that are representative of the most common models used and studied today in quantum machine learning, sometimes referred to as quantum neural networks (McClean et al., 2015; Farhi & Neven, 2018; Cerezo et al., 2020; Schuld et al., 2020). We will use the standard Dirac notation of quantum mechanics throughout. A summary of relevant notation and the fundamentals of quantum mechanics is provided in Appendix A. We define a class models with parameters Θ , taking an input x which is a tensor of size N . The models take the following general form:

Definition 2.1. $\{A_\ell(\theta_\ell^A, x)\}, \{B_\ell(\theta_\ell^B, x)\}$ for $\ell \in \{1, \dots, L\}$ are each a set of unitary matrices of size $N' \times N'$ for some N' such that $\log N' = O(\log N)$ ¹. The $\theta_\ell^A, \theta_\ell^B$ are vectors of P parameters each. For every ℓ, i , we assume

¹We will consider some cases where $N' = N$, but will find it helpful at times to encode nonlinear features of x in these unitaries, in which case we may have $N' > N$.

that $\frac{\partial A_\ell}{\partial \theta_{\ell i}^A}$ is anti-hermitian and has two eigenvalues, and similarly for B_ℓ ².

The model we consider is defined by

$$|\varphi(\Theta, x)\rangle \equiv \left(\prod_{\ell=L}^1 A_\ell(\theta_\ell^A, x) B_\ell(\theta_\ell^B, x) \right) |\psi(x)\rangle, \quad (2.1)$$

where $|\psi(x)\rangle$ is a fixed state of $\log N'$ qubits.

The loss function is given by

$\mathcal{L}(\Theta, x) \equiv \langle \varphi(\Theta, x) | \mathcal{P}_0 | \varphi(\Theta, x) \rangle$ where \mathcal{P}_0 is a Pauli matrix that acts on the first qubit.

In standard linear algebra notation, the output of the model is a unit norm N' -dimensional complex vector φ_L , defined recursively by

$$\varphi_0 = \psi(x), \quad \varphi_\ell = A_\ell(\theta_\ell^A, x) B_\ell(\theta_\ell^B, x) \varphi_{\ell-1}, \quad (2.2)$$

where the entries of φ_L are represented by the amplitudes of a quantum state. The loss takes the form $\mathcal{L}(\Theta, x) = (\varphi_L^*)^T \mathcal{P}_0 \varphi_L$ where $*$ indicates the entrywise complex conjugate, and this definition includes the standard L^2 loss as a special case.

Subsequently we omit the dependence on x and Θ (or subsets of it) to lighten notation, and consider special cases where only subsets of the unitaries depend on x , or where the unitaries take a particular form and may not be parameterized. Denote by $\nabla_{A(B)} \mathcal{L}$ the entries of the gradient vector that correspond to the parameters of $\{A_\ell\}(\{B_\ell\})$.

In the special case where x is a unit norm N -dimensional vector, a simple choice of $|\psi(x)\rangle$ is the amplitude encoding of x , given by $|\psi(x)\rangle = |x\rangle = \sum_{i=0}^{N-1} x_i |i\rangle$.

However, despite its exponential compactness in representing the data, a naive implementation of the simplest choice is restricted to representing quadratic features of the data that can offer no substantial quantum advantage in a learning task (Huang et al., 2021), so the choice of data encoding is critical to the power of a model. The interesting parameter regime for classical data and models is one where N, P are large, while L is relatively modest. For general unitaries $P = O(N^2)$, which matches the scaling of the number of parameters in fully-connected networks. When the input

²The condition on the derivatives is in fact satisfied by many of the most common quantum neural network architectures (Cerezo et al., 2020; Crooks, 2019; Schuld et al., 2020). It is satisfied for example if $A_\ell = \prod_{j=1}^P e^{i\alpha_{\ell j}^A \theta_{\ell j}^A \mathcal{P}_{\ell j}^A}$ and the $\mathcal{P}_{\ell j}^A$ are Pauli matrices, while $\alpha_{\ell j}^A$ are scalars. Such models are naturally amenable to implementation on quantum devices, and for $P = \tilde{O}(N^2)$ any unitary over $\log N'$ qubits can be written in this form (Nielsen & Chuang, 2010).

tensor x is a batch of datapoints, N is equivalent to the product of batch size and input dimension.

The model in Definition 2.1 can be used to define distributed inference and learning problems by dividing the input x and the parameterized unitaries between two players, Alice and Bob. We define their respective inputs as follows:

$$\begin{aligned} \text{Alice : } & |\psi(x)\rangle, \{A_\ell\}, \\ \text{Bob : } & \{B_\ell\}. \end{aligned} \quad (2.3)$$

The problems of interest require that Alice and Bob compute certain joint functions of their inputs. As a trivial base case, it is clear that in a communication cost model, all problems can be solved with communication cost at most the size of the inputs times the number of parties, by a protocol in which each party sends its inputs to all others. We will be interested in cases where one can do much better by taking advantage of quantum communication.

Figure 1. Distributed quantum circuit implementing \mathcal{L} for $L = 2$. Both \mathcal{L} and its gradients with respect to the parameters of the unitaries can be estimated with total communication that is polylogarithmic in the size of the input data N and the number of trainable parameters per unitary P .

Given the inputs Equation (2.3), we will be interested chiefly in the two problems specified below.

Problem 2.2 (Distributed Inference). *Alice and Bob each compute an estimate of $\langle \varphi | \mathcal{P}_0 | \varphi \rangle$ up to additive error ε .*

The straightforward algorithm for this problem, illustrated in Figure 1, requires L rounds of communication. The other problem we consider is the following:

Problem 2.3 (Distributed Gradient Estimation). *Alice computes an estimate of $\nabla_A \langle \varphi | \mathcal{P}_0 | \varphi \rangle$, while Bob computes an estimate of $\nabla_B \langle \varphi | Z_0 | \varphi \rangle$, up to additive error ε in L^∞ .*

Our main result is that these problems can be solved with exponentially less quantum communication than classical communication:

Theorem 2.4. *If $L = O(\text{polylog}(N))$, $P = O(\text{poly}(N))$ and sufficiently large N , solving Problem 2.2 or Problem 2.3 with nontrivial success probability requires $\Omega(\sqrt{N})$ bits of classical communication, while $O(\text{polylog}(N, 1/\delta) \text{poly}(1/\varepsilon))$ qubits of communication suffice to solve these problems with probability at least $1 - \delta$.*

Proof: Appendix E.

3. Graph neural networks

The communication advantages in the previous section apply to relatively unstructured data and quantum circuits (essentially the only structure in the problem is related to the promise of the vector-in-subspace problem (Raz, 1999)), and it is a priori unclear how relevant they are to circuits that approximate useful neural networks, or act on structured data. Here we consider a class of shallow graph neural networks that achieve good performance on node classification tasks on large graphs (Frasca et al., 2020). We prove that an exponential quantum communication advantage still holds for this class of models.

Consider a graph with N nodes. Define a local message passing operator on the graph A which may be the normalized Laplacian or some other operator. Given some $N \times D_0$ matrix of graph features X , we consider models of the following form $\Phi(X) = \mathcal{P}(\sigma(AXW_1))W_2$ where $W_1 \in \mathbb{R}^{D_0 \times D_1}$, $W_2 \in \mathbb{R}^{D_1 \times D_2}$ are parameter matrices, σ is a non-linearity and \mathcal{P} is a sum pooling operator acting on the first index of its input, which can be represented as multiplication by an $N \times N$ matrix P . Since we would like a scalar output and a nonlinearity that can be implemented on a quantum computer, we instead compute

$$\varphi(X) = \text{tr}[\mathcal{P}(\sigma(AXW_1))W_2], \quad (3.1)$$

with

$$\sigma(x) = ax^2 + bx + c \quad (3.2)$$

and $W_2 \in \mathbb{R}^{D_1 \times N/t}$ where t is the size of the pooling window.

In Appendix F we show an exponential quantum communication advantage holds for inference with models of this form. While they may appear simple, in Section 4, we show that models of this form achieve good performance on standard benchmarks, commensurate with state of the art models. Of particular relevance are the graph classification problems considered in Section 4.2.1, where the output takes the form Equation (3.1).

4. Experimental results

4.1. Model

We evaluate our model (as defined in Equation (3.1)) on several graph tasks using common benchmarks and the DGL library (Wang et al., 2019). We use the SIGN model proposed by (Frasca et al., 2020) as a baseline. The SIGN model can be seen as an instance of our model where the message passing operator A represents a column stack of R hops, the original features of X are duplicated R times and W_1 is a block diagonal matrix. In Section 4.2 we simply

Table 1. Test Accuracy for Node Classification and Decision Problem. Replacing PReLU with a polynomial of degree 2 causes a slight reduction in accuracy (less than 1%) for both node classification and decision problem across all datasets.

Model	Node Classification			Decision Problem		
	ogbn-products	Reddit	Cora	ogbn-products	Reddit	Cora
SIGN (PReLU)	79.48 ± 0.07	96.55 ± 0.02	78.84 ± 0.37	84.39 ± 1.73	90.33 ± 0.33	88.10 ± 5.61
SIGN (Poly)	78.51 ± 0.05	96.31 ± 0.03	78.69 ± 0.26	83.70 ± 1.48	89.37 ± 0.60	87.14 ± 3.92

replace the PReLU activation with a second-degree polynomial with trainable coefficients (Michaeli et al., 2023) and compare the models on three node classification tasks. In Appendix G, we implement a more general form of SIGN by relaxing W_1 to be a dense matrix and evaluate our model over several graph-classification datasets.

4.2. Node classification

We evaluate our model on three public node classification datasets: ogbn-products (Hu et al., 2021), Reddit (Hamilton et al., 2018), and Cora (McCallum et al., 2000). For both the baseline and polynomial model, we use SIGN with 5 hops of the neighbor averaging operator. We train on each dataset for 1000 epochs using Adam optimizer and report the test accuracy averaged on 10 runs (full details in Appendix N). Our results in Table 3 show that replacing the PReLU activation with a second-degree polynomial causes a reduction of less than 1% on all of the tested datasets.

4.2.1. DECISION PROBLEMS

We reduce the node classification task into a binary graph classification task by proposing the following decision problem: for a pair of classes (c_1, c_2) , return 1 if c_1 has more nodes; otherwise return 0. We solve this task for each pair of classes by summing the node classification model output across all nodes and choosing the class with the higher score. We use the *node* classification training, choose the model with the highest validation accuracy on the *graph* classification task, and report its accuracy on the test sets. The model output in this form is given by Equation (3.1).

5. Discussion

This work constitutes a preliminary investigation into a generic class of quantum circuits that has the potential for enabling an exponential communication advantage in problems of classical data processing including training and inference with large parameterized models over large datasets, with inherent privacy advantages. Our results naturally raise further questions regarding the expressive power and trainability of these types of circuits, which may be of independent interest. Additional discussion and open questions are collected in Appendix M.

A. Notation and a very brief review of quantum mechanics

We denote by $\{a_i\}$ a set of elements indexed by i , with 1-based indexing unless otherwise specified, with the maximal value of i explicitly specified when it is not clear from context. $[N]$ denotes the set $\{0, \dots, N-1\}$. The complex conjugate of a number c is denoted by c^* , and the conjugate transpose of a complex-valued matrix A by A^\dagger .

We denote by $|\psi\rangle$ a vector of complex numbers $\{\psi_i\}$ representing the state of a quantum system when properly normalized, and by $\langle\psi|$ its dual (assuming it exists). The inner product between two such vectors of length N is denoted by

$$\langle\psi|\varphi\rangle = \sum_{i=0}^{N-1} \psi_i^* \varphi_i. \quad (\text{A.1})$$

Denoting by $|i\rangle$ for $i \in [N]$ a basis vector in an orthonormal basis with respect to the above inner product, we can also write

$$|\psi\rangle = \sum_{i=0}^{N-1} \psi_i |i\rangle. \quad (\text{A.2})$$

Matrices will be denoted by capital letters, and when acting on quantum states will always be unitary. These can be specified in terms of their matrix elements using the Dirac notation defined above, as in

$$A = \sum_{ij} A_{ij} |i\rangle \langle j|. \quad (\text{A.3})$$

Matrix-vector product are specified naturally in this notation by

Quantum mechanics is, in the simplest possible terms, a theory of probability based on conservation of the L^2 norm rather than the standard probability theory based on the L^1 norm (Aaronson, 2017; Nielsen & Chuang, 2010). The state of a pure quantum system is described fully by a complex vector of N numbers known as amplitudes which we denote by $\{\psi_i\}$ where $i \in \{0, \dots, N-1\}$, and is written using Dirac notation as $|\psi\rangle$. The state is normalized so that

$$\langle\psi|\psi\rangle = \sum_{i=0}^{N-1} \psi_i^* \psi_i = \sum_{i=0}^{N-1} |\psi_i|^2 = 1, \quad (\text{A.4})$$

which is the L^2 equivalent of the standard normalization condition of classical probability theory. It is a curious fact that the choice of L^2 requires the use of complex rather than real amplitudes, and that no consistent theory can be written in this way for any other L^p norm (Aaronson, 2017). The most general state of a quantum system is a probabilistic mixture of pure states, in the sense of the standard L^1 -based rules of probability. We will not be concerned with these types of states, and so omit their description here, and subsequently whenever quantum states are discussed, the assumption is that they are pure.

Since any closed quantum system conserves probability, the L^2 norm of a quantum state is conserved during the evolution of a quantum state. Consequently, when representing and manipulating quantum states on a quantum computer, the fundamental operation is the application of a unitary matrix to a quantum state.

Given a quantum system with some discrete degrees of freedom, the number of amplitudes corresponds to the number of possible states of the system, and is thus exponential in the number of degrees of freedom. The simplest such degree of freedom is a binary one, called a qubit, which is analogous to a bit. Thus a state of $\log N$ qubits is described by N complex amplitudes.

A fundamental property of quantum mechanics is that the amplitudes of a quantum state are not directly measurable. Given a Hermitian operator

$$\mathcal{O} = \sum_{i=0}^{N-1} \lambda_i |v_i\rangle \langle v_i| \quad (\text{A.5})$$

with real eigenvalues $\{\lambda_i\}$, a measurement of \mathcal{O} with respect to a state $|\psi\rangle$ gives the result λ_i with probability $|\langle v_i|\psi\rangle|^2$. The real-valued quantity

$$\langle\psi|\mathcal{O}|\psi\rangle = \sum_{i=0}^{N-1} \lambda_i |\langle\psi|v_i\rangle|^2 \quad (\text{A.6})$$

is the expectation value of \mathcal{O} with respect to $|\psi\rangle$, and its value can be estimated by measurements. After a measurement with outcome λ_i , the original state is destroyed, collapsing to the state $|v_i\rangle$. A consequence of the fundamentally destructive nature of quantum measurement is that simply encoding information in the amplitudes of a quantum state does not necessarily render it useful for downstream computation. It also implies that operations using amplitude-encoded data such as evaluating a simple loss function incur measurement error, unlike their classical counterparts that are typically limited only by machine precision. The design of quantum algorithms essentially amounts to a careful and intricate design of amplitude manipulations and measurements in order to extract useful information from the amplitudes of a quantum state. For a more complete treatment of these topics see (Nielsen & Chuang, 2010).

B. Preliminaries

B.1. Large-scale learning problems and distributed computation

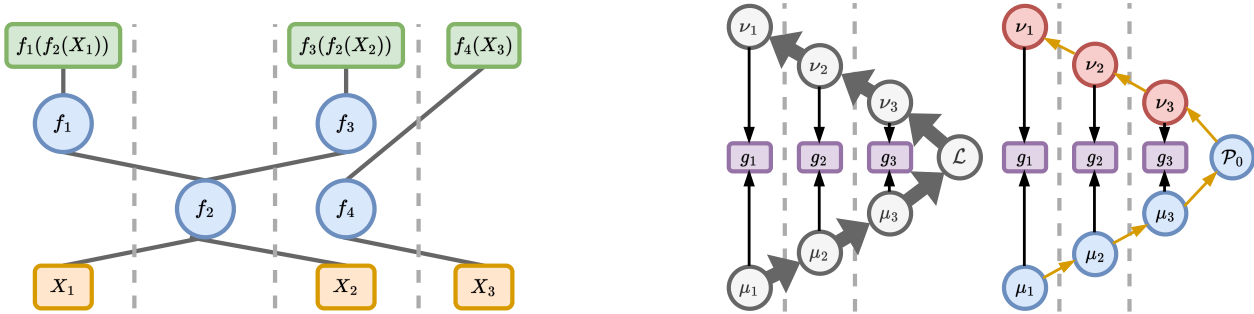

Figure 2. *Left*: Distributed, compositional computation. Dashed lines separate devices with computational and storage resources. The circular nodes represent parameterized functions that are allocated distinct hardware resources and are spatially separated, while the square nodes represent data (yellow) and outputs corresponding to different tasks (green). The vertical axis represents time. This framework of hardware allocation enables flexible modification of the model structure in a task-dependent fashion. *Right*: Computation of gradient estimators g_ℓ at different layers of a model distributed across multiple devices by pipelining. Computing forward features μ_ℓ and backwards features ν_ℓ (also known as computing a forward or backward pass) requires a large amount of classical communication (grey) but an exponentially smaller amount of quantum communication (yellow). \mathcal{L} is the classical loss function, and \mathcal{P}_0 an operator whose expectation value with respect to a quantum model gives the analogous loss function in the quantum case.

Pipelining is a commonly used method of distributing a machine learning workload, in which different layers of a deep model are allocated distinct hardware resources (Huang et al., 2018; Narayanan et al., 2019). Training and inference then require communication of features between nodes. Pipelining enables flexible changes to the model architecture in a task-dependent manner, since subsets of a large model can be combined in an adaptive fashion to solve many downstream tasks. Additionally, pipelining allows sparse activation of a subset of a model required to solve a task, and facilitates better use of heterogeneous compute resources since it does not require storing identical copies of a large model. The potential for large models to be easily fine-tuned to solve multiple tasks is well-known (Brown et al., 2020; Bommasani et al., 2021), and pipelined architectures which facilitate this are the norm in the latest generation of large language models (Rasley et al., 2020; Barham et al., 2022). Data parallelism, in contrast, involves storing multiple copies of the model on different nodes, training each on a subsets of the data and exchanging information to synchronize parameter updates. In practice, different parallelization strategies are combined in order to exploit trade-offs between latency and throughput in a task-dependent fashion (Xu et al., 2021; Jouppi et al., 2023; Pope et al., 2022). Distributed quantum models were considered recently in (Pira & Ferrie, 2023), but the potential for quantum advantage in communication in these settings was not discussed.

B.2. Communication complexity

Communication complexity (Yao, 1979; Kushilevitz & Nisan, 2011; Rao & Yehudayoff, 2020) is the study of distributed computational problems using a cost model that focuses on the communication required between players rather than the time or computational complexity. The key object of study in this area is the tree induced by a communication protocol whose nodes enumerate all possible communication histories and whose leaves correspond to the outputs of the protocol. The product structure induced on the leaves of this tree as a function of the inputs allows one to bound the depth of the tree from below, which gives an unconditional lower bound on the communication complexity. The power of replacing classical bits

of communication with qubits has been the subject of extensive study (Chi-Chih Yao, 1993; Brassard, 2001; Buhrman et al., 2009). For certain problems such as Hidden Matching (Bar-Yossef et al., 2008) and a variant of classification with deep linear models (Raz, 1999) an exponential quantum communication advantage holds, while for other canonical problems such as Disjointness only a polynomial advantage is possible (Razborov, 2002). Exponential advantage was also recently shown for the problem of sampling from a distribution defined by the solution to a linear regression problem (Montanaro & Shao, 2022). While there are many models of both quantum and classical communication, our results apply to *randomized* classical communication complexity, wherein the players are allowed to exchange random bits independent of their problem inputs, and are allowed to output an incorrect answer with some probability (bounded away from 1/2 for a problem with binary output). It is also worth noting that communication advantages of the type we demonstrate can be naturally related to space advantages in streaming algorithms that may be of interest even in settings that do not involve distributed training (Roughgarden, 2015).

At a glance, the development of networked quantum computers may seem much more challenging than the already herculean task of building a fault tolerant quantum computer. However, for some quantum network architectures, the existence of a long-lasting fault tolerant quantum memory as a quantum repeater, may be the enabling component that lifts low rate shared entanglement to a fully functional quantum network (Munro et al., 2015), and hence the timelines for small fault tolerant quantum computers and quantum networks may be more coincident than it might seem at first. As such, it is well motivated to consider potential communication advantages alongside computational advantages when talking about the applications of fault tolerant quantum computers. In Appendix K we briefly survey approaches to implementing quantum communication in practice, and the associated challenges.

In addition, while we largely restrict ourselves here to discussions of communication advantages, and most other studies focus on purely computational advantages, there may be interesting advantages at their intersection. For example, it is known that no quantum state built from a simple (or polynomial complexity) circuit can confer an exponential communication advantage, however states made from simple circuits can be made computationally difficult to distinguish (Ji et al., 2018). Hence the use of quantum pre-computation (Huggins & McClean, 2023) and communication may confer advantages even when traditional computational and communication cost models do not admit such advantages due to their restriction in scope.

C. Proofs

Proof of Lemma E.1. $\langle \varphi | \mathcal{P}_0 | \varphi \rangle$ can be estimated by preparing $|\varphi\rangle$ and measuring it $O(1/\varepsilon^2)$ times. Preparing each copy of $|\varphi\rangle$ requires $O(L)$ rounds of communication, with each round involving the communication of a $\log N^L$ -qubit quantum state. Alice first prepares $|\psi(x)\rangle$, and this state is passed back and forth with each player applying A_ℓ or B_ℓ respectively for $\ell \in \{1, \dots, L\}$.

□

Proof of Lemma E.2. We consider the parameters of the unitaries that Alice possesses first, and an identical argument follows for the parameters of Bob’s unitaries.

We have

$$\begin{aligned} \frac{\partial}{\partial \theta_{\ell i}^A} \langle \varphi | \mathcal{P}_0 | \varphi \rangle &= 2\text{Re} \langle \varphi | \mathcal{P}_0 \prod_{k=L}^{\ell+1} A_k B_k \frac{\partial A_\ell}{\partial \theta_{\ell i}^A} B_\ell \prod_{k=\ell-1}^1 A_k B_k | \psi(x) \rangle \\ &\equiv 2\text{Re} \langle \nu_{\ell i}^A | \mu_\ell^A \rangle \end{aligned} \quad (\text{C.1})$$

where

$$|\mu_\ell^A\rangle = B_\ell \prod_{k=\ell-1}^1 A_k B_k | \psi(x) \rangle, \quad |\nu_{\ell i}^A\rangle = \left(\frac{\partial A_\ell}{\partial \theta_{\ell i}^A} \right)^\dagger \prod_{k=L}^{\ell+1} B_k^\dagger A_k^\dagger \mathcal{P}_0 | \varphi \rangle, \quad (\text{C.2})$$

correspond to forward and backward features for the i -th parameter of A_ℓ respectively. This is illustrated graphically in Figure 2. We also write

$$|\nu_{\ell 0}^A\rangle = \prod_{k=L}^{\ell+1} B_k^\dagger A_k^\dagger \mathcal{P}_0 | \varphi \rangle. \quad (\text{C.3})$$

Attaching an ancilla qubit denoted by a to the feature states defined above, we define

$$|\psi_{\ell i}^A\rangle \equiv \frac{1}{\sqrt{2}} (|0\rangle |\mu_\ell^A\rangle + |1\rangle |\nu_{\ell i}^A\rangle), \quad (\text{C.4})$$

and a Hermitian measurement operator

$$\begin{aligned} E_{\ell i}^A &\equiv \left(|0\rangle \langle 0| \otimes I + |1\rangle \langle 1| \otimes \left(\frac{\partial A_\ell}{\partial \theta_{\ell i}^A} \right) \right) X_a \left(|0\rangle \langle 0| \otimes I + |1\rangle \langle 1| \otimes \left(\frac{\partial A_\ell}{\partial \theta_{\ell i}^A} \right)^\dagger \right) \\ &= |1\rangle \langle 0| \otimes \left(\frac{\partial A_\ell}{\partial \theta_{\ell i}^A} \right) + |0\rangle \langle 1| \otimes \left(\frac{\partial A_\ell}{\partial \theta_{\ell i}^A} \right)^\dagger, \end{aligned} \quad (\text{C.5})$$

we then have

$$\begin{aligned} \langle \psi_{\ell 0}^A | E_{\ell i}^A | \psi_{\ell 0}^A \rangle &= \langle \psi_{\ell i}^A | X_a | \psi_{\ell i}^A \rangle \\ &= \frac{\partial}{\partial \theta_{\ell i}^A} \langle \varphi | \mathcal{P}_0 | \varphi \rangle, \end{aligned} \quad (\text{C.6})$$

where X_a acts on the ancilla.

Note that $|\psi_{\ell 0}^A\rangle^{\otimes k}$ can be prepared by Alice first preparing $(|+\rangle |\psi(x)\rangle)^{\otimes k}$ and sending this state back and forth at most $2L$ times, with each player applying the appropriate unitaries conditioned on the value of the ancilla. Additionally, for any choice of ℓ and any i , Alice has full knowledge of the $E_{\ell i}^A$. They can thus be applied to quantum states and classical hypothesis states without requiring any communication.

The gradient can then be estimated using shadow tomography (Theorem E.3). Specifically, for each ℓ , Alice prepares $\tilde{O}(\log^2 P \log N \log(L/\delta)/\varepsilon^4)$ copies of $|\psi_0^A\rangle$, which requires $O(L)$ rounds of communication, each of $\tilde{O}(\log^2 P \log^2 N \log(L/\delta)/\varepsilon^4)$ qubits. She then runs shadow tomography to estimate $\nabla_{A_\ell} \langle \varphi | Z_0 | \varphi \rangle$ up to error ε with no additional communication. Bob does the same to estimate $\nabla_{B_\ell} \langle \varphi | Z_0 | \varphi \rangle$. In total $O(L^2)$ rounds are needed to estimate the full gradient. The success probability of all L applications of shadow tomography is at least $1 - \delta$ by a union bound.

Based on the results of (Brandão et al., 2017), the space and time complexity of each application of shadow tomography is $\sqrt{P} \text{poly}(N, \log P, \varepsilon^{-1}, \log(1/\delta))$. This is the query complexity of the algorithm to oracles that implement the measurement operators $\{E_{\ell i}^Q\}$. Instantiating these oracles will incur a cost of at most $O(N^2)$. In cases where these operators have low rank the query complexity will depend polynomially only on the rank instead of on N .

□

Proof of Lemma E.4. We first prove an $\Omega(\sqrt{N})$ lower bound on the amount of classical communication. Consider the following problem:

Problem C.1 ((Raz, 1999)). Alice is given a vector $x \in S^{N-1}$ and two orthogonal linear subspaces of \mathbb{R}^N each of dimension $N/2$, denoted M_1, M_2 . Bob is given an orthogonal matrix O . Under the promise that either $\|M_1 O x\|_2 \geq \sqrt{1 - \theta^2}$ or $\|M_2 O x\|_2 \geq \sqrt{1 - \theta^2}$ for $0 < \theta < 1/\sqrt{2}$, Alice and Bob must determine which of the two cases holds.

Ref. (Raz, 1999) showed that the randomized³ classical communication complexity of the problem is $\Omega(\sqrt{N})$.

The reduction from Problem C.1 to Problem 2.2 is obtained by choosing $\theta = 1/2$ and simply setting $L = 1, B_1 = O, |\psi(x)\rangle = |x\rangle, \mathcal{P}_0 = Z_0$, and

$$A_1 = \sum_{j=0}^{N/2-1} |0\rangle |j\rangle \langle v_j^1| + \sum_{j=0}^{N/2-1} |1\rangle |j\rangle \langle v_j^2|, \quad (\text{C.7})$$

where the first register contains a single qubit and $\{v_j^k\}$ form an orthonormal basis of M_k , and picking any $\varepsilon < 1/2$. Note that this choice of $|\psi(x)\rangle$ implies $N' = N$. Estimating \mathcal{L} to this accuracy now solves the desired problem since

³In this setting Alice and Bob can share an arbitrary number of random bits that are independent of their inputs.

$\mathcal{L} = \langle x | O^T (\Pi_1 - \Pi_2) O | x \rangle$ where Π_k is a projector onto M_k , and hence estimating this quantity up to error $1/2$ allows Alice and Bob to determine which subspace has large overlap with Ox .

The reduction from Problem C.1 to Problem 2.3 is obtained by setting $L = 2$, picking $|\psi(x)\rangle, A_1, B_1$ as before, and additionally $B_2 = I, A_2 = e^{-i\theta_{2,1}^A X_0/2}$ initialized at $\theta_{2,1}^A = -\pi/2$. By the parameter shift rule (Crooks, 2019), we have that if $U = e^{-i\theta^P/2}$ for some Pauli matrix \mathcal{P} , and U is part of the parameterized circuit that defines $|\varphi\rangle$, then

$$\frac{\partial \mathcal{L}}{\partial \theta} = \frac{1}{2} (\mathcal{L}(\theta + \frac{\pi}{2}) - \mathcal{L}(\theta - \frac{\pi}{2})). \quad (\text{C.8})$$

It follows that

$$\begin{aligned} \left. \frac{\partial \mathcal{L}}{\partial \theta_{2,1}^A} \right|_{\theta_{2,1}^A = -\pi/2} &= \frac{1}{2} (\mathcal{L}(0) - \mathcal{L}(-\pi)) \\ &= \frac{1}{2} \left(\mathcal{L}(0) - \langle x | B_1^\dagger A_1^\dagger e^{-i\frac{\pi}{2} X_0} Z_0 e^{i\frac{\pi}{2} X_0} A_1 B_1 | x \rangle \right) \\ &= \frac{1}{2} \left(\mathcal{L}(0) - \langle x | B_1^\dagger A_1^\dagger X_0 Z_0 X_0 A_1 B_1 | x \rangle \right) \\ &= \frac{1}{2} \left(\mathcal{L}(0) + \langle x | B_1^\dagger A_1^\dagger Z_0 A_1 B_1 | x \rangle \right) \\ &= \mathcal{L}(0). \end{aligned} \quad (\text{C.9})$$

Estimating $\nabla_A \langle \varphi | Z_0 | \varphi \rangle$ to accuracy $\varepsilon < 2$ allows one to determine the sign of $\mathcal{L}(0)$, which as before gives the solution to Problem C.1.

Next, we show that $\Omega(L)$ rounds are necessary in both the quantum and classical setting by a reduction from the bit version of pointer-chasing, as studied in (Jain et al., 2002; Ponzio et al., 2001).

Problem C.2 (Pointer-chasing, bit version). *Alice receives a function $f_A : [N] \rightarrow [N]$ and Bob receives a function $f_B : [N] \rightarrow [N]$. Alice is also given a starting point $x \in [N]$, and both receive an integer L_0 . Their goal is to compute the least significant bit of $f^{(L_0)}(x)$, where $f^{(1)}(x) = f_B(x), f^{(2)}(x) = f_A(f_B(x)), \dots$*

Ref. (Jain et al., 2002) show that the quantum communication complexity of L_0 -round bit pointer-chasing when Bob speaks first is $\Omega(N/L_0^4)$ (which holds for classical communication as well). This also bounds the $(L_0 - 1)$ -round complexity when Alice speaks first (since such a protocol is strictly less powerful given that there are fewer rounds of communication). On the other hand, there is a trivial L_0 -round protocol when Alice speaks first that requires $\log N$ bits of communication per round, in which Alice sends Bob x , he sends back $f^{(1)}(x)$, she replies with $f^{(2)}(f^{(1)}(x))$, and so forth. This, combined with the lower bound, implies an exponential separation in communication complexity as a function of the number of rounds.

To reduce this problem to Problem 2.2, we assume f_A, f_B are invertible. This should not make the problem any easier since it implies that f_A, f_B have the largest possible image. In this setting, f_A, f_B can be described by unitary permutation matrices:

$$U_A = \sum_i |f_A(i)\rangle \langle i|, U_B = \sum_i |f_B(i)\rangle \langle i|. \quad (\text{C.10})$$

The corresponding circuit Equation (2.3) is then given by

$$|\varphi\rangle = \text{SWAP}_{0 \leftrightarrow \log N - 1} U_B \dots U_A U_B |x\rangle \quad (\text{C.11})$$

in the case where Bob applies the function last, with an analogous circuit in the converse situation (if Bob performed the swap, Alice applies an additional identity map). Estimating Z_0 to accuracy $\varepsilon < 1$ using this state will then reveal the least significant bit of $f^{(L_0)}(x)$. This gives a circuit with L layers, where $L_0 \leq 2L - 1$. Thus any protocol with less than L_0 rounds (meaning less than $2L - 1$ rounds) would require communicating $\Omega(N/L_0^4) = \Omega(N/L^4)$ qubits, since the converse will contradict the results of (Jain et al., 2002). The reduction to Problem 2.3 is along similar lines to the one described by Equation (C.9), with the state in that circuit replaced by Equation (C.11). This requires at most two additional rounds of communication.

Since quantum communication is at least as powerful than classical communication, these bounds also hold for classical communication. Since each round involves communicating at least a single bit, this gives an $\Omega(L)$ bound on the classical communication complexity. \square

825 *Proof of Lemma F.2.* The proof is based on a reduction from the f -Boolean Hidden Partition problem (f -BHP $_{N,t}$) studied
826 in (Doriguello & Montanaro, 2020). This is defined as follows:

827
828 **Problem C.3** (Boolean Hidden Partition (Doriguello & Montanaro, 2020) (f -BHP $_{N,t}$)). Assume t divides N . Alice is
829 given $x \in \{-1, 1\}^N$. Bob is given a permutation Π over $[N]$, a boolean function $f : \{-1, 1\}^t \rightarrow \{-1, 1\}$, and a vector
830 $v \in \{-1, 1\}^{N/t}$. We are guaranteed that for any $k \in \{1, \dots, N/t\}$,

$$831 \quad f([\Pi x]_{[(k-1)t+1:kt]}) * v_k = s \quad (C.12)$$

832 for some $s \in \{-1, 1\}$. Their goal is to determine the value of s .

833
834 A polynomial $p_f : \{-1, 1\}^t \rightarrow \mathbb{R}$ is said to sign-represent a boolean function f if $\text{sign}(p_f(y)) = f(y)$ for all $y \in \{0, 1\}^t$.
835 The *sign-degree* of f ($\text{sdeg}(f)$) is the minimal degree of a polynomial that sign-represents it. In the special case $\text{sdeg}(f) = 2$,
836 f -BHP $_{N,t}$ can be solved with exponential quantum communication advantage (Doriguello & Montanaro, 2020). For a
837 vector $y \in \{0, 1\}^t$, define $\tilde{y} = (1, y_1, \dots, y_t)$. It is also known that if $\text{sdeg}(f) = 2$, then there exists a sign-representing
838 polynomial p_f that can be written as

$$839 \quad p_f(y) = \tilde{y}^T R \tilde{y} \quad (C.13)$$

840 for some matrix real R (Aaronson et al., 2016). Moreover, for any f there exists such a p_f with $\max_{x \in \{-1, 1\}^t} |p_f(x)| \leq 3$.
841 We denote by $\beta = \min_{x \in \{-1, 1\}^t} |p_f(x)|$ the *bias* of p_f .

842
843 We now describe a reduction from f -BHP $_{N,t}$ with $\text{sdeg}(f) = 2$ to QGNI $_{CN,t}$ for some constant $1 \leq C \leq 3/2$. As is
844 typical in communication complexity, the parties are allowed to exchange bits that are independent of the problem input,
845 and these are not counted when measuring the communication complexity of a protocol that depends on the inputs. Before
846 receiving their inputs, Alice thus sends two orthogonal vectors u_0, u_1 of length D_0 to Bob, with each entry described by K
847 bits⁴.

848 Assume Alice and Bob are given an instance of BHP $_{N,t}$. They use it to construct an instance of QGNI $_{(t+1)N/t,t}$ with
849 $D_1 = 1$. Alice constructs $X \in \mathbb{R}^{(t+1)N/t}$ by picking the rows X_i according to

$$850 \quad X_i = \begin{cases} \frac{1}{\sqrt{(t+1)N/t}} \left(\frac{1-x_i}{2} u_0^T + \frac{1+x_i}{2} u_1^T \right) & i \leq N \\ \frac{1}{\sqrt{(t+1)N/t}} u_1 & i > N \end{cases} \quad (C.14)$$

851 Note that with this definition $\|X\|_F = 1$. Bob defines a permutation π' over $[(t+1)N/t]$ by

$$852 \quad \pi'(i) = \begin{cases} \lfloor i/t \rfloor (t+1) + i \% t + 1 & i \leq N \\ (i - N - 1)(t+1) + 1 & i > N \end{cases} \quad (C.15)$$

853 denoting the corresponding permutation matrix Π' . Define by \bar{x} the concatenation of Alice's input x with $1^{(t+1)N/t}$. The
854 purpose of this permutation is that $\Pi' \Pi \bar{x} \equiv \tilde{x}$ will be a concatenation of N/t vectors of length $t+1$, with the i -th vector
855 equal to $(1, [\Pi x]_{t(i-1)+1}, \dots, [\Pi x]_{ti}) \equiv \tilde{x}_{(i)}$.

856 Note that we can assume wlog that R in Equation (C.13) is symmetric since p_f is independent of its anti-symmetric part. It
857 can thus be diagonalized by an orthogonal matrix U , and denoting the diagonal matrix of its real eigenvalues by D , we
858 define a (complex-valued) matrix $S = U\sqrt{D}$ that satisfies $R = SS^T$. Bob therefore defines his model by

$$859 \quad A = (I_{N/t} \otimes S^T) \Pi' \Pi, \quad W_1 = u_1 - u_0, \quad W_2 = v^T. \quad (C.16)$$

860 Additionally, he picks the pooling operator $\mathcal{P} : \mathbb{R}^{(t+1)N/t} \rightarrow \mathbb{R}^{N/t}$ to be sum pooling with window size $t+1$ (i.e.
861 $\mathcal{P}(x)_j = \sum_{k=(j-1)(t+1)+1}^{j(t+1)} x_k$). Bob also uses a simple quadratic nonlinearity by choosing $a = 1, b = c = 0$ in
862 Equation (3.2).

874
875
876
877
878
879
⁴Since D_0 is arbitrary and in particular independent of N , even if we count this communication it will not affect the scaling with N
which the main property we are interested in. This independence is also natural since it implies that the number of local graph features is
independent of the size of the graph.

To see that solving $\text{QGNI}_{(t+1)N/t,t}$ to error $\varepsilon < 1/2$ indeed provides a solution to $\text{BHP}_{N,t}$, note that

$$\mathcal{P}(\sigma(\text{AXW}_1))_i = \mathcal{P}\left(\sigma\left(\frac{1}{\sqrt{(t+1)N/t}}\text{A}\bar{x}\right)\right)_i \quad (\text{C.17})$$

$$= \mathcal{P}\left(\sigma\left(\frac{1}{\sqrt{(t+1)N/t}}(I_{N/t} \otimes S^T)\Pi'\Pi\bar{x}\right)\right)_i \quad (\text{C.18})$$

$$= \mathcal{P}\left(\sigma\left(\frac{1}{\sqrt{(t+1)N/t}}(I_{N/t} \otimes S^T)\tilde{x}\right)\right)_i \quad (\text{C.19})$$

$$= \frac{1}{(t+1)N/t} \sum_{j=1}^{t+1} ([S^T \tilde{x}_{(i)}]_j)^2 \quad (\text{C.20})$$

$$= \frac{1}{(t+1)N/t} \tilde{x}_{(i)}^T S S^T \tilde{x}_{(i)} \quad (\text{C.21})$$

$$= \frac{1}{(t+1)N/t} p_f([\Pi x]_{[(i-1)t+1:it]}). \quad (\text{C.22})$$

Given the choice of W_2 , one obtains

$$\varphi(X/\|X\|_F) = \frac{1}{(t+1)N/t} \sum_{i=1}^{N/t} p_f([\Pi x]_{[(i-1)t+1:it]})v_i. \quad (\text{C.23})$$

It follows that $\text{sign}(\varphi(X)) = s$ and $|\varphi(X)| \geq \beta$. It is thus possible to decide the value of s if $\varphi(X/\|X\|_F)$ is estimated to some error smaller than β .

From Theorem 4 of (Doriguello & Montanaro, 2020), we have $R^\rightarrow(f - \text{BHP}_{N,t}) = \Omega(\sqrt{N/t})$ for any f that has sign-degree 2 and satisfies some additional conditions. The reduction then implies

$$R_\beta^\rightarrow(\text{QGNI}_{N,t}) = \Omega(\sqrt{(t/(t+1))N/t}). \quad (\text{C.24})$$

This can be simplified by noting that since $t \geq 2$, $t/(t+1) \geq 2/3$. The lower bound in (Doriguello & Montanaro, 2020) is based on choosing f which belongs to a specific class of symmetric boolean functions (meaning $f(y) = \tilde{f}(|y|)$ where $|y| = |\{i : y_i = -1\}|$). Specifically, \tilde{f} is defined by the choice of t and two additional integer parameters θ_1, θ_2 such that $0 \leq \theta_1 < \theta_2 < t$ and

$$\tilde{f}(|y|) = \begin{cases} 1 & 0 \leq |y| \leq \theta_1 \text{ or } \theta_2 < |y|, \\ -1 & \theta_1 < |y| \leq \theta_2, \end{cases} \quad (\text{C.25})$$

(and an additional technical condition that will not be of relevance to our analysis).

We next construct a sign-representing polynomial p_f for any f that takes the above form, and compute its bias β . Since f is symmetric of sign degree 2, it suffices to construct a polynomial $\tilde{p}_f : \mathbb{R} \rightarrow \mathbb{R}$ such that $p_f(y) = \tilde{p}_f(|y|)$ for this purpose. If we can produce some β' that bounds β from below for any choice of t, θ_1, θ_2 , then the lower bound from Theorem 4 of (Doriguello & Montanaro, 2020) holds for any error smaller than β' .

We choose $\tilde{p}_f(z) = \tilde{a}z^2 + \tilde{b}z + 1$, with the constraints $\tilde{p}_f(\theta_1 + 1/2) = 0, \tilde{p}_f(\theta_2 + 1/2) = 0$. These lead to the solution

$$\tilde{p}_f(z) = \frac{1}{\theta_1^+ \theta_2^+} z^2 - \frac{1}{\theta_1^+ \theta_2^+} \frac{\theta_2^{+2} - \theta_1^{+2}}{\theta_2^+ - \theta_1^+} z + 1. \quad (\text{C.26})$$

Since this is a quadratic function with known roots that is only evaluated at integer inputs, if we want to bound the bias of p_f it suffices to check the values of \tilde{p}_f at the integers closest to the roots, namely $\{\theta_1, \theta_1 + 1, \theta_2, \theta_2 + 1\}$. Plugging in these

values gives

$$\begin{aligned}
\tilde{p}_f(\theta_1) &= 1 - \frac{\theta_2 - 1}{\left(1 + \frac{1}{2\theta_1}\right)\left(\theta_2 + \frac{1}{2}\right)} \\
&\geq 1 - \frac{1}{1 + \frac{1}{2\theta_1}} \\
&\geq \frac{1}{4\theta_1} \\
&\geq \frac{1}{4t},
\end{aligned} \tag{C.27}$$

where in the third line we used $\frac{1}{1+x} \leq 1 - x/2$ which holds for $0 \leq x \leq 1$. Using $\theta_2 \leq \theta_1 + 1$, we also have

$$\begin{aligned}
\tilde{p}_f(\theta_1 + 1) &= 1 - \frac{\theta_1 + 1}{\left(\theta_1 + \frac{1}{2}\right)\left(1 + \frac{1}{2\theta_2}\right)} \\
&\leq 1 - \frac{\theta_1 + 1}{\left(\theta_1 + \frac{1}{2}\right)\left(1 + \frac{1}{2\theta_1+2}\right)} \\
&= -\frac{1}{4\left(\theta_1 + \frac{1}{2}\right)\left(\theta_1 + \frac{3}{2}\right)} \\
&\leq -\frac{1}{4\left(t + \frac{1}{2}\right)\left(t + \frac{3}{2}\right)}.
\end{aligned} \tag{C.28}$$

$\tilde{p}_f(\theta_2)$ takes the same value as $\tilde{p}_f(\theta_1 + 1)$. Similarly,

$$\begin{aligned}
\tilde{p}_f(\theta_2 + 1) &= 1 - \frac{\theta_2 + 1}{\left(\theta_2 + \frac{1}{2}\right)\left(1 + \frac{1}{2\theta_1}\right)} \\
&\geq 1 - \frac{\theta_2 + 1}{\left(\theta_2 + \frac{1}{2}\right)\left(1 + \frac{1}{2\theta_2-2}\right)} \\
&= \frac{2\theta_2^2 - \frac{5}{4}}{\theta_2^2 - \frac{1}{4}}.
\end{aligned} \tag{C.29}$$

For $\theta_2 \leq 1$ this is a monotonically increasing function of θ_2 , and is thus lower bounded by picking $\theta_2 = 1$, giving $\tilde{p}_f(2) \geq 1$. It follows that for any choice of t, θ_1, θ_2 , the bias is bounded from below by

$$\beta^t = \frac{1}{4\left(t + \frac{1}{2}\right)\left(t + \frac{3}{2}\right)}. \tag{C.30}$$

Note that our bound on the bias allows us to use the reduction from $f - \text{BHP}_{N,t}$ to $\text{QGNI}_{(t+1)N/t,t}$ for any valid choice of f (satisfying Equation (C.24)).

□

Proof of Lemma F.3. Alice encodes her input in the quantum state

$$|\tilde{X}\rangle_0 \equiv \frac{1}{\sqrt{2}\|X\|_F} |0\rangle \sum_{i=0}^{N-1} \sum_{j=0}^{D_0-1} X_{ij} |i, j\rangle + \frac{1}{\sqrt{2}} |1\rangle |0^{\otimes N}, 0^{\otimes D_0}\rangle \tag{C.31}$$

over $\log(ND_0) + 1$ qubits. She sends this state to Bob. Define $D = \max\{D_0, D_1\}$. Bob augments this state by attaching zero qubits and, reordering the first two qubits, obtains the state

$$\begin{aligned}
|\tilde{X}\rangle &\equiv \frac{1}{\sqrt{2}\|X\|_F} |0\rangle |0\rangle \sum_{i=0}^{N-1} \sum_{j=0}^{D_0-1} X_{ij} |i, j, 0^{\otimes(D-D_0)}\rangle + \frac{1}{\sqrt{2}} |1\rangle |0\rangle |0^{\otimes N}, 0^{\otimes D}\rangle \\
&\equiv \frac{1}{\sqrt{2}} |0\rangle |0\rangle |\bar{X}\rangle + \frac{1}{\sqrt{2}} |1\rangle |0\rangle |0^{\otimes N}, 0^{\otimes D}\rangle
\end{aligned} \tag{C.32}$$

over $\log(ND) + 2$ qubits.

Define by \overline{W}_1 the $D \times D$ matrix obtained by appending zero rows or columns to the rectangular matrix W_1 to obtain a square matrix, and denote $\alpha = \|A \otimes \overline{W}_1\|$. Bob prepares an $(\alpha, 1, 0)$ -block-encoding of $A \otimes \overline{W}_1$, denoted $U_{A \otimes \overline{W}_1}$, which acts on $\log(ND) + 1$ qubits. Bob then applies this unitary conditioned on the value of the first qubit, giving

$$\begin{aligned}
(|0\rangle\langle 0| U_{A \otimes \overline{W}_1} + |1\rangle\langle 1|) |\tilde{X}\rangle &= \frac{1}{\sqrt{2}} |0\rangle U_{A \otimes \overline{W}_1} |0\rangle |\overline{X}\rangle + \frac{1}{\sqrt{2}} |1\rangle |0\rangle |0^{\otimes N}, 0^{\otimes D}\rangle \\
&= \frac{1}{\sqrt{2}} |0\rangle \left(\frac{1}{\alpha} |0\rangle A \otimes \overline{W}_1 |\overline{X}\rangle + |1\rangle |g\rangle \right) + \frac{1}{\sqrt{2}} |1\rangle |0\rangle |0^{\otimes N}, 0^{\otimes D}\rangle \\
&\equiv \frac{1}{\sqrt{2}} |0\rangle \left(\frac{1}{\alpha} |0\rangle |\overline{AXW}_1\rangle + |1\rangle |g\rangle \right) + \frac{1}{\sqrt{2}} |1\rangle |0\rangle |0^{\otimes N}, 0^{\otimes D}\rangle \\
&\equiv |\psi\rangle
\end{aligned} \tag{C.33}$$

where $|g\rangle$ is an unnormalized garbage state. Above, \overline{AXW}_1 is an $N \times D$ matrix obtained by adding zero columns to W_1 as needed.

The sum pooling operator \mathcal{P} can be implemented by multiplication by an $N/t \times N$ matrix which we denote by P . Define by \overline{W}_2 the $D \times N/t$ matrix obtained by appending zero rows to W_2 if needed. Given a matrix M of size $N_1 \times N_2$, denote by $V[M]$ the vectorization of M . Bob then constructs the Hermitian matrix

$$\mathcal{O} = \begin{pmatrix} 2a\alpha^2 |0\rangle\langle 0| \otimes \text{diag}(V[\overline{W}_2 P]) & b\alpha |0\rangle\langle 0| \otimes V[\overline{W}_2 P] \langle 0^{\otimes N}, 0^{\otimes D}| \\ b\alpha |0\rangle\langle 0| \otimes |0^{\otimes N}, 0^{\otimes D}\rangle V[\overline{W}_2 P]^\dagger & 0 \end{pmatrix}. \tag{C.34}$$

It follows that

$$\begin{aligned}
\langle \psi | \mathcal{O} | \psi \rangle + \text{ctr} [W_2 P 1^{N \times D_1}] &= \frac{a}{\|X\|_F^2} \text{tr} [W_2 P (AXW_1)^2] + \frac{b}{\|X\|_F} \text{tr} [W_2 P AXW_1] + \text{ctr} [W_2 P 1^{N \times D_1}] \\
&= \text{tr} \left[W_2 P \sigma \left(A \frac{X}{\|X\|_F} W_1 \right) \right] \\
&= \varphi(X / \|X\|_F),
\end{aligned} \tag{C.35}$$

where $1^{N \times D_1}$ is an all ones matrix. The last term on the RHS is independent of X and can be computed by Bob without requiring Alice's message. Estimating $\langle \psi | \mathcal{O} | \psi \rangle$ to accuracy ε requires $O(\|\mathcal{O}\| / \varepsilon)$ measurements. Since

$$\begin{aligned}
\|\mathcal{O}\| &\leq \|2a\alpha^2 |0\rangle\langle 0| \otimes \text{diag}(V[\overline{W}_2 P])\| + 2 \|b\alpha |0\rangle\langle 0| \otimes V[\overline{W}_2 P] \langle 0^{\otimes N}, 0^{\otimes D}|\| \\
&\leq 2(|a|\alpha^2 + |b|\alpha) \|W_2 P\|_\infty,
\end{aligned} \tag{C.36}$$

Bob requires $O((|a|\alpha^2 + |b|\alpha) \|W_2 P\|_\infty / \varepsilon)$ copies of Alice's state in order to do this. \square

Proof of Lemma F.4. For the parameter choices used to obtain the classical lower bound (Equation (C.14) and Equation (C.16)), we have $\|W_1\| = 1, \|W_2 P\|_\infty \leq t$. Additionally, for the polynomials constructed in Equation (C.26), we have $|p_f(y)| \leq Ct^2$ from which it follows that the matrix R used in the matrix representation of p_f has constant operator norm C , and thus $\|A\| = \|S\| = \sqrt{C}$. We also have $a = 1, b = c = 0$ for the nonlinearity used (Equation (3.2)), and it thus follows from Lemma F.3 that $Q_\varepsilon^{\rightarrow}(\text{QGN}_{N,t}) = O(t^3 \log(ND_0))$ for $\varepsilon \leq \frac{1}{4(t+\frac{1}{2})(t+\frac{3}{2})}$. With this choice of ε , the classical lower bound in Lemma F.2 holds, and thus an exponential advantage in communication is obtained by using quantum communication. \square

Proof of Lemma J.2. Consider first a single variable z , with data-dependent unitaries given by Equation (J.4a). If $\{\lambda_{\ell i}\}$ are chosen i.i.d. from a uniform distribution over say $[0, 1]$, then with probability 1 they are all unique and so are all sums of the form $\Lambda_{\bar{j}} = \sum_{\ell=1}^L \lambda_{\ell j_\ell}$ as well as differences $\Lambda_{\bar{j}} - \Lambda_{\bar{k}}$ for $\bar{k} < \bar{j}$ where the inequality holds element-wise. Set B_ℓ to be the

1045 Hadamard transform over $\log N'$ qubits for all ℓ , and pick the measurement operator $\mathcal{P}_0 = X_0$. We then have

$$\begin{aligned}
1046 \mathcal{L}_1 &= \langle \varphi | X_0 | \varphi \rangle \\
1047 &= \sum_{\bar{j}, \bar{k} \in [N']^L} e^{2\pi i (\Lambda_{\bar{j}} - \Lambda_{\bar{k}}) z} \left(B_1^\dagger \right)_{1j_1} \left(B_2^\dagger \right)_{j_1 j_2} \cdots \left(B_L^\dagger \right)_{j_{L-1} j_L} (X_0)_{j_L k_L} (B_L)_{k_L k_{L-1}} \cdots (B_1)_{k_1 1} \\
1048 &= \sum_{\bar{j}, \bar{k} \in [N']^L, \bar{j} \neq \bar{k}} e^{2\pi i (\Lambda_{\bar{j}} - \Lambda_{\bar{k}}) z} \left(B_1^\dagger \right)_{1j_1} \left(B_2^\dagger \right)_{j_1 j_2} \cdots \left(B_L^\dagger \right)_{j_{L-1} j_L} (X_0)_{j_L k_L} (B_L)_{k_L k_{L-1}} \cdots (B_1)_{k_1 1} \\
1049 &= \sum_{\bar{j} \in [N']^L} \sum_{\bar{k} < \bar{j}} 2 \cos \left(2\pi (\Lambda_{\bar{j}} - \Lambda_{\bar{k}}) z \right) \left(B_1^\dagger \right)_{1j_1} \cdots \left(B_L^\dagger \right)_{j_{L-1} j_L} (X_0)_{j_L k_L} \cdots (B_1)_{k_1 1} \\
1050 &= \sum_{\bar{j}[: -1] \in [N']^{L-1}} \sum_{\bar{k}[: -1] < \bar{j}[: -1]} \sum_{j_L=1}^{N'} 2 \cos \left(2\pi (\Lambda_{\bar{j}[: -1]} - \Lambda_{\bar{k}[: -1]} + \lambda_{L j_L} - \lambda_{L \bar{j}_L}) z \right) \\
1051 &\quad \left(B_1^\dagger \right)_{1j_1} \cdots \left(B_L^\dagger \right)_{j_{L-1} j_L} (B_L)_{\bar{j}_L, k_{L-1}} \cdots (B_1)_{k_1 1}
\end{aligned} \tag{C.37}$$

1052 where $\bar{j}_L = j_L + (-1)^{\lfloor j_L / (N'/2+1) \rfloor} N'/2$. In the third line, we dropped the diagonal terms in the double sum since they
1053 vanish due to the X_0 matrix having 0 on its diagonal. In the fourth line, we collected terms and used the symmetry of
1054 $\left(B_1^\dagger \right)_{1j_1} \cdots \left(B_L^\dagger \right)_{j_{L-1} j_L} (X_0)_{j_L k_L} \cdots (B_1)_{k_1 1}$ to the permutation of \bar{j} and \bar{k} . In the last line we performed the sum over
1055 k_L using the structure of X_0 . By our assumption about the $\{\lambda_{\ell i}\}$, each term in the final sum has a unique frequency so no
1056 cancellations are possible. The coefficient of each cosine is nonzero (and is equal to $2N'^{-L}$ or $-2N'^{-L}$). There are a total
1057 of $\left(\frac{N'(N'-1)}{2} \right)^{L-1} N'$ such summands. This completes the first part of the proof for this choice of $\{B_\ell\}$.

1058 Considering instead the case of two variables, with unitaries given by Equation (J.4b), an equivalent calculation gives

$$\begin{aligned}
1059 \mathcal{L}_2 &= \sum_{\bar{j}[: -1] \in [N']^{L-1}} \sum_{\bar{k}[: -1] < \bar{j}[: -1]} \sum_{j_L=1}^{N'} 2 \cos \left(\omega_{\bar{j}\bar{k}}^1 y + \omega_{\bar{j}\bar{k}}^2 z \right) \left(B_1^\dagger \right)_{1j_1} \cdots \left(B_L^\dagger \right)_{j_{L-1} j_L} (B_L)_{\bar{j}_L, k_{L-1}} \cdots (B_1)_{k_1 1}, \\
1060 &\tag{C.38}
\end{aligned}$$

1061 where

$$\begin{aligned}
1062 \omega_{\bar{j}\bar{k}}^1 &= 2\pi \left(\Lambda_{\bar{j}[: N'/2+1]} - \Lambda_{\bar{k}[: N'/2+1]} \right), \quad \omega_{\bar{j}\bar{k}}^2 = 2\pi \left(\Lambda_{\bar{j}[: N'/2+1; -1]} - \Lambda_{\bar{k}[: N'/2+1; -1]} + \lambda_{L j_L} - \lambda_{L \bar{j}_L} \right). \\
1063 &\tag{C.39}
\end{aligned}$$

1064 As before, there are $\left(\frac{N'(N'-1)}{2} \right)^{L-1} N'$ summands in total. Since

$$\begin{aligned}
1065 \cos \left(\omega_{\bar{j}\bar{k}}^1 y + \omega_{\bar{j}\bar{k}}^2 z \right) &= \cos \left(\omega_{\bar{j}\bar{k}}^1 y \right) \cos \left(\omega_{\bar{j}\bar{k}}^2 z \right) - \sin \left(\omega_{\bar{j}\bar{k}}^1 y \right) \sin \left(\omega_{\bar{j}\bar{k}}^2 z \right), \\
1066 &\tag{C.40}
\end{aligned}$$

1067 we can rewrite Equation (C.38) as a sum over $2 \left(\frac{N'(N'-1)}{2} \right)^{L-1} N'$ terms that are pairwise orthogonal w.r.t. the L^2 inner
1068 product over \mathbb{R}^2 . It follows from the definition of the separation rank that

$$\begin{aligned}
1069 \text{sep}(\mathcal{L}_2; y, z) &= 2 \left(\frac{N'(N'-1)}{2} \right)^{L-1} N'. \\
1070 &\tag{C.41}
\end{aligned}$$

1071 We next use the assumption that the real and imaginary parts of each element of B_ℓ are real analytic function of parameters
1072 Θ . This implies that the same property holds for product of entries of the form

$$\begin{aligned}
1073 \left(B_1^\dagger \right)_{1j_1} \cdots \left(B_L^\dagger \right)_{j_{L-1} j_L} (B_L)_{\bar{j}_L, k_{L-1}} \cdots (B_1)_{k_1 1} \\
1074 &\tag{C.42}
\end{aligned}$$

1075 for any choice of \bar{j}, \bar{k} . This coefficient is equal to 0 iff both the real and imaginary parts are equal to 0. Since the zero
1076 set of a real analytic function has measure 0 (Mityagin, 2015), the set of values of Θ for which any of the coefficients in
1077 Equation (C.38) vanishes also has measure 0, for all choices of \bar{j}, \bar{k} . The result follows. \square

1100 *Proof of Lemma J.3.* Consider a periodic function f with period 1. Denote by $S_M[f]$ the truncated Fourier series of f
 1101 written in terms of trigonometric functions:

$$\begin{aligned}
 1103 \quad S_M[f](y) &= \sum_{m=0}^{M-1} \int_{x=-1/2}^{1/2} f(x) \cos(2\pi m x) dx \cos(2\pi m y) + \sum_{m=0}^{M-1} \int_{x=-1/2}^{1/2} f(x) \sin(2\pi m x) dx \sin(2\pi m y) \\
 1104 & \\
 1105 & \\
 1106 & \\
 1107 & \equiv \sum_{m=0}^{M-1} \hat{f}_m^+ \cos(2\pi m y) + \sum_{m=0}^{M-1} \hat{f}_m^- \sin(2\pi m y). \\
 1108 & \\
 1109 &
 \end{aligned} \tag{C.43}$$

1110 If f is p -times continuously differentiable, it is known that the Fourier series converges uniformly, with rate

$$1111 \quad \|S_M[f] - f\|_\infty < \frac{C}{M^{p-1/2}}. \tag{C.44}$$

1112 for some absolute constant C (Osgood, 2019). For analytic functions the rate is exponential in M .

1113 We now define the following circuit:

$$1114 \quad A_1(x) = \text{diag}(\underbrace{(1, \dots, 1)}_{N'/2}, \underbrace{1, e^{2\pi i x}, e^{2\pi i 2x}, \dots, e^{2\pi i (N'/4-1)x}}_{N'/4}, \underbrace{1, e^{2\pi i x}, e^{2\pi i 2x}, \dots, e^{2\pi i (N'/4-1)x}}_{N'/4}), \tag{C.45}$$

$$1115 \quad B_1 = |\hat{f}\rangle \langle 0| + |0\rangle \langle \hat{f}|, \tag{C.46}$$

1116 where

$$1117 \quad |\hat{f}\rangle = \frac{1}{\sqrt{\sum_m |\hat{f}_m|}} \sum_{m=0}^{N'/4-1} \left(\frac{\sqrt{\hat{f}_m^+} |0\rangle + \text{sign}(\hat{f}_m^+) |1\rangle}{\sqrt{2}} |0\rangle + \frac{\sqrt{\hat{f}_m^-} |0\rangle - i \text{sign}(\hat{f}_m^-) |1\rangle}{\sqrt{2}} |1\rangle \right) |m\rangle. \tag{C.47}$$

1118 Choosing $|\psi(x)\rangle = |0\rangle$ as the initial state, this gives

$$\begin{aligned}
 1119 \quad |\varphi\rangle &= A_1 B_1 |0\rangle \\
 1120 &= A_1 |\hat{f}\rangle \\
 1121 &= \frac{1}{\sqrt{\sum_m |\hat{f}_m|}} \sum_{m=0}^{N'/4-1} \left(\frac{\sqrt{\hat{f}_m^+} |0\rangle + \text{sign}(\hat{f}_m^+) e^{2\pi i m x} |1\rangle}{\sqrt{2}} |0\rangle + \frac{\sqrt{\hat{f}_m^-} |0\rangle - i \text{sign}(\hat{f}_m^-) e^{2\pi i m x} |1\rangle}{\sqrt{2}} |1\rangle \right) |m\rangle \\
 1122 & \\
 1123 & \\
 1124 & \\
 1125 & \\
 1126 & \\
 1127 &
 \end{aligned} \tag{C.48}$$

1128 It follows that

$$\begin{aligned}
 1129 \quad \langle \varphi | X_0 | \varphi \rangle &= \frac{1}{\sum_m |\hat{f}_m|} \sum_{m=0}^{N'/4-1} \left[\frac{|\hat{f}_m^+|}{\sqrt{2}} \frac{\langle 0 | + \text{sign}(\hat{f}_m^+) e^{-2\pi i m x} \langle 1 |}{\sqrt{2}} X_0 \frac{|0\rangle + \text{sign}(\hat{f}_m^+) e^{2\pi i m x} |1\rangle}{\sqrt{2}} \right. \\
 1130 & \\
 1131 & \\
 1132 & \\
 1133 & \\
 1134 & \\
 1135 & \\
 1136 & \\
 1137 & \\
 1138 & \\
 1139 & \\
 1140 & \\
 1141 & \\
 1142 & \\
 1143 & \\
 1144 & \\
 1145 & \\
 1146 & \\
 1147 & \\
 1148 & \\
 1149 & \\
 1150 & \\
 1151 & \\
 1152 & \\
 1153 & \\
 1154 &
 \end{aligned} \tag{C.49}$$

1151 This approximation thus converges uniformly according to Equation (C.44), with error decaying exponentially with number
 1152 of qubits $\log N'$ as long as f is continuously differentiable at least once. \square

1155 *Proof of Lemma J.1.* The algorithm in Theorem 5 of (Rattew & Reberstrost, 2023) takes as input a state-preparation unitary
 1156 U acting on $n = \log N$ qubits such that $U |0\rangle^{\otimes n} = |z\rangle$. Using $O(\log 1/\varepsilon)$ queries to U and U^\dagger and $n + 4$ ancillas, it creates
 1157 a state $|\varphi\rangle$ such that measuring 0 on the first $n + 4$ qubits of $|\varphi\rangle$ results in a state $|\hat{\varphi}\rangle$ that obeys

$$1158 \left\| |\hat{\varphi}\rangle - \frac{1}{\|\sigma(z)\|_2} |\sigma(z)\rangle \right\|_2 < \varepsilon. \quad (\text{C.50})$$

1160 Additionally, the probability of measuring 0 on the first $n + 4$ qubits is $O(1)$.

1161 We will be interested in applying this algorithm to the state $|U_1 x\rangle$. The state preparation unitary can be instantiated with a
 1162 single round of communication by Alice starting with the state $|0\rangle^{\otimes 2n+4}$, applying a unitary that encodes x in the last n
 1163 qubits of this state, and then sending it to Bob who applies U_1 to the same n qubits. The conjugate of the state-preparation
 1164 unitary can be applied in a similar fashion by reversing this procedure. This can include any conditioning required on the
 1165 values of the other qubits.

1166 Based on the query complexity of the algorithm in (Rattew & Reberstrost, 2023) to the state preparation unitary, $O(\log(1/\varepsilon))$
 1167 rounds will suffice to obtain a state

$$1168 |\tilde{\varphi}_\sigma\rangle = \alpha |0\rangle^{\otimes n+4} |\tilde{y}\rangle + |\phi\rangle, \quad (\text{C.51})$$

1169 such that

$$1170 \left\| |\tilde{y}\rangle - \left| \frac{1}{\|\sigma(U_1 x)\|_2} \sigma(U_1 x) \right\rangle \right\|_2 < \varepsilon. \quad (\text{C.52})$$

1171 Bob then applies U_2 to the state $|\tilde{\varphi}_\sigma\rangle$ conditioned on the first $n + 4$ qubits being in the state $|0\rangle^{\otimes n+4}$. The state $|\phi\rangle$ is
 1172 unaffected. Unitary of U_2 combined with the above bound guarantees

$$1173 \left\| |\hat{y}\rangle - \left| U_2 \frac{1}{\|\sigma(U_1 x)\|_2} \sigma(U_1 x) \right\rangle \right\|_2 < \varepsilon. \quad (\text{C.53})$$

1174 Additionally, from Theorem 3 of (Rattew & Reberstrost, 2023) we are guaranteed that $\alpha = O(1)$. □

1183 D. Data parallelism

1184 Data parallelism involves storing multiple copies of a model on different devices and training each copy on a subset of the
 1185 full data. We consider a model of the form

$$1186 |\varphi(\Theta, x)\rangle \equiv \left(\prod_{\ell=L}^1 U_\ell(\theta_\ell, x) \right) |x\rangle, \quad (\text{D.1})$$

1187 where x is an $N_1 \times N_2$ matrix which we write as $x = [x_A, x_B]$ for two $N_1/2 \times N_2$ matrices x_A, x_B . Assume also that
 1188 $\|x\|_F = 1$. This model can be used to define a distributed problem with data parallelism by considering the following inputs
 1189 to both players:

$$1190 \begin{aligned} \text{Alice : } & x_A, \{U_\ell\}, \\ \text{Bob : } & x_B, \{U_\ell\}. \end{aligned} \quad (\text{D.2})$$

1191 The state $|x\rangle$ can be prepared in a single round of communication involving $\log(N_1 N_2)$ qubits. Alice simply prepares the
 1192 state

$$1193 \begin{aligned} |x_A\rangle + \sqrt{1 - \|x_A\|_F^2} |N_1/2, 0\rangle &= (x_A)_{ij} \sum_{i=0}^{N_1/2-1} \sum_{j=0}^{N_2-1} |i, j\rangle + \sqrt{1 - \|x_A\|_F^2} |N_1/2, 0\rangle \\ &= (x_A)_{ij} \sum_{i=0}^{N_1/2-1} \sum_{j=0}^{N_2-1} |i, j\rangle + \|x_B\|_F |N_1/2, 0\rangle, \end{aligned} \quad (\text{D.3})$$

1194 using zero-based indexing of the elements of x_A . After sending this to Bob, he applies the unitary

$$1195 \frac{1}{\|x_B\|_F} (x_B)_{i,j} \sum_{i=0}^{N_1/2-1} \sum_{j=0}^{N_2-1} |ij\rangle \langle N_1/2, 0| + h.c.. \quad (\text{D.4})$$

1210 The resulting state is $|x\rangle$. As before, the gradients with respect to the parameters of the unitaries $\{U_\ell\}$ can be estimated by
 1211 preparing copies of this state and using shadow tomography. The number of copies will again be logarithmic in N_1, N_2 and
 1212 the number of trainable parameters.

1213

1214 E. Communication complexity of inference and gradient estimation

1215

1216 We show that inference and gradient estimation are achievable with a logarithmic amount of quantum communication, which
 1217 will represent an exponential improvement over the classical cost for some cases:

1218 **Lemma E.1.** *Problem 2.2 can be solved by communicating $O(\log N)$ qubits over $O(L/\varepsilon^2)$ rounds.*

1219

1220 Proof: Appendix C.

1221

1222 **Lemma E.2.** *Problem 2.3 can be solved with probability greater than $1 - \delta$ by communicating*
 1223 *$\tilde{O}(\log N(\log P)^2 \log(L/\delta)/\varepsilon^4)$ qubits over $O(L^2)$ rounds. The time and space complexity of the algorithm is*
 1224 *$\sqrt{P} L \text{poly}(N, \log P, \varepsilon^{-1}, \log(1/\delta))$.*

1225

1226 Proof: Appendix C.

1227 This upper bound is obtained by simply noting that the problem of gradient estimation at every layer can be reduced to a
 1228 shadow tomography problem (Abbas et al., 2023):

1229

1230 **Theorem E.3** (Shadow Tomography (Aaronson, 2018) solved with Threshold Search (Bădescu & O’Donnell, 2021)). *For*
 1231 *an unknown state $|\psi\rangle$ of $\log N$ qubits, given K known two-outcome measurements E_i , there is an explicit algorithm that*
 1232 *takes $|\psi\rangle^{\otimes k}$ as input, where $k = \tilde{O}(\log^2 K \log N \log(1/\delta)/\varepsilon^4)$, and produces estimates of $\langle \psi | E_i | \psi \rangle$ for all i up to additive*
 1233 *error ε with probability greater than $1 - \delta$. \tilde{O} hides subdominant polylog factors.*

1234 Using reductions from known problems in communication complexity, we can show that the amount of classical commu-
 1235 nication required to solve this problem is polynomial in the size of the input, and additionally give a lower bound on the
 1236 number of rounds of communication required by any quantum or classical algorithm:

1237 **Lemma E.4.** *i) The classical randomized communication complexity of Problem 2.2 and Problem 2.3 with $\varepsilon < 1/2$ is*
 1238 *$\Omega(\max(\sqrt{N}, L))$.*⁵

1239 *ii) Any algorithm (quantum or classical) for Problem 2.2 or Problem 2.3 requires either $\Omega(L)$ rounds of communication or*
 1240 *$\Omega(N/L^4)$ qubits (or bits) of communication.*

1241 Proof: Appendix C

1242 The implication of the second result in Lemma E.4 is that $\Omega(L)$ rounds of communication are necessary in order to obtain
 1243 an exponential communication advantage for small L , since otherwise the number of qubits of communication required can
 1244 scale linearly with N .

1245 The combination of Lemma E.1, Lemma E.2 and Lemma E.4 immediately implies exponential savings in communication
 1246 for gradient estimation and inference. Restating the theorem from the main text, we have

1247 **Theorem E.5.** *If $L = O(\text{polylog}(N))$, $P = O(\text{poly}(N))$ and sufficiently large N , solving Problem 2.2 or Problem 2.3*
 1248 *with nontrivial success probability requires $\Omega(\sqrt{N})$ bits of classical communication, while $O(\text{polylog}(N, 1/\delta)\text{poly}(1/\varepsilon))$*
 1249 *qubits of communication suffice to solve these problems with probability at least $1 - \delta$.*

1250 The regime where $L = O(\text{polylog}(N))$ is relevant for many classes of machine learning models. The required overhead in
 1251 terms of time and space is only polynomial when compared to the straightforward classical algorithms for these problems.

1252 The distribution of the model as in Equation (2.3) is an example of pipelining. Data parallelism is another common approach
 1253 to distributed machine learning in which subsets of the data are distributed to identical copies of the model. In Appendix D
 1254 we show that it can also be implemented using quantum circuits, which can then trained using gradient descent requiring
 1255 quantum communication that is logarithmic in the number of parameters and input size.

1261 ⁵The inputs to Problem 2.2 and Problem 2.3 are defined in terms of real numbers, which is seemingly incompatible with the setting
 1262 of communication complexity which typically deals with finite inputs. However, similar (but slightly worse) lower bounds hold for
 1263 discretized analogs of these problem that use $O(\log N)$ bits to represent the real numbers (Raz, 1999).
 1264

Quantum advantage is possible in these problems because there is a bound on the complexity of the final output, whether it be correlated elements of the gradient up to some finite error or the low-dimensional output of a model. This might lead one to believe that whenever the output takes such a form, encoding the data in the amplitudes of a quantum state will trivially give an exponential advantage in communication complexity. We show however that the situation is slightly more nuanced, by considering the problem of inference with a linear model:

Lemma E.6. *For the problem of distributed linear classification, there can be no exponential advantage in using quantum communication in place of classical communication.*

The precise statement and proof of this result are presented in Appendix I. This result also highlights that the worst case lower bounds such as Lemma E.4 may not hold for circuits with certain low-dimensional or other simplifying structure.

F. Quantum communication advantage in graph network inference

This allows us to define the following problem:

Problem F.1 (Quadratic graph network inference (QGNI $_{N,t}$)). *Alice is given X , Bob is given A, W_1, W_2 . Only Alice is allowed to send messages. Their goal is to estimate $\varphi(X/\|X\|_F)$ to additive error ε .*

This models a scenario where only Bob has access to the connectivity of the graph, while Alice has access to the graph features. The normalization ensures that the choice of X does not introduce a dependence of the final output on N .

In the following, we denote by $R_\varepsilon^\rightarrow$ and $Q_\varepsilon^\rightarrow$ the classical (public key randomized) communication complexity and quantum communication complexity respectively. We show:

Lemma F.2. $R_\varepsilon^\rightarrow(\text{QGNI}_{N,t}) = \Omega(\sqrt{N/t})$ for any $\varepsilon \leq \frac{1}{4(t+\frac{1}{2})(t+\frac{3}{2})}$.

Proof: Appendix C.

Lemma F.3. $Q_\varepsilon^\rightarrow(\text{QGNI}_{N,t}) = O((|a|\alpha^2 + |b|\alpha) \|W_2 P\|_\infty \log(ND_0)/\varepsilon)$ where $\alpha = \|W_1\| \|A\|$.

Proof: Appendix C.

If this upper bound was a polynomial function of N , it would imply that an exponential communication advantage is impossible. For the parameter choices that realize classical communication lower bound, this is not the case, implying the following:

Lemma F.4. *An exponential quantum advantage in communication holds for solving the inference problem QGNI $_{N,t}$ up to error $\varepsilon \leq \frac{1}{4(t+\frac{1}{2})(t+\frac{3}{2})}$, for any t such that $t = \text{polylog}(N)$.*

Proof: Appendix C.

Note that this exponential advantage does not hold only for a single setting of the model weights, but rather for the entire family of models that can be used to solve $f - \text{BHP}_{N,t}$ for functions f that satisfy Equation (C.24).

Note that generically, one would not expect the numerator in the upper bound of Lemma F.3 to scale polynomially with N . If A is for example a normalized graph Laplacian then $\|A\| \leq 2$. If we use a standard initialization scheme for the weights (say Gaussians with variance $1/(n_{in} + n_{out})$), the upper bound scales like $O((|a| + |b|) \log(ND_0) \text{poly}(t, D_0, D_1)/\varepsilon)$ in expectation. Note that if the model output decays polynomially with N , the upper bound will not be useful since one would need to choose ε to be inverse polynomial in N . This could happen for example in a classification task considered in Section 4.2.1 when the classes are exactly balanced, or when the network is untrained and not sensitive to the structure in the data. While it is difficult to argue analytically about the scaling out the network output or the norms of the weight matrices after training due to the nonlinearity of the dynamics, we empirically compute these and find that they remain controlled for the datasets we study (see Appendix N.3).

G. Graph classification

We evaluate our model on several graph classification benchmarks: bioinformatics datasets (MUTAG, PTC, NCI1, PROTEINS)(Sheravashidze et al., 2011; Helma et al., 2001; Debnath et al., 1991; Borgwardt et al., 2005) and social networks (COLLAB, IMDB-BINARY, IMDB-MULTI, REDDIT-BINARY, REDDIT-MULTI) (Yanardag & Vishwanathan, 2015). For

Table 2. Graph Classification Test Accuracy. Our model achieves comparable results to GIN and other known models on most datasets (see full table in Table 5).

Model	Dataset						
	MUTAG	PTC	NCI1	PROTEINS	COLLAB	IMDB-M	REDDIT-M
GIN (Xu et al., 2019)	89.40±5.60	64.60±7.0	82.17±1.7	76.2 ±2.8	80.2 ±1.90	52.3 ±2.8	57.5±1.5
DropGIN(Papp et al., 2021)	90.4 ±7.0	66.3 ±8.6	-	76.3 ±6.1	-	51.4 ±2.8	-
DGCNN(Zhang et al., 2018)	85.8 ±1.7	58.6 ±2.5	-	75.5 ±0.9	-	47.8 ±0.9	-
U2GNN (Nguyen et al., 2022)	89.97±3.65	69.63±3.60	-	78.53±4.07	77.84±1.48	53.60±3.53	-
HGP-SL(Zhang et al., 2019)	-	-	78.45±0.77	84.91±1.62	-	-	-
WKPI(Zhao & Wang, 2019)	88.30±2.6	68.10±2.4	87.5 ±0.5	78.5±0.4	-	49.5 ± 0.4	59.5 ± 0.6
SIGN (ours)	92.02±6.45	68.0 ±8.17	77.25±1.42	76.55±5.10	81.82±1.42	53.13±3.01	54.09±1.76

the bioinformatics datasets, we use the standard categorical node features. As proposed in (Xu et al., 2019), we use one-hot encodings of node degree as the node features for the COLLAB and IMDB datasets, and the for REDDIT datasets all nodes have an identical scalar feature of 1. We convert the polynomial SIGN model in Section 4.2 into a graph classification model by inserting a SumPool operator as described in Equation (3.1). We use the sign diffusion operator (Wang et al., 2019) and stack R_i instances of each of its four message passing operators, where $\{R_i\}_{i=1}^4$ are selected during a hyperparameter tuning, as well as the hidden dimension size and optimization setting (see Appendix N for more details). We follow the validation regime proposed by (Xu et al., 2019); we perform 10-fold cross-validation, train each fold for 350 epochs using Adam optimizer, and report in Table 2 the maximal value and standard-deviation of the averaged validation accuracy curve. For all datasets, except for REDDIT, our model achieves comparable to or better than other commonly used models, despite most of them using multiple layers. While the results show that on most datasets our shallow architecture suffices given sufficient width in the message passing and hidden layer, we hypothesize that datasets without any node features (such as REDDIT) require at least two layers of message passing.

H. Exponential advantages in end-to-end training

So far we have discussed the problems of inference and estimating a single gradient vector. It is natural to also consider when these or other gradient estimators can be used to efficiently solve an optimization problem (i.e. when the entire training processes is considered rather than a single iteration). Applying the gradient estimation algorithm detailed in Lemma E.2 iteratively gives a distributed stochastic gradient descent algorithm which we detail in Algorithm 2, yet one may be concerned that a choice of $\varepsilon = O(\log N)$ which is needed to obtain an advantage in communication complexity will preclude efficient convergence. Here we present a simpler algorithm that requires a single quantum measurement per iteration, and can provably solve certain convex problems efficiently, as well as an application of shadow tomography to fine-tuning where convergence can be guaranteed, again with only logarithmic communication cost. In both cases, there is an exponential advantage in communication even when considering the entire training process.

H.1. “Smooth” circuits

Consider the case where A_ℓ are product of rotations for all ℓ , namely

$$A_\ell = \prod_{j=1}^P e^{-\frac{1}{2}i\beta_{\ell_j}^A \theta_{\ell_j}^A \mathcal{P}_{\ell_j}^A}, \quad (\text{H.1})$$

where $\mathcal{P}_{\ell_j}^A$ are Pauli matrices acting on all qubits, and similarly for B_ℓ . These can also be interspersed with other non-trainable unitaries. This constitutes a slight generalization of the setting considered in (Harrow & Napp, 2021), and the algorithm we present is essentially a distributed distributed version of theirs. Denote by β an $2PL$ -dimensional vector with elements $\beta_{\ell_j}^Q$ where $Q \in \{A, B\}$ ⁶. The quantity $\|\beta\|_1$ is the total evolution time if we interpret the state $|\varphi\rangle$ as a sequence of Hamiltonians applied to the initial state $|x\rangle$.

In Appendix H.3 we describe an algorithm that converges to the neighborhood of a minimum, or achieves $\mathbb{E}\mathcal{L}(\Theta) - \mathcal{L}(\Theta^*) \leq$

⁶(Harrow & Napp, 2021) actually consider a related quantity for which has smaller norm in cases where multiple gradient measurements commute, leading to even better rates.

1375 ε_0 , for a convex \mathcal{L} after

$$1376 \quad 2 \left\| \Theta^{(0)} - \Theta^* \right\|_2^2 \|\beta\|_1^2 / \varepsilon_0^2 \quad (\text{H.2})$$

1377
 1378 iterations, where Θ^* are the parameter values at the minimum of \mathcal{L} . The expectation is with respect to the randomness
 1379 of quantum measurement and additional internal randomness of the algorithm. The algorithm is based on classically
 1380 sampling a single coordinate to update at every iteration, and computing an unbiased estimator of the gradient with a single
 1381 measurement. It can thus be seen as a form of probabilistic coordinate descent.

1382 This implies an exponential advantage in communication for the entire training process as long as $\|\Theta^{(0)} - \Theta^*\|_2^2 \|\beta\|_1^2 =$
 1383 $\text{polylog}(N)$. Such circuits either have a small number of trainable parameters ($P = O(\text{polylog}(N))$), depend weakly on
 1384 each parameter (e.g. $\beta_{\ell_j}^Q = O(1/P)$ for arbitrary P), or have structure that allows initial parameter guesses whose quality
 1385 diminishes quite slowly with system size. Nevertheless, over a convex region the loss can rapidly change by an $O(1)$ amount.
 1386 One may also be concerned that in the setting $\|\Theta^{(0)} - \Theta^*\|_2^2 \|\beta\|_1^2 = \text{polylog}(N)$ only a logarithmic number of parameters
 1387 is updated during the entire training process and so the total effect of the training process may be negligible. It is important
 1388 to note however that each such sparse update depends on the structure of the entire gradient vector as seen in the sampling
 1389 step. In this sense the algorithm is a form of probabilistic coordinate descent, since the probability of updating a coordinate
 1390 $|\beta_{\ell_j}^Q| / \|\beta\|_1$ is proportional to the magnitude of the corresponding element in the gradient (actually serving as an upper
 1391 bound for it).

1392 Remarkably, the time complexity of a single iteration of this algorithm is proportional to a forward pass, and so matches the
 1393 scaling of classical backpropagation. This is in contrast to the polynomial overhead of shadow tomography (Theorem E.3).
 1394 Additionally, it requires a single measurement per iteration, without any of the additional factors in the sample complexity
 1395 of shadow tomography.

1396 H.2. Fine-tuning the last layer of a model

1397 Consider a model given by Equation (2.1) where only the parameters of A_L are trained, and the rest are frozen, and denote
 1400 this model by $|\varphi_f\rangle$. The circuit up to that unitary could include multiple data-dependent unitaries that represent complex
 1401 features in the data. Training only the final layer in this manner is a common method of fine-tuning a pre-trained model
 1402 (Howard & Ruder, 2018). If we now define

$$1403 \quad \tilde{E}_{L_i}^A = |1\rangle \langle 0| \otimes A_L^\dagger \mathcal{P}_0 \frac{\partial A_L}{\partial \theta_{L_i}^A} + |0\rangle \langle 1| \otimes \left(\frac{\partial A_L}{\partial \theta_{L_i}^A} \right)^\dagger \mathcal{P}_0 A_L, \quad (\text{H.3})$$

1404 the expectation value of $\tilde{E}_{L_i}^A$ using the state $|+\rangle |\mu_L^A\rangle$ gives $\frac{\partial \mathcal{L}}{\partial \theta_{L_i}^A}$. Here $|\mu_L^A\rangle = B_L(x) \prod_{k=L-1}^1 A_k(x) B_k(x) |\psi(x)\rangle$ is the
 1405 forward feature computed by Alice at layer L with the parameters of all the other unitaries frozen (hence the dependence on
 1406 them is dropped). Since the observables in the shadow tomography problem can be chosen in an online fashion (Aaronson
 1407 et al., 2019; Aaronson & Rothblum, 2019; Bădescu & O’Donnell, 2021), and adaptively based on previous measurements,
 1408 we can simply define a stream of measurement operators by measuring P observables to estimate the gradients w.r.t. an
 1409 initial set of parameters, updating these parameters using gradient descent with step size η , and defining a new set of
 1410 observables using the updated parameters. Repeating this for T iterations gives a total of PT observables (a complete
 1411 description of the algorithm is given in Algorithm 3).

1412 By the scaling in Lemma E.2, the total communication needed is $\tilde{O}(\log N (\log TP)^2 \log(1/\delta) / \varepsilon^4)$ over $O(L)$ rounds (since
 1413 only $O(L)$ rounds are needed to create copies of $|\mu_L^A\rangle$). This implies an exponential advantage in communication for
 1414 the entire training process (under the reasonable assumption $T = O(\text{poly}(N, P))$), despite the additional stochasticity
 1415 introduced by the need to perform quantum measurements. For example, assume one has a bound $\|\nabla \mathcal{L}\|_2^2 \leq K$. If the
 1416 circuit is comprised of unitaries with Hermitian derivatives, this holds with $K = PL$. In that case, denoting by g the gradient
 1417 estimator obtained by shadow tomography, we have

$$1418 \quad \|g\|_2^2 \leq \|\nabla \mathcal{L}\|_2^2 + \|\nabla \mathcal{L} - g\|_2^2 \leq K + \varepsilon^2 PL. \quad (\text{H.4})$$

1419 It then follows directly from Lemma H.1 that for an appropriately chosen step size, if \mathcal{L} is convex one can find parameter
 1420 values $\bar{\Theta}$ such that $\mathcal{L}(\bar{\Theta}) - \mathcal{L}(\Theta^*) \leq \varepsilon_0$ using

$$1421 \quad T = 2 \left\| \Theta^{(0)} - \Theta^* \right\|_2^2 (K + \varepsilon^2 PL)^2 / \varepsilon_0^2 \quad (\text{H.5})$$

1430 iterations of gradient descent. Similarly if \mathcal{L} is λ -strongly convex then $T = 2(K + \varepsilon^2 PL)^2 / \lambda \varepsilon_0 + 1$ iterations are sufficient.
 1431 In both cases therefore an exponential advantage is achieved for the optimization process as a whole, since in both cases one
 1432 can implement the circuit that is used to obtain the lower bounds in Lemma E.4.

1433 In the following, we make use of well-known convergence rates for stochastic gradient descent:
 1434

1435 **Lemma H.1** ((Bubeck, 2014)). *Given an objective function $\mathcal{L}(\Theta)$ with a minimum at Θ^* and a stochastic gradient oracle
 1436 that returns a noisy estimate of the gradient $g(\Theta)$ such that $\mathbb{E}g(\Theta) = \nabla\mathcal{L}(\Theta)$, $\mathbb{E}\|g\|_2^2 \leq G^2$, and denoting by $\Theta^{(0)}$ a point
 1437 in parameter space and $R = \|\Theta^{(0)} - \Theta^*\|_2$, we have:*

1438
 1439 i) *If \mathcal{L} is convex in a Euclidean ball of radius R around Θ^* , then gradient descent with step size $\eta = \frac{R}{G} \sqrt{\frac{2}{T}}$ achieves*

$$1441 \mathbb{E}\mathcal{L}\left(\frac{1}{T} \sum_{t=1}^T \Theta^{(t)}\right) - \mathcal{L}(\Theta^*) \leq RG \sqrt{\frac{2}{T}}. \quad (\text{H.6})$$

1442
 1443
 1444 ii) *If \mathcal{L} is λ -strongly convex in a Euclidean ball of radius R around Θ^* , then gradient descent with step size $\eta_t = \frac{2}{\lambda(t+1)}$
 1445 achieves*

$$1446 \mathbb{E}\mathcal{L}\left(\frac{1}{T(T+1)} \sum_{t=1}^T 2t\Theta^{(t)}\right) - \mathcal{L}(\Theta^*) \leq \frac{2G^2}{\lambda(T+1)}. \quad (\text{H.7})$$

1450 H.3. Distributed Probabilistic Coordinate Descent

1451 Algorithm 1 Distributed Probabilistic Coordinate Descent

1452
 1453 **Input:** Alice: $x, \{A_\ell\}, \Theta_A, \{\eta_t\}, T$. Bob: $\{B_\ell\}, \Theta_B, \{\eta_t\}, T$.

1454 **Output:** Alice: Updated parameters $\Theta_A^{(T)}$. Bob: Updated parameters $\Theta_B^{(T)}$.

- 1455
 1456 1: Alice and Bob each pre-process their coefficient vectors β_A, β_B to enable efficient sampling.
 1457 2: Alice sends $\|\beta_A\|_1$ to Bob. $\{O(\log P)$ bits of classical communication. $\}$
 1458 3: **for** $t \in \{1, \dots, T\}$ **do**
 1459 4: Bob samples $b \sim \text{Bernoulli}(\|\beta_A\|_1 / \|\beta\|_1)$ and sends b to Alice $\{1$ bit of classical communication. $\}$
 1460 5: **if** $b == 0$ **then**
 1461 6: Bob samples (ℓ, i) from the discrete distribution defined by $\text{abs}(\beta_B)$
 1462 7: Bob create the state $|\psi_{\ell 0}^B\rangle$ $\{O(L)$ rounds of quantum communication $\}$
 1463 8: Bob measures $\hat{E}_{\ell i}^B$, as defined in Equation (H.8), obtaining a result $m \in \{-1, 1\}$
 1464 9: Bob sets $\theta_{\ell i}^B \leftarrow \theta_{\ell i}^B - \eta_t \text{sign}(\beta_{\ell i}^B) \|\beta\|_1 m$
 1465 10: **else**
 1466 11: Alice runs steps 6-9, (replacing B with A)
 1467 12: **end if**
 1468 13: **end for**
-

1470 Given distributed states of the form Equation (H.1), optimization over Θ can be performed using Algorithm 1. We verify
 1471 the correctness of this algorithm and provide convergence rates following (Harrow & Napp, 2021). Define the Hermitian
 1472 measurement operator

$$1473 \hat{E}_{\ell i}^Q = \left(|0\rangle\langle 0| \otimes I - i |1\rangle\langle 1| \otimes \mathcal{P}_{\ell i}^Q \right)^\dagger X_a \left(|0\rangle\langle 0| \otimes I - i |1\rangle\langle 1| \otimes \mathcal{P}_{\ell i}^Q \right), \quad (\text{H.8})$$

1474 with eigenvalues in $\{-1, 1\}$. Note that $\beta_{\ell i}^Q \langle \psi_{\ell 0}^Q | \hat{E}_{\ell i}^Q | \psi_{\ell 0}^Q \rangle = \frac{\partial \mathcal{L}}{\partial \theta_{\ell i}^Q}$, and this is essentially a compact way of representing
 1475 a Hadamard test for the relevant expectation value. Now consider a gradient estimator that first samples (Q, ℓ, i) with
 1476 probability $|\beta_{\ell i}^Q| / \|\beta\|_1$, then returns a one-sparse vector with $g_{\ell i}^Q = \text{sign}(\beta_{\ell i}^Q) \|\beta\|_1 m$, where m is the result of a single
 1477 measurement of $\hat{E}_{\ell i}^Q$ using the state $|\psi_{\ell 0}^Q\rangle$. For this estimator we have

$$1481 \mathbb{E}g_{\ell i}^Q = \text{sign}(\beta_{\ell i}^Q) \|\beta\|_1 \frac{|\beta_{\ell i}^Q|}{\|\beta\|_1} \langle \psi_{\ell 0}^A | \hat{E}_{\ell i}^Q | \psi_{\ell 0}^A \rangle = \frac{\partial \mathcal{L}}{\partial \theta_{\ell i}^Q}, \quad (\text{H.9})$$

1485 where the expectation is taken over both the index sampling process and the quantum measurement. The procedure generates
 1486 a valid gradient estimator.

1487 In order to show convergence, one simply notes that by construction, $\|g\|_2 = \|\beta\|_1$. It then follows immediately from
 1488 Lemma H.1 that, with an appropriately chosen step size, Algorithm 1 achieves $\mathbb{E}\mathcal{L}(\Theta) - \mathcal{L}(\Theta^*) \leq \varepsilon_0$ for a convex \mathcal{L} using
 1489

$$1490 \frac{2 \|\Theta^{(0)} - \Theta^*\|_2^2 \|\beta\|_1^2}{\varepsilon_0^2} \quad (\text{H.10})$$

1493 queries. For a λ -strongly convex \mathcal{L} , only

$$1494 \frac{2 \|\beta\|_1^2}{\lambda \varepsilon_0} + 1 \quad (\text{H.11})$$

1496 queries are required. The pre-processing in step 1 of Algorithm 1 requires time $O(P \log P)$ and subsequently enables
 1497 sampling in time $O(1)$ using e.g. (Walker, 1974)⁷.
 1498

1499 H.4. Algorithms based on Shadow Tomography

1501 Algorithm 2 Shadow Tomographic Distributed Gradient Descent

1503 **Input:** Alice: $x, \{A_\ell\}, \Theta_A^{(1)}, \eta, T$. Bob: $\{B_\ell\}, \Theta_B^{(1)}, \eta, T$.

1504 **Output:** Alice: Updated parameters $\Theta_A^{(T)}$. Bob: Updated parameters $\Theta_B^{(T)}$.

- 1506 1: **for** $t \in \{1, \dots, T\}$ **do**
 - 1507 2: **for** $\ell \in \{1, \dots, L\}$ **do**
 - 1508 3: Alice prepares $\tilde{O}(\log^2 P \log N' \log(L/\delta)/\varepsilon^4)$ copies of $|\psi_{\ell 0}^A(\Theta^{(t)})\rangle$ $\{O(L)$ rounds of communication
 - 1509 4: Alice runs Shadow Tomography to estimate $\{\mathbb{E}E_{\ell i}^A(\Theta^{(t)})\}_{i=1}^P$ up to error ε , denoting these $\{g_{\ell i}^A(\Theta^{(t)})\}_{i=1}^P$.
 - 1510 5: Bob prepares $\tilde{O}(\log^2 P \log N' \log(L/\delta)/\varepsilon^4)$ copies of $|\psi_{\ell 0}^B(\Theta^{(t)})\rangle$ $\{O(L)$ rounds of communication
 - 1511 6: Bob runs Shadow Tomography to estimate $\{\mathbb{E}E_{\ell i}^B(\Theta^{(t)})\}_{i=1}^P$ up to error ε , denoting these $\{g_{\ell i}^B(\Theta^{(t)})\}_{i=1}^P$.
 - 1512 7: Alice sets $\theta_\ell^{A(t+1)} \leftarrow \theta_\ell^{A(t)} - \eta g_\ell^A(\Theta^{(t)})$.
 - 1513 8: Bob sets $\theta_\ell^{B(t+1)} \leftarrow \theta_\ell^{B(t)} - \eta g_\ell^B(\Theta^{(t)})$.
 - 1514 9: **end for**
 - 1515 10: **end for**
-

1518 Algorithm 3 Shadow Tomographic Distributed Fine-Tuning

1520 **Input:** Alice: $x, \{A_\ell\}, \theta_L^{A(1)}, \eta, T$. Bob: $\{B_\ell\}$

1521 **Output:** Alice: Updated parameters $\Theta_A^{(T)}$.

- 1523 1: Alice prepares $\tilde{O}(\log^2(PT) \log N' \log(1/\delta)/\varepsilon^4)$ copies of $|\mu_L^A\rangle$ $\{O(L)$ rounds of communication
 - 1524 2: **for** $t \in \{1, \dots, T\}$ **do**

1530 I. Communication Complexity of Linear Classification

1532 While the separation in communication complexity for expressive networks can be quite large, interestingly we will show
 1533 that for some of the simplest models this advantage can vanish due to the presence of structure. In particular, when a linear
 1534 classifier is well-suited to a task such that the margin is large, the communication advantage will start to wane, while a lack
 1535 of structure in linear classification will make the problem difficult for quantum algorithms as well. More specifically, we
 1536 consider the following classification problem:

1537 ⁷An even simpler algorithm that sorts the lists as a pre-processing step and uses inverse CDF sampling will enable sampling with cost
 1538 $O(\log P)$
 1539

1540 **Problem I.1** (Distributed Linear Classification). *Alice and Bob are given $x, y \in S^N$, with the promise that $|x \cdot y| \geq \gamma$ for*
 1541 *some $0 \leq \gamma \leq 1$. Their goal is to determine the sign of $x \cdot y$.*

1542
 1543 This is one of the simplest distributed inference problem in high dimensions that one can formulate. x can be thought of as
 1544 the input to the model, while y defines a separating hyperplane with some margin. Since with finite margin we are only
 1545 required to resolve the inner product between the vectors to some finite precision, it might seem that an exponential quantum
 1546 advantage should be possible for this problem by encoding the inputs in the amplitudes of a quantum state. However,
 1547 we show that classical algorithms can leverage this structure as well, and consequently that the quantum advantage in
 1548 communication that can be achieved for this problem is at most polynomial in N . We prove this with respect to the the
 1549 randomized classical communication model, in which Alice and Bob are allowed to share random bits that are independent
 1550 of their inputs ⁸.

1551 **Lemma I.2.** *The quantum communication complexity of Problem I.1 is $\Omega\left(\sqrt{N/\max(1, \lceil \gamma N \rceil)}\right)$. The randomized classical*
 1552 *communication complexity of Problem I.1 is $O(\min(N, 1/\gamma^2))$.*

1553
 1554 *Proof.* We first describe a protocol that allows Alice and Bob to solve the linear classification problem with margin γ using
 1555 $O(1/\gamma^2)$ bits of classical communication and shared randomness, assuming $\gamma > 0$. Note that this bound accords with the
 1556 notion that the margin rather than the ambient dimension sets the complexity of these types of problems, which is also
 1557 manifest in the sample complexity of learning with linearly separable data.
 1558

1559 Alice and Bob share kN bits sampled i.i.d. from a uniform distribution over $\{0, 1\}$, and that these bits are arranged in a
 1560 $k \times N$ matrix R . Alice and Bob then receive x and y respectively, which are valid inputs to the linear classification problem
 1561 with margin γ . For any N -dimensional vector z , define the random projection

$$1562 \quad f : \mathbb{R}^n \rightarrow \mathbb{R}^k, \quad f(z) = \frac{1}{k}(2R - 1)z, \quad (\text{I.1})$$

1563 where addition is element-wise. Applying the Johnson-Lindenstrauss lemma for projections with binary variables (Achlioptas,
 1564 2003), we obtain that if $k = C/\varepsilon^2$, for some absolute constant C , then with probability larger than $2/3$ we have for any
 1565 $z, z' \in \{x, y, 0\}$ (all of these being vectors in \mathbb{R}^N), f is an approximate isometry in the sense

$$1566 \quad (1 - \varepsilon) \|z - z'\|_2^2 \leq \|f(z) - f(z')\|_2^2 \leq (1 + \varepsilon) \|z - z'\|_2^2. \quad (\text{I.2})$$

1567 The key feature of this result is that k is completely independent of N . Applying it repeatedly gives

$$1568 \quad \begin{aligned} \|f(x) - f(y)\|_2^2 - \|f(x)\|_2^2 - \|f(y)\|_2^2 &\leq (1 + \varepsilon) \|x - y\|_2^2 - 2(1 - \varepsilon) \\ f(x) \cdot f(y) &\geq (1 + \varepsilon)x \cdot y - 2\varepsilon. \end{aligned} \quad (\text{I.3})$$

1569 Obtaining an upper bound in a similar fashion using the converse inequalities, we have

$$1570 \quad (1 + \varepsilon)x \cdot y - 2\varepsilon \leq f(x) \cdot f(y) \leq (1 - \varepsilon)x \cdot y + 2\varepsilon. \quad (\text{I.4})$$

1571 Assume now that x, y are valid inputs to the linear classification problem with margin γ , and specifically that $x \cdot y \geq \gamma$. The
 1572 lower bound above gives

$$1573 \quad (1 + \varepsilon)\gamma - 2\varepsilon \leq f(x) \cdot f(y), \quad (\text{I.5})$$

1574 and if we choose $\varepsilon = \gamma/8$ we obtain

$$1575 \quad \frac{\gamma}{2} \leq (1 + \frac{\gamma}{8})\gamma - \frac{\gamma}{4} \leq f(x) \cdot f(y), \quad (\text{I.6})$$

1576 where we used $\gamma \leq 1$. Similarly, if instead $x \cdot y \leq -\gamma$ we obtain

$$1577 \quad f(x) \cdot f(y) \leq -(1 - \frac{\gamma}{8})\gamma + \frac{\gamma}{4} \leq -\frac{\gamma}{2}. \quad (\text{I.7})$$

1578 It follows that if Alice computes $f(x)$ and sends the resulting $O(k) = O(1/\gamma^2)$ bits that describe this vector to Bob
 1579 (assuming some finite precision that is large enough so as not to affect the margin, which will contribute), Bob can simply

1580
 1581
 1582 ⁸This resource can have a dramatic effect on the communication complexity of a problem. The canonical example is equality of N bit
 1583 strings, which can be solved with constant success probability using 1 bit of communication and shared randomness, while requiring N
 1584 bits of communication otherwise.

1595 compute $f(x) \cdot f(y)$ which will reveal the result of the classification problem, which he can then communicate to Alice
 1596 using a single bit.

1597 If $\gamma = 0$ there is a trivial $O(N)$ classical algorithm where Alice sends Bob x .
 1598

1599 We next describe the quantum lower bound for Problem I.1. Denote by d_H the Hamming distance between binary vectors.
 1600 We will use lower bounds for the following problem:

1601
 1602
 1603 **Problem I.3** (Gap Hamming with general gap). *Alice and Bob are given $\hat{x}, \hat{y} \in \{0, 1\}^N$ respectively. Given a promise that*
 1604 *either $d_H(\hat{x}, \hat{y}) \geq N/2 + g/2$ or $d_H(\hat{x}, \hat{y}) \leq N/2 - g/2$, Alice and Bob must determine which one is the case.*
 1605
 1606

1607 There is a simple reduction from Problem I.3 to Problem I.1 for certain values of γ , which we will then use to obtain a result
 1608 for all γ . Assuming Alice is given \hat{x} and Bob is given \hat{y} , they construct unit norm real vectors by $x = (2\hat{x} - 1)/\sqrt{N}$, $y =$
 1609 $(2\hat{y} - 1)/\sqrt{N}$ with addition performed element-wise.

1610 If $d_H(x, y) \geq N/2 + g/2$ then
 1611

$$\begin{aligned}
 x \cdot y &= \sum_{i, x_i=y_i} \frac{1}{N} + \sum_{i, x_i \neq y_i} \left(-\frac{1}{N}\right) \\
 &\geq \frac{N+g}{2} \frac{1}{N} + \frac{N-g}{2} \left(-\frac{1}{N}\right) \\
 &= \frac{g}{N}.
 \end{aligned} \tag{I.8}$$

1612
 1613
 1614
 1615
 1616
 1617
 1618
 1619 Similarly, $d_H(\hat{x}, \hat{y}) \leq N/2 - g/2 \Rightarrow x \cdot y \leq -g/N$. It follows that x, y are valid inputs for a linear classification problem
 1620 over the unit sphere with margin $2g/N$. From the results of (Nayak & Wu, 1998), any quantum algorithm for the Gap
 1621 Hamming problem with gap $g \in \{1, \dots, N\}$ requires $\Omega(\sqrt{N/g})$ qubits of communication. It follows that the linear
 1622 classification problem requires $\Omega(\sqrt{1/\gamma})$ qubits of communication. This bound holds for integer γN . To get a result for
 1623 general $0 < \gamma \leq 1$ we simply note that the communication complexity must be a non-decreasing function of $1/\gamma$, since
 1624 any inputs which constitute a valid instance with some γ are also a valid instance for any $\gamma' < \gamma$. Given some real γ , the
 1625 resulting communication problem is at least as hard as the one with margin $\lceil \gamma N \rceil / N \geq \gamma$. It follows that a $\Omega(\sqrt{N/\lceil \gamma N \rceil})$
 1626 bound holds for all $0 < \gamma \leq 1$.
 1627

1628 If $\gamma = 0$, by a similar argument we can apply the lower bound for $\gamma = 1/N$, implying that $\Omega(\sqrt{N})$ qubits of communication
 1629 are necessary. Once again there is only a polynomial advantage at best. \square
 1630

1631 J. Expressivity of quantum circuits

1632 J.1. Expressivity of compositional models

1633 It is natural to ask how expressive models of the form of Equation (2.1) can be, given the unitarity constraint of quantum
 1634 mechanics on the matrices $\{A_\ell, B_\ell\}$. This is a nuanced question that can depend on the encoding of the data that is
 1635 chosen and the method of readout. On the one hand, if we pick $|\psi(x)\rangle = |x\rangle$ and use $\{A_\ell, B_\ell\}$ that are independent of
 1636 x , the resulting state $|\varphi\rangle$ will be a linear function of x and the observables measured will be at most quadratic functions
 1637 of those entries. On the other hand, one could map bits to qubits 1-to-1 and encode any reversible classical function of
 1638 data within the unitary matrices $\{A_\ell(x)\}$ with the use of extra space qubits. However, this negates the possibility of any
 1639 space or communication advantages (and does not provide any real computational advantage without additional processing).
 1640 As above, one prefers to work on more generic functions in the amplitude and phase space, allowing for an exponential
 1641 compression of the data into a quantum state, but one that must be carefully worked with.
 1642

1643 We investigate the consequences of picking $\{A_\ell(x)\}$ that are *nonlinear* functions of x , and $\{B_\ell\}$ that are data-independent.
 1644 This is inspired by a common use case in which Alice holds some data or features of the data, while Bob holds a model that
 1645 can process these features. Given a scalar variable x , define $A_\ell(x) = \text{diag}((e^{-2\pi i \lambda_{\ell 1} x}, \dots, e^{-2\pi i \lambda_{\ell N} x}))$ for $\ell \in \{1, \dots, L\}$.
 1646 We also consider parameterized unitaries $\{B_\ell\}$ that are independent of the $\{\lambda_{\ell i}\}$ and inputs x, y , and the state obtained by
 1647 interleaving the two in the manner of Equation (2.1) by $|\varphi(x)\rangle$.
 1648
 1649

1650 We next set $\lambda_{\ell 1} = 0$ for all $\ell \in \{1, \dots, L\}$ and $\lambda_{L2} = 0$. If we are interested in expressing the frequency

$$1651 \quad 1652 \quad 1653 \quad 1654 \quad \Lambda_{\bar{j}} = \sum_{\ell=1}^{L-1} \lambda_{\ell j_{\ell}}, \quad (\text{J.1})$$

1655 where $j_{\ell} \in \{2, \dots, N'\}$, we simply initialize with $|\psi(x)\rangle = |+\rangle_0 |0\rangle$ and use

$$1656 \quad 1657 \quad B_{\ell} = |j_{\ell} - 1\rangle \langle j_{\ell-1} - 1| + |j_{\ell-1} - 1\rangle \langle j_{\ell} - 1|, \quad (\text{J.2})$$

1658 with $j_1 = j_L = 2$. It is easy to check that the resulting state is $|\varphi(x)\rangle = (|0\rangle + e^{-2\pi i \Lambda_{\bar{j}} x} |1\rangle) / \sqrt{2}$. Since the basis state $|0\rangle$
 1659 does not accumulate any phase, while the B_{ℓ} s swap the $|1\rangle$ state with the appropriate basis state at every layer in order to
 1660 accumulate a phase corresponding to a single summand in Equation (J.1). Choosing to measure the operator $\mathcal{P}_0 = X_0$, it
 1661 follows that $\langle \varphi(x) | X_0 | \varphi(x) \rangle = \cos(2\pi \Lambda_{\bar{j}} x)$.
 1662

1663 It is possible to express $O((N')^{L-1})$ different frequencies in this way, assuming the $\Lambda_{\bar{j}}$ are distinct, which will be the case
 1664 for example with probability 1 if the $\{\lambda_{\ell i}\}$ are drawn i.i.d. from some distribution with continuous support. This further
 1665 motivates the small L regime where exponential advantage in communication is possible. These types of circuits with
 1666 interleaved data-dependent unitaries and parameterized unitaries was considered for example in (Schuld et al., 2020), and is
 1667 also related to the setting of quantum signal processing and related algorithms (Low & Chuang, 2017; Martyn et al., 2021).
 1668 We also show that such circuits can express dense function in Fourier space, and for small N we additionally find that these
 1669 circuits are universal function approximators (Appendix J.2), though in this setting the possible communication advantage is
 1670 less clear.

1671 The problem of applying nonlinearities to data encoded efficiently in quantum states is non-trivial and is of interest due to
 1672 the importance of nonlinearities in enabling efficient function approximation (Maiorov & Pinkus, 1999). One approach
 1673 to resolving the constraints of unitarity with the potential irreversibility of nonlinear functions is the introduction of slack
 1674 variables via additional ancilla qubits, as typified by the techniques of block-encoding (Chakraborty et al., 2018; Gilyén
 1675 et al., 2018). Indeed, these techniques can be used to apply nonlinearities to amplitude encoded data efficiently, as was
 1676 recently shown in (Rattew & Reberntrost, 2023). This approach can be applied to the distributed setting as well. Consider the
 1677 communication problem where Alice is given x as input and Bob is given unitaries $\{U_1, U_2\}$ over $\log N$ qubits. Denote by
 1678 $\sigma : \mathbb{R} \rightarrow \mathbb{R}$ a nonlinear function such as the sigmoid, exponential or standard trigonometric functions, and $n = 2^N$. We
 1679 show the following:
 1680

1681 **Lemma J.1.** *There exists a model $|\varphi_{\sigma}\rangle$ of the form Definition 2.1 with $L = O(\log 1/\varepsilon)$, $N' = 2^{n'}$ where $n' = 2n + 4$ such
 1682 that $|\varphi_{\sigma}\rangle = \alpha |0\rangle^{\otimes n+4} |\hat{y}\rangle + |\phi\rangle$ for some $\alpha = O(1)$, where $|\hat{y}\rangle$ is a state that obeys*

$$1683 \quad 1684 \quad 1685 \quad \left\| |\hat{y}\rangle - \left| U_2 \frac{1}{\|\sigma(U_1 x)\|_2} \sigma(U_1 x) \right\rangle \right\|_2 < \varepsilon. \quad (\text{J.3})$$

1686 $|\phi\rangle$ is a state whose first $n + 4$ registers are orthogonal to $|0\rangle^{\otimes n+4}$.
 1687

1688 Proof: Appendix C.
 1689

1690 This result implies that with constant probability, after measurement of the first $n + 4$ qubits of $|\varphi_{\sigma}\rangle$, one obtains a state
 1691 whose amplitudes encode the output of a single hidden layer neural network. It may also be possible to generalize this
 1692 algorithm and apply it recursively to obtain a state representing a deep feed-forward network with unitary weight matrices.

1693 It is also worth noting that the general form of the circuits we consider resembles self-attention based models with their
 1694 nonlinearities removed (motivated for example by (Sun et al., 2023)), as we explain in Appendix J.3. Finally, in Appendix J.4
 1695 we discuss other strategies for increasing the expressivity of these quantum circuits by combining them with classical
 1696 networks.
 1697

1698 J.2. Additional results on oscillatory features

1699 Extending the unitaries considered in Appendix J.1 to more than one variable, for two scalar variables x, y define

$$1700 \quad 1701 \quad A_{\ell}(x) = \text{diag}((e^{-2\pi i \lambda_{\ell 1} x}, \dots, e^{-2\pi i \lambda_{\ell N'} x})), \quad (\text{J.4a})$$

$$1702 \quad 1703 \quad A_{\ell}(x, y) = \text{diag}((e^{-2\pi i \lambda_{\ell 1} x}, \dots, e^{-2\pi i \lambda_{\ell N'/2} x}, e^{-2\pi i \lambda_{\ell, N'/2+1} y}, \dots, e^{-2\pi i \lambda_{\ell N'} y})) \quad (\text{J.4b})$$

1704

for $\ell \in \{1, \dots, L\}$. Once again $\{B_\ell\}$ are data-independent unitaries, and we denote by $|\varphi(x)\rangle, |\varphi(x, y)\rangle$ the states defined by interleaving these unitaries in the manner of Equation (2.1), and by $\mathcal{L}_1, \mathcal{L}_2$ the corresponding loss functions when measuring X_0 .

While the circuits in Appendix J.1 enable one to represent a small number of frequencies from a set that is exponential in L , one can easily construct circuits that are supported on an exponentially large number of frequencies, as detailed in Lemma J.2. We also use measures of expressivity of classical neural networks known as *separation rank* to show that circuits within the class Equation (2.1) can represent complex correlations between their inputs. For a function f of two variables y, z , its separation rank is defined by

$$\text{sep}(f) \equiv \min \left\{ R : f(x) = \sum_{i=1}^R g_i(y) h_i(z) \right\}. \quad (\text{J.5})$$

If for example f cannot represent any correlations between y and z , then $\text{sep}(f) = 1$. When computed for certain classes of neural networks, y, z are taken to be subsets of a high-dimensional input. The separation rank can be used for example to quantify the inductive bias of convolutional networks towards learning local correlations (Cohen & Shashua, 2016), the effect of depth in recurrent networks (Levine et al., 2017), and the ability of transformers to capture correlations across sequences as a function of their depth and width (Levine et al., 2020).

We find that the output of estimating an observable using circuits of the form Equation (J.4) can be supported on an exponential number of frequencies, and consequently has a large separation rank:

Lemma J.2. *For $\{\lambda_{\ell i}\}$ drawn i.i.d. from any continuous distribution and parameterized unitaries $\{B_\ell\}$ such that the real and imaginary parts of each entry in these matrices is a real analytic function of parameters Θ drawn from a subset of \mathbb{R}^{PL} , aside from a set of measure 0 over the choice of $\{\lambda_{\ell i}\}, \{B_\ell\}$,*

i) *The number of nonzero Fourier components in \mathcal{L}_1 is $\left(\frac{N'(N'-1)}{2}\right)^{L-1} N'$.*

ii)

$$\text{sep}(\mathcal{L}_2) = 2 \left(\frac{N'(N'-1)}{2}\right)^{L-1} N'. \quad (\text{J.6})$$

Proof: Appendix C

This almost saturates the upper bound on the number of frequencies that can be expressed by a circuit of this form that is given in (Schuld et al., 2020). The separation rank implies that complex correlations between different parts of the sequence can in principle be represented by such circuits. The constraint on $\{B_\ell\}$ is quite mild, and applies to standard choices of parameterize unitaries.

The main shortcoming of a result such as Lemma J.2 is that it is not robust to measurement error as it is based on constructing states that are equal weight superpositions of an exponential number of terms. It is straightforward to show that circuits of this form can serve as universal function approximators, at least for a small number of variables. For high-dimensional functions it is unclear when a communication advantage is possible, as we describe below.

Lemma J.3. *Let f be a p -times continuously differentiable function with period 1, and denote by $\hat{f}_{:M}$ the vector of the first M Fourier components of f . If $\|\hat{f}_{:M}\|_1 = 1$ then there exists a circuit of the form Equation (2.1) over $O(\log M)$ qubits such that*

$$\|\mathcal{L} - f\|_\infty \leq \frac{C}{M^{p-1/2}} \quad (\text{J.7})$$

for some absolute constant C .

Proof: Appendix C

This result improves upon the result in (Pérez-Salinas et al., 2019; Schuld et al., 2020) about universal approximation with similarly structured circuits both because it is non-asymptotic and because it shows uniform convergence rather than convergence in L_2 . Non-asymptotic results universal approximation results were also obtained recently by (Gonon & Jacquier, 2023), however their approximation error scales polynomially with the number of qubits, as opposed to exponentially as in Lemma J.3.

1760 The result of Lemma J.3 applies to an $L = 1$ circuit. The special hierarchical structure of the Fourier transform implies that
 1761 the same result can be obtained using even simpler circuits with larger L . Consider instead single-qubit data-dependent
 1762 unitaries over $L + 1$ qubits that take the form

$$1763 \quad A_\ell = |0\rangle_0 \langle 0|_0 + |1\rangle_0 \langle 1|_0 \left(|0\rangle_{\ell+1} \langle 0|_{\ell+1} + e^{2\pi i 2^{\ell-1} x} |1\rangle_{\ell+1} \langle 1|_{\ell+1} \right), \quad (\text{J.8})$$

1766 for $\ell \in \{1, \dots, L\}$. This is simply a single term in a hierarchical decomposition of the same feature matrix we had in the
 1767 shallow case, since

$$1768 \quad \prod_{\ell=1}^L A_\ell = |0\rangle_0 \langle 0|_0 \otimes I_{1:L} + |1\rangle_0 \langle 1|_0 \otimes I_1 \otimes \left(\sum_{m=0}^{2^L-1} e^{2\pi i m x} |m\rangle \langle m| \right), \quad (\text{J.9})$$

1771 which is identical to Equation (C.45). As before, set

$$1772 \quad B_1 = |\hat{f}\rangle \langle 0| + |0\rangle \langle \hat{f}|, \quad (\text{J.10})$$

1774 with $N'/4 = 2^L$ and $B_\ell = I$ for $\ell > 1$. This again gives an approximation of f up to normalization. The data-dependent
 1775 unitaries are particularly simple when decomposed in this way. The fact that they act on a single qubit and thus have "small
 1776 width" is reminiscent of classical depth-separation result such as (Cohen et al., 2015), where it is shown that (roughly
 1777 speaking) within certain classes of neural network, in order to represent the function implemented by a network of depth
 1778 L , a shallow network must have width exponential in L . In this setting as well the expressive power as measured by the
 1779 convergence rate of the approximation error grows exponentially with L by Equation (C.44).
 1780

1781 The circuits above can be generalized in a straightforward way to multivariate functions of the form $f : [-1/2, 1/2]^D \rightarrow \mathbb{R}$
 1782 and combined with multivariate generalization of Equation (C.44). In this case the scalar m is replaced by a D -dimensional
 1783 vector taking M^D possible values, and we can define

$$1784 \quad A_1(x) = |0\rangle_0 \langle 0|_0 \otimes I_{1:D \log M-1} + |1\rangle_0 \langle 1|_0 \otimes I_1 \otimes \left(\sum_{m \in [M]^D} e^{2\pi i m \cdot x} |m\rangle \langle m| \right). \quad (\text{J.11})$$

1788 Note that using this feature map, the number of neurons is linear in the spatial dimension D . Because of this, such circuits
 1789 are not strictly of the form Equation (2.1) for general N since it is *not* the case that $\log N' = O(\log N)$ where N' is the
 1790 Hilbert space on which the unitaries in the circuit act and N is the size of x . An alternative setting where the features
 1791 themselves are also learned from data could enable much more efficient approximation of functions that are sparse in Fourier
 1792 space.
 1793

1794 J.3. Unitary Transformers

1796 Transformers based on self-attention (Vaswani et al., 2017) form the backbone of large language models (Brown et al., 2020;
 1797 Barham et al., 2022) and foundation models more generally (Bommasani et al., 2021). A self-attention layer, which is the
 1798 central component of transformers, is a map between sequences in $\mathbb{R}^{S \times N'}$ (where S is the sequence length) defined in terms
 1799 of weight matrices $W_Q, W_K, W_V \in \mathbb{R}^{N' \times N'}$, given by

$$1800 \quad X'(X) = \text{softmax} \left(\frac{XW_Q W_K^T X^T}{\sqrt{N}} \right) XW_V \equiv A(X)XW_V, \quad (\text{J.12})$$

1804 where $\text{softmax}(x)_i = e^{x_i} / \sum_i e^{x_i}$ for a vector x , and acts row-wise on matrices. There is an extensive literature on replacing
 1805 the softmax-based attention matrix $A(X)$ with matrices that can be computed more efficiently, which can markedly improve
 1806 the time complexity of inference and training without a significant effect on performance (Katharopoulos et al., 2020; Levine
 1807 et al., 2020). In some cases $A(X)$ is replaced by a unitary matrix (Lee-Thorp et al., 2021). Remarkably, recent work shows
 1808 that models without softmax layers can in fact outperform standard transformers on benchmark tasks while enabling faster
 1809 inference and a reduced memory footprint (Sun et al., 2023).
 1810

1811 Considering a simplified model that does not contain the softmax operation as in (Levine et al., 2020) and dropping
 1812 normalization factors, the linear attention map is given by

$$1813 \quad X'_{\text{lin}}(X) = XW_Q W_K^T X^T XW_V. \quad (\text{J.13})$$

1814

1815 Iterating this map twice gives

$$1816$$

$$1817 X'_{\text{lin}}(X'_{\text{lin}}(X)) = \frac{XW_Q^{(1)}W_K^{(1)T}X^T XW_V^{(1)}W_Q^{(2)}W_K^{(2)T}W_V^{(1)T}X^T X^*}{W_K^{(1)}W_Q^{(1)T}X^T XW_Q^{(1)}W_K^{(1)T}X^T XW_V^{(1)}W_V^{(2)}}. \quad (\text{J.14})$$

$$1818$$

$$1819$$

1820 Iterating this map K times (with different weight matrices at each layer) gives a function of the form:

$$1821$$

$$1822 X_{\text{lin}}^{(K)}(X) = XR_0 \prod_{\ell=1}^{(3^K-1)/2} (X^T X R_\ell), \quad (\text{J.15})$$

$$1823$$

$$1824$$

1825 where the $\{R_\ell\}$ matrices depend only on the trainable parameters. If we now constrain these to be parameterized unitary
 1826 matrices, and additionally replace $X^T X$ with a unitary matrix U_X encoding features of the input sequence itself, then
 1827 the i -th row of the output of this model is encoded in the amplitudes of a state of the form Equation (2.3) with $L =$
 1828 $(3^K - 1)/2 + 1$, $|\psi(x)\rangle = |X_i\rangle$, $A_\ell(x) = U_X$, $B_\ell = R_\ell$.

1830 J.4. Ensembling and point-wise nonlinearities

1832 An additional method for increasing expressivity while maintaining an advantage in communication is through ensembling.
 1833 Given K models of the form Definition 2.1 with P parameters each, one can combine their loss functions $\mathcal{L}_1, \dots, \mathcal{L}_K$ into
 1834 any differentiable nonlinear function

$$1835 \tilde{\mathcal{L}}(\mathcal{L}_1(\Theta_1, x), \dots, \mathcal{L}_K(\Theta_K, x), \tilde{\Theta}, x) \quad (\text{J.16})$$

$$1836$$

1837 that depends on additional parameters $\tilde{\Theta}$. As long as K and $|\tilde{\Theta}|$ scale subpolynomially with N and P , the gradients for this
 1838 more expressive model can be computed while maintaining the exponential communication advantage in terms of N, P .

1840 K. Realizing quantum communication

1842 Given the formidable engineering challenges in building a large, fault tolerant quantum processor (Arute et al., 2019; Google
 1843 Quantum AI, 2023), the problem of exchanging coherent quantum states between such processors might seem even more
 1844 ambitious. We briefly outline the main problems that need to be solved in order to realize quantum communication and the
 1845 state of progress in this area, suggesting that this may not be the case.

1846 We first note that sending a quantum state between two processors can be achieved by the well-known protocol of quantum
 1847 state teleportation (Bennett et al., 1993; Gordon & Rigolin, 2005). Given an n qubit state $|\psi\rangle$, Alice can send $|\psi\rangle$ to Bob by
 1848 first sharing n Bell pairs of the form

$$1850 |b\rangle = \frac{1}{\sqrt{2}} (|0\rangle |0\rangle + |1\rangle |1\rangle), \quad (\text{K.1})$$

$$1851$$

1852 (sharing such a state involves sending a \mathcal{L} of the two qubits to Bob) and subsequently performing local processing
 1853 on the Bell pairs and exchanging n bits of classical communication. Thus quantum communication can be reduced to
 1854 communicating Bell pairs up to a logarithmic overhead, and does not require say transmitting an arbitrary quantum state in a
 1855 fault tolerant manner, which appears to be a daunting challenge given the difficulty of realizing quantum memory on a single
 1856 processor. Bell pairs can be distributed by a third party using one-way communication.

1857 In order to perform quantum teleportation, the Bell pairs must have high fidelity. As long as the fidelity of the communicated
 1858 Bell pairs is above .5, purification can be used produce high fidelity Bell pairs (Bennett et al., 1995), with the fidelity of the
 1859 purified Bell pair increasing exponentially with the number of pairs used. Thus communicating arbitrary quantum states can
 1860 be reduced to communicating noisy Bell pairs.

1862 Bell pair distribution has been demonstrated across multiple hardware platforms including superconducting waveguides
 1863 (Magnard et al., 2020), optical fibers (Krutyanskiy et al., 2022), free space optics at distances of over 1, 200 kilometers (Li
 1864 et al., 2022). At least in theory, even greater distances can be covered by using quantum repeaters, which span the distance
 1865 between two network nodes. Distributing a Bell pair between the nodes can then be reduced to sharing Bell pairs only
 1866 between adjacent repeaters and local processing (Azuma et al., 2022).

1867 A major challenge in implementing a quantum network is converting entangled states realized in terms of photons used for
 1868 communication to states used for computation and vice versa, known as transduction (Lauk et al., 2020). Transduction is a
 1869

difficult problem due to the several orders of magnitude in energy that can separate optical photons from the energy scale of the platform used for computation. Proof of principle experiments have been performed across a number of platforms including trapped ions (Krut'yanskiy et al., 2022), solid-state systems (Pompili et al., 2021), and superconducting qubits operating at microwave frequencies (Balram & Srinivasan, 2021; Wang et al., 2022).

L. Privacy of Quantum Communication

In addition to an advantage in communication complexity, the quantum algorithms outlined above have an inherent advantage in terms of privacy. It is well known that the number of bits of information that can be extracted from an unknown quantum state is proportional to the number of qubits. It follows immediately that since the above algorithm requires exchanging a logarithmic number of copies of states over $O(\log N)$ qubits, even if all the communication between the two players is intercepted, an attacker cannot extract more than a logarithmic number of bits of classical information about the input data or model parameters. Specifically, we have:

Corollary L.1. *If Alice and Bob are implementing the quantum algorithm for gradient estimation described in Lemma E.2, and all the communication between Alice and Bob is intercepted by an attacker, the attacker cannot extract more than $\tilde{O}(L^2(\log N)^2(\log P)^2 \log(L/\delta)/\varepsilon^4)$ bits of classical information about the inputs to the players.*

This follows directly from Holevo’s theorem (Holevo, 1973), since the multiple copies exchanged in each round of the protocol can be thought of as a quantum state over $\tilde{O}((\log N)^2(\log P)^2 \log(L/\delta)/\varepsilon^4)$ qubits. As noted in (Aaronson, 2018), this does not contradict the fact that the protocol allows one to estimate all P elements of the gradient, since if one were to place some distribution over the inputs, the induced distribution over the gradient elements will generally exhibit strong correlations. An analogous result holds for the inference problem described in Lemma E.1.

It is also interesting to ask how much information either Bob or Alice can extract about the inputs of the other player by running the protocol. If this amount is logarithmic as well, it provides additional privacy to both the model owner and the data owner. It allows two actors who do not necessarily trust each other, or the channel through which they communicate, to cooperate in jointly training a distributed model or using one for inference while only exposing a vanishing fraction of the information they hold.

It is also worth mentioning that data privacy is also guaranteed in a scenario where the user holding the data also specifies the processing done on the data. In this setting, Alice holds both data x and a full description of the unitaries she wishes to apply to her state. She can send Bob a classical description of these unitaries, and as long as the data and features are communicated in the form of quantum states, only a logarithmic amount of information can be extracted about them. In this setting there is of course no advantage in communication complexity, since the classical description of the unitary will scale like $\text{poly}(N, P)$.

M. Some Open Questions

Communication constraints may become even more relevant if such models are trained on data that is obtained by inherently distributed interaction with the physical world (Driess et al., 2023). The ability to compute using data with privacy guarantees can be potentially applied to proprietary data. This could become highly desirable even in the near future as the rate of publicly-available data production appears to be outstripped by the growth rate of training sets of large language models (Villalobos et al., 2022).

A limitation of the current results is that it’s unclear to what extent powerful neural networks can be approximated using quantum circuits, even though we provide positive evidence in the form of the results on graph networks in Section 3. Additionally, the advantages we study require deep (poly(N)), fault-tolerant quantum circuits. While this is a common feature of problems for which quantum communication advantages hold, the overhead of quantum error-correction in such circuits may be considerable. Detailed resource estimates would be necessary to understand better the practicality of this approach for achieving useful quantum advantage.

M.1. Expressivity

Circuits that interleave parameterized unitaries with unitaries that encode features of input data are also used in Quantum Signal Processing (Low & Chuang, 2017; Martyn et al., 2021), where the data-dependent unitaries are time evolution operators with respect to some Hamiltonian of interest. The original QSP algorithm involved a single parameterized rotation

at each layer, and it is also known that extending the parameter space from $U(1)$ to $SU(2)$ by including an additional rotation improves the complexity of the algorithm and improves its expressivity (Motlagh & Wiebe, 2023). In both cases however the expressive power (in terms of the degree of the polynomial of the singular values that can be expressed) grows only linearly with the number of interleaved unitaries. Given the natural connection to the distributed learning problems considered here, it is interesting to understand the expressive power of such circuits with more powerful multi-qubit parameterized unitaries.

We present a method of applying a single nonlinearity to a distributed circuit using the results of (Rattew & Rebentrost, 2023). Since this algorithm requires a state-preparation unitary as input and produces a state with a nonlinearity applied to the amplitudes, it is natural to ask whether it can be applied recursively to produce a state with the output of a deep network with nonlinearities encoded in its amplitudes. This will require extending the results of (Rattew & Rebentrost, 2023) to handle noisy state-preparation unitaries, yet the effect of errors on compositions of block encodings (Chakraborty et al., 2018; Gilyén et al., 2018), upon which these results are based, is relatively well understood. It is also worth noting that these approaches rely on the approximation of nonlinear functions by polynomials, and so it may also be useful to take inspiration directly from classical neural network polynomial activations, which in some settings are known to outperform other types of nonlinearities (Michaeli et al., 2023).

M.2. Optimization

The results of Appendix H rely on sublinear convergence rates for general stochastic optimization of convex functions (Lemma H.1). It is known however that using additional structure, stochastic gradients can be used to obtain linear convergence (meaning that the error decays exponentially with the number of iterations). This is achievable when subsampling is the source of stochasticity (Le Roux et al., 2012), or with occasional access to noiseless gradients in order to implement a variance reduction scheme (Johnson & Zhang, 2013; Moritz et al., 2016; Gower et al., 2016), neither of which seem applicable to the setting at hand. It is an interesting open question to ascertain whether there is a way to exploit the structure of quantum circuits to obtain linear convergence rates using novel algorithms. Aside from advantages in time complexity, this could imply an exponential advantage in communication for a more general class of circuits.

Conversely, it is also known that given only black-box access to a noisy gradient oracle, an information-theoretic lower bound of $\Omega(1/T)$ on the error holds given T oracle queries, precluding linear convergence without additional structure, even for strongly convex objectives (Agarwal et al., 2010). (Harrow & Napp, 2021) provide a similar lower bound for their algorithm, at least for a restricted class of circuits. Perhaps these results be used to show optimality of algorithms that rely on the standard variational circuit optimization paradigm that involves making quantum measurements at every iteration and using these to update the parameters. This might imply that linear convergence is only possible if the entire optimization process is performed coherently.

In this context, we note that the treatment of gradient estimation at every layer and every iteration as an independent shadow tomography problem is likely highly suboptimal, since no use is made of the correlations across iterations between the states and the observables of interest. While in Appendix H.2 this is not the case, that algorithm applies only to fine-tuning of a single layer. Is there a way to re-use information between iterations to reduce the resource requirements of gradient descent using shadow tomography? One approach could be warm-starting the classical resource states by reusing them between iterations. Improvements along these lines might find applications for other problems as well.

M.3. Exponential advantage under weaker assumptions

The lower bound in Lemma E.4 applies to circuits that contain general unitaries, and thus have depth $\text{poly}(N)$ when compiled using a reasonable gate set. One can ask whether the lower bound can be strengthened to apply to more restricted classes of unitaries as well, and in particular log-depth unitaries. While it is known that exponential communication advantages require the circuits to have $\text{poly}(N)$ gate complexity overall (Abbas et al., 2023), this does not rule out the possibility of computational separations resulting from the clever encoding and transmission of states nor does it rule out communication advantages resulting from very short time preparations from log-depth protocols. The rapid growth of complexity of random circuits composed from local gates with depth suggests that this might be possible (Brown & Susskind, 2017). This is particularly interesting since Algorithm 1 requires only a single measurement per iteration and may thus be suitable for implementation on near-term devices whose coherence times restrict them to implementing shallow circuits. It has also been recently shown that an exponential quantum advantage in communication holds for a problem which is essentially equivalent to estimating the loss of a circuit of the form Definition 2.1 with $L = 2$, under a weaker model of quantum communication than the standard one we consider (Arunachalam et al., 2023). This is the one-clean-qubit

Table 3. Hyper parameters of node classification training

model, in which the initial state $|\psi(x)\rangle$ consists of a single qubit in a pure state, while all other qubits are in a maximally mixed state.

N. Experiments additional details

N.1. Node classification training

We use the same training regime for all datasets using the recommended hyperparameters in DGL (Wang et al., 2019) examples, reported in Table 3.

We trained each model 10 times for all three datasets using a single NVIDIA RTX A6000, taking approximately 15 minutes per execution.

N.2. Graph classification training

As, to the best of our knowledge, we are the first to use a SIGN variant on graph classification tasks, we conducted a comprehensive hyperparameter tuning for the model structure (including the number of message passing operators, the hidden dimension, and normalization after the hidden layer) and optimization settings. The tuning was performed using Bayesian hyperparameter optimization to identify the optimal values for each dataset. This process involved varying the hidden dimension, the number of SIGN hops per operation, the learning rate, and dropout rates. The values considered for each hyperparameter are detailed in Table 4. The full results of these experiments are in Table 5.

We scan each task for approximately 150 runs, using a single NVIDIA RTX A6000.

N.3. Empirical bounds

We measure $\|W_1\|$ and $\|W_2\|_\infty$ of the trained graph classification models in Section 4.2.1, corresponding to Equation (3.1) and report the average results over 10 runs in Table 6 (note that we use $P = I$ so that no pooling matrix is present, and in any case the pooling window will typically be a small constant). W_1 is constructed as a block diagonal matrix of the weights of the SIGN hidden layer. $\|W_2\|_\infty$ is the infinity norm of the weight matrix of the output layer of SIGN, multiplied by 2 (since we compute differences between numbers of nodes in two classes).

We measure the score difference of the graph classification task in Section 4.2.1 and compare them to the differences of the

class sizes in Figure 3. Most of the differences are significant (larger than $1/\text{poly}(N)$ where N is the number of nodes; see Figure 3(c)). Some class pairs have low differences making them indistinguishable, however, Figure 3(a),(b) indicate those are typically classes with similar number of nodes. This provides evidence that when there is a considerable class imbalance (i.e. one that scales with system size), the magnitude of the model output when computing this difference will not decay with the size of the graph.

While evidence of asymptotic scaling will require experiments on graphs of different sizes, our results suggest that the upper bound in Lemma F.3 is not large for models trained on standard benchmarks, implying that they can be efficiently simulated on a quantum computer.

Figure 3. (a): Difference between class sizes in ogbn-products test set. (b) Difference between the graph classification model class scores. The score differences are correlated to the class size differences. (c) Histogram of the class pairs differences. Most of the differences are significantly larger than $1/N$.
