ASYMMETRY IN LOW-RANK ADAPTERS OF FOUNDATION MODELS

Anonymous authors
Paper under double-blind review

ABSTRACT

Parameter-efficient fine-tuning optimizes large, pre-trained foundation models by updating a subset of parameters; in this class, Low-Rank Adaptation (LoRA) is particularly effective. Inspired by an effort to investigate the different roles of LoRA matrices during fine-tuning, this paper characterizes and leverages unexpected asymmetry in the importance of low-rank adapter matrices. Specifically, when updating the parameter matrices of a neural network by adding a product $BA$, we observe that the $B$ and $A$ matrices have distinct functions: $A$ extracts features from the input, while $B$ uses these features to create the desired output. Based on this observation, we demonstrate that fine-tuning $B$ is inherently more effective than fine-tuning $A$ and that a random untrained $A$ should perform nearly as well as a fine-tuned one. Using an information-theoretic lens, we also bound generalization of low-rank adapters, showing that the parameter savings of exclusively training $B$ improves the bound. We support our conclusions with experiments on RoBERTa, BART, LLaMA-2, and ViT.

1 INTRODUCTION

Foundation models for data-rich modalities like text and imagery have achieved significant success by pre-training large models on vast amounts of data. While these models are designed to be general-purpose, it is often necessary to fine-tune them for downstream tasks. The huge size of foundation models, however, can make fine-tuning the entire model impossible, inspiring parameter-efficient fine-tuning (PEFT) methods that selectively update fewer parameters (c.f. Lialin et al., 2023). PEFT’s effectiveness demonstrates that updating even a tiny fraction of the parameters can retain or enrich the capabilities of pretrained models, and has become a necessary ingredient, e.g., the PEFT package [HuggingFace Year] has been supporting more than 4.4k projects since its creation in November 2022.

Among PEFT methods, low-rank adaptation (LoRA) (Hu et al., 2021) has become increasingly popular, leveraging an assumption that over-parameterized models have a low intrinsic dimension (Aghajanyan et al., 2021). To update a neural network, LoRA trains a subset of the parameters (usually attention) by representing weight matrices as $W_0 + \Delta W$, where $W_0$ is the fixed weight matrix form the pre-trained model and $\Delta W$ is a low-rank update. Compared to full fine-tuning, LoRA considerably reduces the number of trainable parameters and memory requirements and often achieves similar or better performance.

Most LoRA implementations factor $\Delta W = BA$ and optimize for $A$ and $B$, where $A$ and $B$ have fewer rows and columns (resp.) than $\Delta W$; this is the approach proposed by [Hu et al., 2021]. With this set of variables, the standard LoRA training procedure—wherein $A$ is initialized to a random matrix and $B$ is initialized to zero—reflects a curious asymmetry, which is leveraged in some empirical follow-ups [Zhang et al., 2023a; Kopiczko et al., 2024]. In particular, while training $B$ is critical for the performance of LoRA, even a randomly initialized $A$ seems to suffice for strong performance. Reversing the roles of $A$ and $B$ substantially decreases performance.

Digging into this empirical suggestion from prior work, this paper shows that LoRA’s components are inherently asymmetric. In fact, the asymmetry occurs even for linear models (§B.1.1). Indeed, our theoretical (§B) and empirical analysis (§C) suggests that fixing $A$ to a random orthogonal matrix can yield similar performance to full LoRA training, and that this adjustment may even promote...
generalization. This observation is backed by a comprehensive empirical study, leading to practical suggestions for improving parameter efficiency and generalization of LoRA models.

**Contributions.** Our contributions are as follows: (1) We provide simple theoretical and empirical analysis demonstrating asymmetry of training the two adapter matrices, showing that tuning $B$ is more impactful than tuning $A$. This confirms and builds on prior empirical observations (Zhang et al., 2023a; Kopiczko et al., 2024). (2) We show theoretically and empirically that randomly drawing and freezing $A$ while tuning only $B$ can improve generalization vs. tuning both $B$ and $A$, in addition to practical gains achieved by $2 \times$ parameter reduction. (3) We validate our findings through experiments using models including RoBERTa, BART-Large, Llama-2, and the vision transformer (ViT).

## 2 Preliminaries & Background

**Motivating example.** In Figure 1, we investigate the similarity of learned matrices $A$ and $B$ under three scenarios: (a) random initialization, $A$ & $B$ trained multiple times on the same task; (b) fixed initialization, $A$ & $B$ trained multiple times, each time on a different task; and (c) random initialization, $A$ & $B$ trained multiple times, each time on a different task. Here, we fine-tune RoBERTa large (Liu et al., 2019) with LoRA on the tasks from the GLUE benchmark (Wang et al., 2018). Specifically, we fine-tune *mrpc* with 5 random seeds for (a) and on *mrpc, rte, stsb, and cola* for (b) and (c). The figure plots similarity of learned $A$ and $B$ matrices across layers in Figure 1, measured by canonical correlation analysis goodness of fit (Ramsay et al., 1984); see Appendix D for motivation. These plots suggest that $B$ is predominantly responsible for learning, while $A$ is less important. Specifically, when training on the same task with different initializations (scenario (a)), the learned $B$ matrices are similar to each other, while when training on different tasks (scenarios (b) and (c)), they are different. On the contrary, the similarity of learned $A$ matrices is insensitive to training data and is determined by initialization; it is highest in scenario (b) when the initialization is fixed even though training data differs.

## 3 Theoretical Analysis Results

In this section, we show the results of the theoretical analysis of the asymmetry in prediction tasks and its effect on generalization. A complete analysis is presented in the appendix.

We discuss a general case rather than a specific neural network architecture, considering rank $r$ adaptation of any parameter matrix $W = W_0 + BA$ used multiplicatively on some input-dependent vector, i.e.,

$$\text{layerOutput} = \psi((W_0 + BA) \cdot \phi(\text{layerInput}), \ldots)$$  \hspace{1cm} (1)

for some differentiable functions $\psi, \phi$. Here, $\psi$ may take more arguments depending on $\text{layerInput}$, which may have their own low rank adapted parameter matrices. This generic form encompasses both feedforward and attention layers.

In this setting, $A$ serves to extract $r$ features from $\phi(\text{layerInput})$, which are then used by $B$ to predict some desired output for future layers. We will argue that training $B$ to predict the output is crucial for correct outputs, while using a random $A$ is often sufficient, as $B$ can be optimized to use whatever information is retained in the $r$-dimensional projection $A \cdot \phi(\text{layerInput})$. 

---

Figure 1: Similarity of learned LoRA matrices $A$ & $B$ across layers of a RoBERTa model fine-tuned with different initialization and data settings. The experiment demonstrates the asymmetric roles of $A$ and $B$ in LoRA. A detailed discussion is in motivating example.
3.1 A, B Asymmetry in Prediction Tasks

If we wish to reduce the effort of training both A and B in (1), in principle either A could be frozen and B tuned or B frozen and A tuned. As shown in §B.2.1 and elsewhere, these two options are not empirically equivalent: It is best to freeze A and tune B. In this section, we seek to understand the principle behind this asymmetry by theoretically analyzing the fine-tuning of a class of prediction models. We first build intuition with least-squares linear regression.

3.1.1 Multivariate Linear Least-Squares

As a simple example analogous to a single network layer, we study $d_{in}$-to-$d_{out}$ least-squares linear regression (in (1), set $\phi, \psi$ to be identity). Specifically, suppose there is an input $X \in \mathbb{R}^{d_{in}}$, an output $Y \in \mathbb{R}^{d_{out}}$, and a pre-trained linear model

$$y_{\text{pre}}(X) = W_0 X + b_0,$$

where $W_0 \in \mathbb{R}^{d_{out} \times d_{in}}$ and $b_0 \in \mathbb{R}^{d_{out}}$. With this model held constant, our goal is regressing $(Y_{\text{targ}}, X_{\text{targ}})$ pairs where $Y_{\text{targ}}$ is given by: $Y_{\text{targ}} = W_{\text{targ}}X_{\text{targ}} + b_{\text{targ}}$ with $W_{\text{targ}} = W_0 + \Delta$. Following LoRA, we model the target $\Delta$ using a low rank update to the pre-trained $W_0$, i.e. $W = W_0 + BA: \hat{y}(x) = (W_0 + BA)x + b$, where $B \in \mathbb{R}^{d_{out} \times r}$ and $A \in \mathbb{R}^{r \times d_{in}}$ for some $r$.

To find an $A$ and $B$ that best matches the output, we optimize the least squares loss on the difference between $\hat{y}$ and $Y_{\text{targ}}$:

$$\mathcal{L}(A, B) = \mathbb{E}_{(Y_{\text{targ}}, X_{\text{targ}})}[\|Y_{\text{targ}} - (W_0 + BA)X_{\text{targ}} - b\|^2].$$

(2)

Below, we present lemmas on minimizing this loss while freezing either A or B. In both, for simplicity, we set $b = b_{\text{targ}}$ and $\mathbb{E}[X_{\text{targ}}] = 0$ and defer proofs to Appendix E.

**Lemma 3.1 (Freezing A yields regression on projected features).** Optimizing $\mathcal{L}(A, B)$ while fixing $A = Q$ with $QQ^\top = I_r$ yields

$$B^* = \Delta \Sigma Q^\top (Q \Sigma Q^\top)^{-1},$$

where $\Sigma = \text{Cov}[X_{\text{targ}}]$, with expected loss $\mathcal{L}(Q, B^*) = d_{out}\sigma^2 + \text{Tr}[\Delta \Sigma \Delta^\top] - \text{Tr}[Q \Sigma \Delta^\top \Delta \Sigma Q^\top (Q \Sigma Q^\top)^{-1}].$

**Lemma 3.2 (Freezing B yields regression on projected outputs).** Optimizing $\mathcal{L}(A, B)$ while fixing $B = U$ with $U^\top U = I_r$ yields

$$A^* = U^\top (W_{\text{targ}} - W_0),$$

with expected loss $\mathcal{L}(A^*, U) = d_{out}\sigma^2 + \text{Tr}[\Delta \Sigma \Delta^\top] - \text{Tr}[U^\top \Delta \Sigma \Delta^\top U]$, where $\Sigma = \text{Cov}[X_{\text{targ}}]$.

Comparing the lemmas above, $A^*$ is simply the $U$ projection of the targeted change in weight matrix $\Delta = W_{\text{targ}} - W_0$. Unlike $B^*$, the optimal choice of $A^*$ does not consider the input data distribution captured by $\Sigma$.

Intuitively, if the goal of adaptation is to approximate some desired output, then projecting away the majority (since $r \ll d_{out}$) of the output is undesirable. In contrast, projecting away a portion of the input feature space will be less damaging, if the information $X_{\text{targ}}$ contains about $Y_{\text{targ}}$ is redundant (c.f., neuron dropout (Srivastava et al., 2014) in neural network training) or if the distribution of $X_{\text{targ}}$ tends to be low-rank. We validate the above intuition with the following theorem:

**Theorem 3.3 (A, B output fit asymmetry).** Consider the settings of Lemmas 3.1 and 3.2 and suppose $U, Q$ are sampled uniformly from their respective Stiefel manifolds. Then, $\mathcal{L}(A^*, U) \geq \mathcal{L}(Q, B^*)$ with high probability as $d/r \to \infty$.

In other words, the least-squares prediction loss of only fine-tuning $B$ is at least as good as only fine-tuning $A$. Moreover, in the appendix we further show the performance advantage of tuning $B$ over $A$ is large when $d \gg r$, which is the typical regime in practice.

Based on our above result, we extend our theoretical analysis to §B.1.2 nonlinear losses and multilayer models. Also, we show the advantages of tuning only $B$ matrix (§B.2.1) including parameter efficiency (§B.2.1) and provable better generalization (§B.2.2). In sum, our analysis characterizes the different roles of $A$ and $B$ matrix. Our theory shows that just fine-tuning $B$ while freezing $A$ corresponds to learning projected feature space, and should yield better performance than freezing $B$. Next, our experimental results will verify our understanding across multiple models and datasets.
We illustrate differences between the two matrices from both theoretical and empirical perspectives. We investigate the asymmetry of low-rank adaptation methods with RoBERTa (Liu et al., 2019), where we fine-tune a Llama-2-7b model (Touvron et al., 2023). In addition, only updating matrix \( B \) consistently outperforms conventional LoRA. We can also observe similar asymmetry in natural language summarization task (Table 2) and the more complicated MMLU benchmark (Table 3) where we fine-tune a Llama-2-7b model (Touvron et al., 2023). In addition, only updating matrix \( B \) generally results in better out-of-domain test accuracy when fine-tuning the Vision Transformer model on multidomain image classification task (DomainBed (Gulrajani & Lopez-Paz, 2020), (Table 4)).

### 4 Experiments

We investigate the asymmetry of low-rank adaptation methods with RoBERTa (Liu et al., 2019), BART (Lewis et al., 2020), Llama-2 (Touvron et al., 2023), and Vision Transformer (Dosovitskiy et al., 2020). We evaluate the performance of fine-tuning strategies on natural language understanding (GLUE (Wang et al., 2018), MMLU (Hendrycks et al., 2020)), natural language generation (XSum (Narayan et al., 2018) and CNN/DailyMail (Chen et al., 2016)), and multi-domain image classification (Gulrajani & Lopez-Paz, 2020). The details of experimental results, including implementation, baselines, and analysis are in the appendix.

Using the General Language Understanding Evaluation (GLUE, Wang et al., 2018) benchmark (Table 1), we can see a clear trend where solely updating the \( B \) matrix outperforms just learning the \( A \) matrix. In addition, when doubling the rank to match the trainable parameters, \( B_{\text{LoRA}} \) consistently outperforms conventional LoRA. We can also observe similar asymmetry in natural language summarization task (Table 2) and the more complicated MMLU benchmark (Table 3) where we fine-tune a Llama-2-7b model (Touvron et al., 2023). In addition, only updating matrix \( B \) generally results in better out-of-domain test accuracy when fine-tuning the Vision Transformer model on multidomain image classification task (DomainBed (Gulrajani & Lopez-Paz, 2020), (Table 4)).

### 5 Conclusion

In this paper, we formally identify and investigate asymmetry in the roles of low-rank adapter matrices in LoRA fine-tuning. The \( A \) matrices extract features from the input, while the \( B \) matrices project these features towards the desired objective.

We illustrate differences between the two matrices from both theoretical and empirical perspectives. Our theoretical analysis explains asymmetry in the fine-tuning of large models. Our theoretical findings further suggest that freezing \( A \) as a random orthogonal matrix can improve generalization, a claim we corroborate with experiments across multiple models and datasets.

Our work serves as an initial step to unveil the mechanisms of fine-tuning large models. Our interpretation of low-rank adapters provides an understanding that can benefit future research directions, promoting efficiency and interpretability in foundational models.

A RELATED WORK

LoRA [Hu et al., 2021] has inspired a vast array of improvements to the basic technique. For example, quantization can reduce memory usage during training (Gholami et al., 2021; Dettmers et al., 2023; Guo et al., 2024). Also, the number of trainable parameters can be further reduced by adaptively allocating the rank (Zhang et al., 2023b), pruning during training (Benedek & Wolf, 2024), or pruning and quantizing after training (Yadav et al., 2023).

To further reduce the number of trainable LoRA parameters, the idea of reusing (randomly generated) weights or projections (Frankle & Carbin, 2018; Ramanujan et al., 2020) suggests strategies from learning diagonal matrices rescaling randomly-drawn and frozen $B$, $A$ matrices (VeRA) (Kopiczko et al., 2024), deriving $B$ and $A$ from the SVD decomposition of the pre-trained $W$ and optimizing for a smaller matrix in the resulting basis (SVDiff) (Han et al., 2023), learning a linear combination of fixed random matrices (NOLA) (Koohpayegani et al., 2023), or fine-tuning using orthogonal matrices (BOFT) (Liu et al., 2024). As echoed in our empirical results, previous methods observe that freezing $A$ in conventional LoRA preserves performance (Zhang et al., 2023a). While nearly all recent studies treat the two matrices asymmetrically in their initialization or freezing schemes, there is a lack of formal investigation into this asymmetry in low-rank adaptation.

Even before LoRA, fine-tuning was shown to succeed despite low dimensionality (Aghajanyan et al., 2021). Zeng & Lee (2023) specifically investigate the expressive power of LoRA, focusing on linear networks and linear parts of networks. Their analysis does not consider aspects such as the particular distribution of fine-tuning target data, generalization, and the differing roles of various factors.

B FULL THEORETICAL ANALYSIS

In this section, we analyze the asymmetry in prediction tasks and its effect on generalization. We discuss a general case rather than a specific neural network architecture, considering rank $r$ adaptation of any parameter matrix $W = W_0 + BA$ used multiplicatively on some input-dependent vector, i.e.,

$$\text{layerOutput} = \psi((W_0 + BA) \cdot \phi(\text{layerInput}), \ldots)$$

for some differentiable functions $\psi, \phi$. Here, $\psi$ may take more arguments depending on layerInput, which may have their own low rank adapted parameter matrices. This generic form encompasses both feedforward and attention layers.

In this setting, $A$ serves to extract $r$ features from $\phi(\text{layerInput})$, which are then used by $B$ to predict some desired output for future layers. We will argue that training $B$ to predict the output is crucial for correct outputs, while using a random $A$ is often sufficient, as $B$ can be optimized to use whatever information is retained in the $r$-dimensional projection $A \cdot \phi(\text{layerInput})$.

B.1 $A$, $B$ ASYMMETRY IN PREDICTION TASKS

If we wish to reduce the effort of training both $A$ and $B$ in (3), in principle either $A$ could be frozen and $B$ tuned or $B$ frozen and $A$ tuned. As shown in §C and elsewhere, these two options are not empirically equivalent: It is best to freeze $A$ and tune $B$. In this section, we seek to understand the principle behind this asymmetry by theoretically analyzing the fine-tuning of a class of prediction models. We first build intuition with least-squares linear regression.

B.1.1 MULTIVARIATE LINEAR LEAST-SQUARES

As a simple example analogous to a single network layer, we study $d_{in}$-to-$d_{out}$ least-squares linear regression (in (3), set $\phi, \psi$ to be identity). Specifically, suppose there is an input $X \in \mathbb{R}^{d_{in}}$, an output $Y \in \mathbb{R}^{d_{out}}$, and a pre-trained linear model

$y_{\text{pre}}(X) = W_0 X + b_0$,

where $W_0 \in \mathbb{R}^{d_{out} \times d_{in}}$ and $b_0 \in \mathbb{R}^{d_{out}}$. With this model held constant, our goal is regressing ($Y_{\text{targ}}, X_{\text{targ}}$) pairs where $Y_{\text{targ}}$ is given by:

$Y_{\text{targ}} = W_{\text{targ}} X_{\text{targ}} + b_{\text{targ}}$
with \( W_{\text{targ}} = W_0 + \Delta \). Following LoRA, we model the target \( \Delta \) using a low rank update to the pre-trained \( W_0 \), i.e. \( W = W_0 + BA \):

\[
\hat{y}(x) = (W_0 + BA)x + b,
\]

where \( B \in \mathbb{R}^{d_{\text{out}} \times r} \) and \( A \in \mathbb{R}^{r \times d_{\text{in}}} \) for some \( r \).

To find an \( A \) and \( B \) that best matches the output, we optimize the least squares loss on the difference between \( \hat{y} \) and \( Y_{\text{targ}} \):

\[
\mathcal{L}(A, B) = \mathbb{E}_{(Y_{\text{targ}}, X_{\text{targ}})}[\|Y_{\text{targ}} - (W_0 + BA)X_{\text{targ}} - b\|^2_2].
\]

Below, we present lemmas on minimizing this loss while freezing either \( A \) or \( B \). In both, for simplicity, we set \( b = b_{\text{targ}} \) and \( \mathbb{E}[X_{\text{targ}}] = 0 \) and defer proofs to Appendix E.

**Lemma B.1** (Freezing \( A \) yields regression on projected features). Optimizing \( \mathcal{L}(A, B) \) while fixing \( A = Q \) with \( QQ^\top = I_r \) yields

\[
B^* = \Delta \Sigma Q^\top (Q \Sigma Q^\top)^{-1},
\]

where \( \Sigma = \text{Cov}[X_{\text{targ}}] \), with expected loss

\[
\mathcal{L}(Q, B^*) = d_{\text{out}} \sigma^2 + \text{Tr}[\Delta \Sigma \Delta^\top] - \text{Tr}[Q \Sigma \Delta^\top \Delta \Sigma Q^\top (Q \Sigma Q^\top)^{-1}].
\]

**Lemma B.2** (Freezing \( B \) yields regression on projected outputs). Optimizing \( \mathcal{L}(A, B) \) while fixing \( B = U \) with \( U^\top U = I_r \) yields

\[
A^* = U^\top (W_{\text{targ}} - W_0),
\]

with expected loss

\[
\mathcal{L}(A^*, U) = d_{\text{out}} \sigma^2 + \text{Tr}[\Delta \Sigma \Delta^\top] - \text{Tr}[U^\top \Delta \Sigma \Delta^\top U],
\]

where \( \Sigma = \text{Cov}[X_{\text{targ}}] \).

Comparing the lemmas above, \( A^* \) is simply the \( U \) projection of the targeted change in weight matrix \( \Delta = W_{\text{targ}} - W_0 \). Unlike \( B^* \), the optimal choice of \( A^* \) does not consider the input data distribution captured by \( \Sigma \).

Intuitively, if the goal of adaptation is to approximate some desired output, then projecting away the majority (since \( r \ll d_{\text{out}} \)) of the output is undesirable. In contrast, projecting away a portion of the input feature space will be less damaging, if the information \( X_{\text{targ}} \) contains about \( Y_{\text{targ}} \) is redundant (c.f., neuron dropout \cite{srivastava2014dropout} in neural network training) or if the distribution of \( X_{\text{targ}} \) tends to be low-rank.

Consider the following extreme example. If \( \Sigma = FF^\top \) is at most rank \( r \), e.g. if \( F \in \mathbb{R}^{d_{\text{in}} \times r} \), then for each \( X \) there exists an \( N = F^\top X \in \mathbb{R}^r \) such that \( X = FN \). Suppose you have tuned a pair \( A_*, B_* \). For any orthonormal \( Q \in \mathbb{R}^{r \times d_{\text{out}}} \) (e.g. one drawn at random), we can write

\[
B_*, A_* X = B_*, A_* FN = (B_*, A_* F (QF)^{-1}) Q X,
\]

i.e. regardless of \( A_*, B_* \), for any (random) \( Q \), there is an exactly equivalent LoRA adaptation with \( A = Q \) and \( B = (B_*, A_* F (QF)^{-1}) \). In this setting, therefore, randomizing \( A \) (to \( Q \)) is equally expressive to tuning it (using \( A_* \)).

This intuition is also reflected in the typical LoRA initialization. When doing full LoRA (tuning both \( A, B \)), \( A \) is usually initialized to a random Gaussian matrix, and \( B \) is initialized to zero. This procedure—presumably empirically derived by \cite{hu2021lora}—intuitively fits our analysis above, since random \( A \) yields good random predictive features, in contrast to using a random output prediction basis. Initializing \( B \) to zero then starts the optimization at a zero perturbation of the pretrained model.

We validate the above intuition with the following theorem:

**Theorem B.3** (\( A, B \) output fit asymmetry). Consider the settings of Lemmas B.1 and B.2 and suppose \( U, Q \) are sampled uniformly from their respective Stiefel manifolds. Then, \( \mathcal{L}(A^*, U) \geq \mathcal{L}(Q, B^*) \) with high probability as \( d_{\text{out}} / r \to \infty \).

\(^1\)Here \( F^\dagger \) denotes pseudoinverse.
In other words, the least-squares prediction loss of only fine-tuning $B$ is at least as good as only fine-tuning $A$.

**Intuition on asymmetry gap.** Theorem [B.3] is built on the following inequality:

$$\text{Tr}[E Q^T (Q \Sigma Q^T)^{-1} Q \Sigma \Delta \Delta] \geq \text{Tr}[(Q^T Q) \Sigma Q^T (Q \Sigma Q^T)^{-1} Q \Sigma \Delta \Delta].$$

Let us consider an example regime to build intuition on the size of this gap. Following intuition that freezing $A$ is most successful when the information content of the input is redundant (c.f., Aghajanyan et al. [2021]), suppose the distribution of $X$ is low rank, i.e., $\Sigma$ is of rank $r_X$. We can then write $\Sigma = U_X S_X U_X^\top$, where $U_X \in \mathbb{R}^{d_{in} \times r_X}$ is orthogonal and $S_X \in \mathbb{R}^{r_X \times r_X}$ is diagonal with nonnegative real entries.

For intuition, set $r_X = r$ and $S_X = \sigma^2 I_r$. We then have

$$\Sigma Q^T (Q \Sigma Q^T)^{-1} Q \Sigma \Delta \Delta = \sigma^2 U_X U_X^\top \Delta \Delta,$$

which no longer depends on $Q$. The expectation of the key inequality gap in (??) then becomes

$$\mathbb{E}_Q \text{Tr}[\Sigma Q^T (Q \Sigma Q^T)^{-1} Q \Sigma \Delta \Delta] - \mathbb{E}_Q \text{Tr}[(Q^T Q) \Sigma Q^T (Q \Sigma Q^T)^{-1} Q \Sigma \Delta \Delta]$$

$$= \mathbb{E}_Q \text{Tr}[(I - Q^T Q) \sigma^2 U_X U_X^\top \Delta \Delta] \rightarrow \left(1 - \frac{r}{d}ight) \text{Tr}[U_X U_X^\top \Delta \Delta]$$

as $d$ becomes large. In other words, the performance advantage of tuning $B$ over $A$ is large when $d \gg r$, which is the typical regime in practice.

### B.1.2 Nonlinear losses and multilayer models

Recalling (5) with an input transformation $\phi$ and output transformation $\psi$, consider losses on the output of the form

$$\mathcal{L}(W) = \sum_{i=1}^{n} h(f(W \phi(x_i))) - y_i^T f(W \phi(x_i)), \quad (5)$$

where $f, h$ are differentiable functions specified by the desired loss, $y_i \in \mathbb{R}^K$, $x_i \in \mathbb{R}^{d_{in}}$, and $W \in \mathbb{R}^{d_{out} \times d_{in}}$. This class contains logistic regression (with $y$ being a one-hot encoded class vector), least-squares regression, and generalized linear regression—including a neural network with cross entropy loss with one layer being tuned.

We next analyze the gradient of this loss. Our argument is stated with one adapted parameter matrix, but it directly applicable to multilayer and transformer networks with multiple matrices being adapted, where $\phi, \psi, f$ will in that scenario vary depending on each parameter matrix’s position in the network; $\phi, \psi, f$ will depend on other parameter matrices and the current value of their adaptations (by definition of gradients). The interpretation will now be that fixing $A$ when adapting a parameter matrix $W^{(j)}$ projects the inputs of the corresponding parameter matrix to a lower-dimensional subspace while retaining the ability to fully match the outputs, and fixing $B$ correspondingly projects the parameter matrix’s outputs.

For simplicity of notation, the remaining derivation in this section takes $\phi, \psi$ to be the identity; the extension to general $\phi, \psi$ is clear. Then, the gradient of (5) is

$$\nabla_W \mathcal{L}(W) = \sum_{i=1}^{n} J_f^T (W x_i) [\nabla h(f(W x_i)) - y_i] x_i^\top, \quad (6)$$

where $J_f$ is the Jacobian of $f$. Starting from this formula, below we incorporate (3) by taking $W = W_0 + BA$.

**Freezing $A$.** Freezing $A = Q$ yields

$$\nabla_B \mathcal{L}(BQ + W_0) = \sum_{i=1}^{n} J_f^T ((BQ + W_0) x_i) [\nabla h(f((W_0 + BQ) x_i)) - y_i] (Q x_i)^\top.$$
Freezing $B$. Freezing $B = U$ yields

$$
\nabla_A \mathcal{L}(UA + W_0) = U^T \sum_{i=1}^n J_i \left[ \nabla h(f((W_0 + UA)x_i)) - y_i \right] x_i^\top.
$$

Here, the coefficient of $x_i^\top$ can be thought of as the output fit term. It includes the Jacobian of $f$ since $f$ is applied between the weights and the output. Compared to (6) and (??), in (??) this output fit term is projected by $U$. If $f$ is (near) linear, then this projection will be (approximately) data-independent, highlighting the loss of output information when freezing $B$.

Hence, in this more general setting, the different roles of $A$ and $B$ are still apparent, and we expect an asymmetry in being able to fit the output.

Example: Logistic regression. For multiclass logistic regression, we have a training dataset $\{(x_i, c_i)\}_{i=1}^n$ where $x_i \in \mathbb{R}^d$ (features) and $c_i \in \{1, \ldots, K\}$ (label). Denote by $y_i \in \mathbb{R}^K$ the vector with $y_{c_i} = 1$ and $y_k = 0$ for $k \neq c_i$. The log likelihood is the cross-entropy error

$$
\mathcal{L}(w_1, \ldots, w_K) = \sum_{i=1}^n \sum_{k=1}^K y_{i,k} \ln(p_{i,k}),
$$

where $p_{i,k} = \frac{\exp(w_{i,k}^\top x_i)}{\sum_{j=1}^K \exp(w_{i,j}^\top x_i)}$ and $w_k \in \mathbb{R}^d$. Let $W \in \mathbb{R}^{K \times d}$ whose $k$-th row is $w_k$. Then, (7) becomes

$$
\mathcal{L}(W) = \sum_{i=1}^n \ln(1^\top e^{Wx_i}) - y_i^\top W x_i,
$$

where $1$ is the column vector of size $K$ with all elements equal to 1; note $y_i^\top 1 = 1$ due to the one-hot structure. This loss can be put in the form (5) by setting $f(z) = z$ and $h(z) = \ln(1^\top e^z)$. For freezing, we then have

$$
\nabla_A \mathcal{L}(UA) = U^T \sum_{i=1}^n (y_i - p_i(UA)) x_i^\top \quad \text{and} \quad \nabla_B \mathcal{L}(BQ) = \sum_{i=1}^n (y_i - p_i(BQ))(Qx_i)^\top,
$$

where $p_i(W) = \frac{e^{Wx_i}}{1^\top e^{Wx_i}} \in \mathbb{R}^K$. Freezing $B = U$, as in least-squares, implies that each output $y_i$ is projected as $U^\top y_i$, implying that, at best, the model can hope to only learn outputs in the small random subspace $U$. In contrast, freezing $A = Q$ is equivalent to logistic regression on the full output with features projected by $Q$: $\{(Qx_i, y_i)\}_{i=1}^n$.

### B.2 Advantages of tuning only $B$ over $BA$ together

In the previous section, we established that fine-tuning $B$ alone is typically superior to fine-tuning $A$ alone. It remains, however, to motivate fine-tuning $B$ alone over fine-tuning both $A$ and $B$ together. In this section, we show that the reduced amount of adapted parameters by (roughly) half provides computational gains and improvements in information-theoretic generalization bounds.

#### B.2.1 Number of parameters

The key benefit of LoRA is parameter efficiency, which saves memory during training, storage and communication [Lian et al. 2023]. Fine-tuning $B$ alone as opposed to both $A$ and $B$ reduces the number of parameters by a factor of $\frac{d_{out}}{d_{out} + d_{in}}$, which equals 0.5 when $d_{in} = d_{out}$.

#### B.2.2 Generalization bounds

Consider a learning task, where the training examples lie in $Z = \mathcal{X} \times \mathcal{Y}$; here, $\mathcal{X}$ denotes the feature space and $\mathcal{Y}$ is the label space. Suppose one observes a training set $S_n \triangleq (Z_1, \ldots, Z_n) \in \mathcal{Z}^n$, with $n$ i.i.d. training examples from unknown distribution $\mu$. Denote by $\mu^{S_n} = \mu \times \cdots \times \mu$ the distribution of $S_n$. The objective of the learner is to find a predictor $f : \mathcal{X} \to \mathcal{Y}$ that maps features to their labels. We assume each predictor is parameterized by $w \in \mathcal{W}$ (e.g., if $f$ is a neural network, $w$ denotes its weights). Denote by $A : \mathcal{Z}^n \to \mathcal{W}$ the learning algorithm which selects a predictor given $S_n$. $A$ is,
in general, a probabilistic mapping, and we denote by $P_{W|S_n}$ the distribution of its output $W$ given input $S_n$. If $\ell : W \times Z \rightarrow \mathbb{R}_+$ is a loss, we define:

Population risk: $\mathcal{R}_\mu(w) \triangleq \mathbb{E}_{Z \sim \mu}[\ell(w, Z)]$

Empirical risk: $\hat{\mathcal{R}}_n(w) \triangleq \frac{1}{n} \sum_{i=1}^n \ell(w, Z_i)$.

The generalization error of $A$ is

$$\text{gen}(\mu, A) \triangleq \mathbb{E}_{(W, S_n) \sim P_{W|S_n} \times \mu \otimes \eta}[\mathcal{R}_\mu(W) - \hat{\mathcal{R}}_n(W)].$$

We bound this generalization error using the information-theoretic generalization framework of Xu & Raginsky (2017). Consider the following incarnations of fine-tuning algorithms, corresponding to classic LoRA (tuning both $A, B$ matrices), tuning only $B$, and tuning only $A$:

**Definition B.4 (Fine-tuning algorithms).** Let $W = \{W_i\}_{i=1}^L$ be the $L$ parameter matrices of a pretrained model. Let $\mathcal{I} \subseteq \{1, \ldots, L\}$ be a specified subset of the parameter matrices to be fine-tuned. Given a fine-tuning training set $S_n$, let $r$ be a chosen rank and suppose each tuned parameter is quantized to $q$ bits. We define the following algorithmic frameworks (other details can be arbitrary) for choosing an adaptation $\Delta W = \{\Delta_i\}_{i \in \mathcal{I}}$, yielding a fine-tuned $W_{\text{tuned}} = \{W_{\text{tuned}, i}\}_{i=1}^L$ with $W_{\text{tuned}, i} = W_i + \Delta_i$ for $i \in \mathcal{I}$ and $W_{\text{tuned}, i} = W_i$ otherwise:

- $A_{BA}$: For each $i \in \mathcal{I}$, constrain $\Delta_i = B_i A_i$ and optimize $\{B_i, A_i\}_{i \in \mathcal{I}}$ to fit the data $S_n$.
- $A_B$: For each $i \in \mathcal{I}$, sample $Q_i \in \mathbb{R}^{r \times d_{\text{in}}^{(i)}}$ at random, constrain $\Delta_i = B_i Q_i$, and optimize $\{B_i\}_{i \in \mathcal{I}}$ to fit the data $S_n$.
- $A_A$: For each $i \in \mathcal{I}$, sample $U_i \in \mathbb{R}^{d_{\text{out}}^{(i)} \times r}$ at random, constrain $\Delta_i = U_i A_i$, and optimize $\{A_i\}_{i \in \mathcal{I}}$ to fit the data $S_n$.

We have the following lemma, proved in Appendix F.

**Lemma B.5 (Generalization bounds on adapting $A$ and/or $B$).** Consider the algorithms of Definition B.4. Assume that $f^{W,B}(\Delta W, Z)$ is $\sigma$-sub-Gaussian under $(\Delta W, Z) \sim P_{\Delta W|W,B} \times \mu$. Then,

$$|\text{gen}(\mu, A_{BA})| \leq \sqrt{\frac{2rq\sigma^2 \ln 2n}{n} \sum_{i \in \mathcal{I}} (d_{\text{in}}^{(i)} + d_{\text{out}}^{(i)})},$$

$$|\text{gen}(\mu, A_B)| \leq \sqrt{\frac{2rq\sigma^2 \ln 2n}{n} \sum_{i \in \mathcal{I}} d_{\text{out}}^{(i)}},$$

$$|\text{gen}(\mu, A_A)| \leq \sqrt{\frac{2rq\sigma^2 \ln 2n}{n} \sum_{i \in \mathcal{I}} d_{\text{in}}^{(i)}}.$$

This generalization bound increases with the number of parameters being tuned, which is an increasing function of $r$ and the dimensions of the parameter matrices. Importantly, since tuning just one factor ($A$ or $B$) involves tuning fewer parameters than $A$ and $B$ together, the generalization bound is correspondingly smaller. In the case where the $d_{\text{in}}^{(i)} = d_{\text{out}}^{(i)}$, the bound for tuning one factor only is a factor of $\sqrt{2}$ smaller than the bound for tuning both factors, implying that the rank $r$ for $A_B$ could be doubled and have a generalization bound matching that of $A_{BA}$.

**B.3 DISCUSSION OF THEORETICAL ANALYSIS**

The previous two sections establish two conclusions: (1) Tuning $A$ has limited importance when trying to match a desired output; and (2) Tuning one factor instead of two reduces the number of parameters for the same $r$, while improving generalization bounds and potentially providing memory benefits.

Given a fixed parameter count and generalization budget, therefore, we can use a larger $r = r_B$ when fine-tuning $B$ alone than the $r_{BA}$ that would be used on standard LoRA fine-tuning both $A$ and $B$.\footnote{Bounded losses are sub-Gaussian.}
We compare to the following methods: We implement all algorithms using PyTorch starting from the publicly-available Huggingface Transformers code base (Wolf et al., 2019). The conventional LoRA method applies a scaling coefficient \( \alpha/r \) to \( \Delta W \). Following LoRA (Hu et al., 2021), we fix \( \alpha = 2r \) to be twice the rank. Throughout our experiments, we use \( A \) to indicate matrix \( A \) is being updated during fine-tuning and use subscripts \( \{ r, 0, km \} \) to indicate that the matrix is initialized as a random orthonormal matrix, zero matrix, and the random uniform initialization used in the original LoRA, respectively. Note that a properly normalized \( d \times r \) random matrix with independent entries will have close to orthonormal columns when \( d \gg r \) (see e.g. Theorem 4.6.1 of Vershynin (2020)), implying that the random orthonormal and random uniform initializations should be essentially equivalent.

We compare to the following methods:
1. **Full fine-tuning (FT):** The most straightforward adaptation method, which initializes model parameters with the pre-trained weights and updates the whole model with gradient back-propagation.
2. **Linear Probing (LP) (Kumar et al., 2022):** A simple yet effective method that updates the last linear layer.
3. **IA³ (Liu et al., 2022):** Injects learned vectors in the attention and feedforward modules.
4. **LoRA: (Hu et al., 2021)** Fine-tunes both \( A \) and \( B \) matrices of an additive \( BA \) adaptation as introduced in previous sections, with a separate adaptation for each query/key/value parameter matrix.
5. **AdaLoRA: (Zhang et al., 2023b)** A variant of LoRA that adaptively changes the rank for each layer.

### C.1 Natural Language Understanding

We use the General Language Understanding Evaluation (GLUE, Wang et al., 2018) to evaluate the fine-tuning performance of different fine-tuning strategies. The GLUE benchmark contains a wide variety of tasks including question-answering, textual similarity, and sentiment analysis. We applied
Table 5: Different initialization of classic LoRA, setting either $A$ or $B$ to be zeros. Note that the trained result is not sensitive to different initializations, with performance differences tending to be smaller than the standard error.

fine-tuning methods to the RoBERTa (large) model (Liu et al., 2019), which has 355M parameters. To enable a fair comparison, we initialize the weights for all tasks with the original pretrained RoBERTa weights.

In Table 4 (see the appendix for an expanded table), we compare different freezing & initialization strategies with LoRA and other bases. We underline to indicate that performance is better than conventional LoRA also we use **bold** to denote the best performance when freezing one of the matrices. First, we can see a clear trend where solely updating the $B$ matrix outperforms just learning the $A$ matrix. In addition, when doubling the rank to match the trainable parameters, $B_{r=8}$, $A_{r=16}$ consistently outperforms conventional LoRA. This confirms our hypothesis in §5 that any loss in expressive power by not tuning $A$ can be made up for by the larger intrinsic rank of $B$ at no additional parameter cost. In fact, its performance statistically matches that of AdaLoRA, which uses over 3 times the parameters (incuring the associated memory and training costs).

To assess the effects of different initialization methods for low-rank adaptation, we investigate different initialization methods thoroughly in Table 5. We can see that the best results always come from orthogonal initialization, which further supports our conclusions in §B.

### C.2 Natural Language Generation

To investigate the asymmetry of low-rank fine-tuning in natural language generation (NLG), we fine-tune a BART-large model (Lewis et al., 2020) and evaluate model performance on the XSum (Narayan et al., 2018) and CNN/DailyMail (Chen et al. 2016) datasets. Following Zhang et al. (2023b), we apply low-rank adaptation to every query/key/value matrix and report ROUGE 1/2/L scores (R-

1/2/L. (Lin, 2004)). We fine-tune models for 15 epochs. We select the beam length as 8 and batch size as 48 for XSum, and the beam length as 4, batch size as 48 for CNN/DailyMail. More details of the configurations are in the Appendix [G].

The results are summarized in Table [G]. In the first two rows, we observe the asymmetry between the factors since freezing \( A \) and only updating \( B \) always outperforms only updating \( A \). The last two rows show the results of tuning both matrices with different initializations, showing that the asymmetry is not explained by the initialization strategy.

### C.3 Massive Multitask Language Understanding

We fine-tune the pretrained Llama-2-7B model (Touvron et al., 2023) using instruction tuning on the Alpaca dataset (Wang et al., 2023). We assess the asymmetry on the MMLU benchmark (Hendrycks et al., 2020), which consists of 57 distinct language tasks. As shown in Table 8, the asymmetry also exists in larger language models, and updating \( B \) consistently outperforms updating \( A \). Moreover, it also outperforms standard LoRA except for “Other” where it matches the performance, reflecting the benefits of being able to increase \( r \) without tuning more parameters.

### C.4 Vision Transformers and Generalization

We next measure generalization, motivated by the theory in §B.2. In particular, we work with ViTs in image classification tasks using the Domainbed testbed for domain generalization (Gulrajani & Lopez-Paz, 2020). Domainbed contains several datasets, each composed of multiple environments (or domains). Classes in each environment tend to be similar at a high level but differ in terms of style. We fine-tune a pre-trained ViT, originally trained on ImageNet, on the LabelMe, Cartoon, and Clipart environments within the VLCS, PACS, and Office-Home datasets, respectively. We employ different benchmark fine-tuning methods such as full fine-tuning, linear probing, and LoRA, and compare their performance to freezing either \( A \) or \( B \) in in-domain and out-of-domain generalization. We adhere to the original 80% training and 20% testing splits.

Results are presented in Table [G]. In line with our expectations, randomly initializing and freezing matrix \( A \) while only updating matrix \( B \) generally results in better out-of-domain test accuracy. We report additional generalization results in Appendix [I] in which we compare the train set and test set accuracy of the different approaches. We consistently find that fine-tuning a single matrix leads to smaller gaps between these two quantities compared to LoRA, paralleling the corresponding reduction in the generalization bounds of §B.2.

### D Similarity Metric in Figure 1

To measure the similarity of learned \( A \) and \( B \) matrices we adopted a measure that accounts for the invariance of LoRA fine-tuning. Let \( \Delta W = BA \) denote the learned LoRA adapter. Since \( BA = BCC^{-1}A \) for any invertible matrix \( C \in \mathbb{R}^{r \times r} \), we can define \( B = BC \) and \( A = C^{-1}A \) resulting in the same LoRA adapter \( \Delta W = BA \). Thus, to measure the similarity of LoRA matrices we need a metric that is invariant to invertible linear transformations, i.e., dissimilarity \((B, BC) = 0\) for any invertible \( C \). In our experiment, we used Canonical Correlation Analysis goodness of fit (Ramsay et al., 1984), similar to prior work comparing neural network representations (Kornblith...
The key idea is to compare orthonormal bases of the matrices, thus making this similarity metric invariant to invertible linear transformations.

More specifically, given two matrices $X \in \mathbb{R}^{n \times r_1}$ and $Y \in \mathbb{R}^{n \times r_2}$, the similarity is computed as $\|U_Y^T U_X\|^2_F / \min\{r_1, r_2\}$, where $U_X / U_Y$ is the orthonormal bases for the columns of $X / Y$.

Following a similar method as in Hu et al. (2021), for $A$ we perform SVD and use the right-singular unitary matrices as the bases, and use left-singular unitary matrices for $B$.

### E Asymmetry Proofs for Multivariate Least Squares

#### E.1 Proof of Lemma B.2

Consider freezing $B = U$ where $U$ is orthogonal ($U^T U = I_r$) and fine-tuning $A$. The objective becomes

$$A^* = \arg \min_A \mathcal{L}(A, U)$$

$$= \arg \min_A \mathbb{E}_{(Y_{targ}, X_{targ})} \|Y_{targ} - (W_0 + UA)X_{targ} - b\|^2_2$$

$$= \arg \min_A \mathbb{E} \|(W_{targ}X_{targ} - W_0X_{targ}) - UAX_{targ}\|^2_2$$

$$= \arg \min_A \mathbb{E} \|U^T ((W_{targ} - W_0)X_{targ} + n) - AX_{targ}\|^2_2$$

$$= U^T \Delta.$$

Interestingly, note that this solution $A^*$ does not depend on the distribution of $X_{targ}$, it is simply the projection of the difference between the pretrained $W_0$ and the target $W_{targ}$. This is because, intuitively, freezing $B$ is projecting down the outputs into $r$ dimensional space, and then optimizing $A$ to match these projected outputs. It can be shown that the expected squared prediction error is

$$\mathcal{L}(A^*, U) = d_{out} \sigma^2 + \text{Tr}[\Delta \Sigma \Delta^T] - \text{Tr}[U^T \Delta \Sigma \Delta^T U],$$

where $\Sigma = \text{Cov}[X_{targ}]$.

#### E.2 Proof of Lemma B.1

Consider freezing $A = Q$ where $Q$ is orthogonal ($QQ^T = I_r$) and fine-tuning $B$. The objective becomes

$$B^* = \arg \min_B \mathcal{L}(Q, B)$$

$$= \arg \min_B \mathbb{E}_{(Y_{targ}, X_{targ})} \|Y_{targ} - (W_0 + BQ)X_{targ}\|^2_2$$

$$= \arg \min_B \mathbb{E} \|(Y_{targ} - W_0X_{targ}) - B(QX_{targ})\|^2_2,$$

which is simply an ordinary least squares regression problem mapping $QX_{targ}$ to $(Y_{targ} - W_0X_{targ})$. The solution is known to be

$$B^* = \Delta \Sigma Q^T (Q \Sigma Q^T)^{-1}$$

yielding an expected squared prediction error of

$$\mathcal{L}(Q, B^*) = d_{out} \sigma^2 + \text{Tr}[\Delta \Sigma \Delta^T]$$

$$- \text{Tr}[Q \Sigma \Delta^T \Delta \Sigma Q^T (Q \Sigma Q^T)^{-1}].$$

Note that the solution is now clearly dependent on the distribution of $X_{targ}$, and the first two terms of the squared prediction error are the same but the third term is different.
### E.3 Proof of Theorem B.3

The third term in the expression for freezing \( A \) is

\[
III_A = \text{Tr}[Q\Sigma\Delta^T \Delta Q\Sigma^T (Q\Sigma Q^T)^{-1}] \\
\geq \text{Tr}[Q\Sigma\Delta^T \Delta Q\Sigma^T] \\
= \text{Tr}[Q\Sigma\Delta^T \Delta Q^T],
\]

where the inequality follows by Von Neumann’s trace inequality and the fact that the product of two positive semidefinite matrices has nonnegative real eigenvalues. Compare to the third term in the expression for freezing \( B \):

\[
III_B = \text{Tr}[U^T \Delta \Sigma \Delta^T U].
\]

Recall that \( U, Q \) are drawn uniformly at random from their respective Stiefel manifolds. Then

\[
\mathbb{E}[III_B] \to r \frac{d}{d^2} \text{Tr}[\Delta \Sigma \Delta^T] = \mathbb{E}[III_B].
\]

Hence

\[
\lim_{d/r \to \infty} \mathbb{E}[III_A] \geq \lim_{d/r \to \infty} \mathbb{E}[III_B],
\]

implying that freezing \( A \) to a random orthogonal matrix achieves lower mean squared error loss than freezing \( B \).

### F Proof of Lemma B.5: Generalization bounds

We use the following bound on the generalization error is from [Xu & Raginsky (2017)](2017), specialized to our setting and notation.

**Theorem F.1** (specialized from [Xu & Raginsky (2017)](2017)). Denote by \( A \) a LoRA-based fine-tuning algorithm, which outputs \( \Delta W \) given \( S_n \). Assume that \( \ell^{W,b}(\Delta W, \bar{Z}) \) is \( \sigma \)-sub-Gaussian under \( (\Delta W, \bar{Z}) \sim \mathbb{P}_{\Delta W|W,b} \times \mu \). Then,

\[
|\text{gen}(\mu, A)| \leq \sqrt{\frac{2\sigma^2}{n} l(\Delta W; S_n|A, W).}
\]

(8)

We consider the case of tuning \( B \) only first. Applying the above theorem, note that here

\[
l(\Delta W; S_n|A_B, W = l\{B_i|_{i \in \mathcal{I}}; S_n|A_B, W \}
\]

\[
= l\{B_i|_{i \in \mathcal{I}}; S_n|A_B, W,
\]

where we have used standard information-theoretic equalities, noted that the \( Q_i \) are here considered fixed constants as they are not trained.

We can now bound this expression as

\[
l\{B_i|_{i \in \mathcal{I}}; S_n|A_B, W \leq H(\{B_i\}_{i \in \mathcal{I}})
\]

\[
\leq qr \sum_{i \in \mathcal{I}} d_{\text{out}}^{(i)},
\]

where we have noted that mutual information is upper bounded by discrete entropy, and entropy in turn is upper bounded by the uniform distribution over its possible support set. The bounds for the other two algorithms are similar.

### G Text Generation Training Details

The configuration of our experiments on text generation is listed in Table 9.

H ADDITIONAL LANGUAGE RESULTS

See Table 10

I ADDITIONAL VISION TRANSFORMERS AND GENERALIZATION RESULTS

Table 11 displays a more fine-grained version of Table 7 in the main text and presents results for each out-of-distribution environment independently. Additional results for Terralnognita, as well as generalization results, can be found in Table 12 and Table 13 respectively. Terralnognita seems to be a particularly challenging dataset to which low-rank adapters struggle to fit; the most effective method, in this case, appears to be full fine-tuning. In terms of generalization, we can observe that fine-tuning only a single adapter matrix generally results in a lower difference between training set and test set accuracy compared to standard LoRA for all datasets.
Table 11: DomainBed results (mean accuracy and standard deviation in %). ID and OOD denote in-domain and out-of-domain generalization, respectively.
