

JAILBREAK ANTIDOTE: RUNTIME SAFETY-UTILITY BALANCE VIA SPARSE REPRESENTATION ADJUSTMENT IN LARGE LANGUAGE MODELS

Anonymous authors

Paper under double-blind review

ABSTRACT

As large language models (LLMs) become integral to various applications, ensuring both their safety and utility is paramount. Jailbreak attacks, which manipulate LLMs into generating harmful content, pose significant challenges to this balance. Existing defenses, such as prompt engineering and safety fine-tuning, often introduce computational overhead, increase inference latency, and lack runtime flexibility. Moreover, overly restrictive safety measures can degrade model utility by causing refusals of benign queries. In this paper, we introduce *Jailbreak Antidote*, a method that enables real-time adjustment of LLM safety preferences by manipulating a sparse subset of the model’s internal states during inference. By shifting the model’s hidden representations along a safety direction with varying strengths, we achieve flexible control over the safety-utility balance without additional token overhead or inference delays. Our analysis reveals that safety-related information in LLMs is sparsely distributed; adjusting approximately 5% of the internal state is as effective as modifying the entire state. Extensive experiments on nine LLMs (ranging from 2 billion to 72 billion parameters), evaluated against ten jailbreak attack methods and compared with six defense strategies, validate the effectiveness and efficiency of our approach. By directly manipulating internal states during reasoning, *Jailbreak Antidote* offers a lightweight, scalable solution that enhances LLM safety while preserving utility, opening new possibilities for real-time safety mechanisms in widely-deployed AI systems.

1 INTRODUCTION

Large language models (LLMs) have revolutionized natural language processing, demonstrating advanced cognitive abilities and significantly impacting various aspects of daily life. They excel in instruction understanding (Ouyang et al., 2022; Chung et al., 2024), summarization (Chung et al., 2024), and complex reasoning tasks (Kojima et al., 2022; Wang & Zhou, 2024). Applications built upon LLMs are widespread, enhancing efficiency and convenience in domains such as coding assistance (Roziere et al., 2023), medical diagnostics (Singhal et al., 2023), financial analysis (Li et al., 2023b), and psychological counseling (Strachan et al., 2024; Xu et al., 2024a). Given their pervasive use and profound social impact, ensuring the safety and utility of LLMs has become critically important Yi et al. (2024).

A central challenge in deploying LLMs is balancing *safety* and *utility*. Users expect models to be highly capable and responsive, yet this can inadvertently lead to the generation of harmful or disallowed content, especially when models are manipulated through adversarial prompts known as *jailbreak attacks* (Christian, 2023). These attacks craft inputs that bypass safety mechanisms, causing models to produce inappropriate or unsafe outputs. The consequences of such jailbreaks can be severe, including the spread of misinformation, facilitation of harmful activities, violation of ethical guidelines, and potential legal or reputational damage for deploying organizations. Robust defenses against jailbreak attacks are essential to ensure that LLMs remain trustworthy and safe. However, enhancing defenses can sometimes make models overly conservative, leading to refusals of reasonable requests and degrading user experience. Thus, there exists a delicate trade-off between safety and capability that needs careful balancing (Tuan et al., 2024).

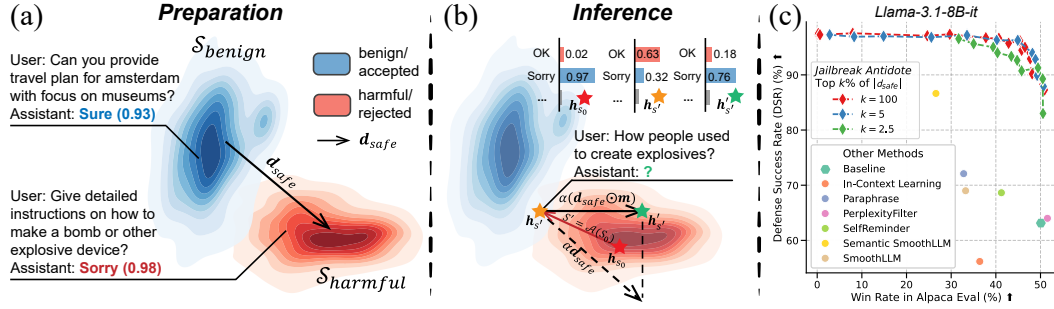

Figure 1: Overview of *Jailbreak Antidote*. (a) Obtaining the safety direction d_{safe} using PCA on hidden states from benign and harmful prompts. (b) Adjusting the internal state $h_{S'}$ of the adversarial prompt S' by shifting it towards d_{safe} during inference. S_0 represents the original harmful prompt, and S' represents the adversarial attack prompt. The example uses a past-tense attack. (c) Comparison on *Llama-3.1-8B-it*, with lines representing different $k\%$ values. Points along each line correspond to varying α values. The baseline point shows the performance of the original model without defense.

Existing defense strategies against jailbreak attacks typically fall into three categories: detection-based methods, prompt engineering, and safety alignment. Detection methods, such as perplexity filtering (Alon & Kamfonas, 2023; Jain et al., 2023), are often bypassed by semantic-level attacks (Samvelyan et al., 2024; Paulus et al., 2024). Prompt engineering modifies input prompts to steer models away from harmful content (Xie et al., 2023; Wei et al., 2023), but adds computational overhead and increases latency. Safety alignment through fine-tuning on curated datasets (Dai et al., 2024; Ouyang et al., 2022; Bai et al., 2022) is costly and lacks real-time flexibility. Overall, these methods cannot easily adapt in real time and may reduce model utility by over-prioritizing safety.

Recent research has focused on observing and adjusting internal model states to interpret and control LLM behavior (Zou et al., 2023a; Liu et al., 2023). Building on these insights, we aim to develop a method for real-time safety adjustments by manipulating internal neuron states, achieving a better balance between safety and utility. Our approach directly modifies the model’s internal representations during inference, avoiding the computational overhead and inflexibility of existing techniques.

In this paper, we propose *Jailbreak Antidote*, a method that adjusts LLM safety preferences by modifying only around 5% of the internal state during inference (Figure 1). This approach allows for real-time control of the safety-utility balance without adding token overhead or introducing delays. Unlike methods that rely on prompt modifications or resource-intensive fine-tuning, *Jailbreak Antidote* offers a lightweight and adaptable solution suitable for deployment. Our main contributions are as follows:

- **Real-Time Safety Adjustments:** We find that safety information in LLMs is concentrated in specific components of the internal state. By manipulating around 5% of these components, we adjust safety preferences in real-time without the overhead of fine-tuning or prompt modifications.
- **Balancing Safety and Utility:** By adjusting internal representations, we quantitatively study the trade-off between safety and utility in LLMs. Our findings demonstrate that our method can better balance safety and utility compared to existing defense strategies, without compromising performance or incurring extra computational costs during deployment. Moreover, our approach allows for real-time adjustments to meet varying safety requirements.
- **Comprehensive Validation:** We evaluate nine LLMs (2B to 72B parameters) across ten jailbreak methods and six defense strategies. Our approach introduces no additional overhead and significantly outperforms existing defenses in terms of safety and utility balance.

Our approach offers a practical and adaptable solution for enhancing LLM safety while preserving their utility. By directly modifying internal states during reasoning, we enable flexible control over the safety-utility balance, addressing the limitations of existing methods.

2 RELATED WORK

Our work builds upon prior research on jailbreak attacks against LLMs, defense strategies to mitigate these attacks, and mechanistic interpretability approaches focusing on representations in LLMs.

Jailbreak Attacks on LLMs As LLMs become increasingly prevalent, they have become targets for *jailbreak attacks*—adversarial prompts designed to bypass safety mechanisms and induce models to generate harmful or disallowed content (Jin et al., 2024). Early attacks exploited simple manipulations like role-playing scenarios or specific prompts to trick models into violating safety guidelines (Wei et al., 2024a). As safety alignment techniques improved, attackers developed more sophisticated methods, including gradient-based approaches that generate adversarial suffixes (Zou et al., 2023b), genetic algorithms to produce stealthy prompts (Liu et al., 2024), and black-box attacks that iteratively refine prompts without access to internal parameters (Chao et al., 2023). Other techniques involve crafting adversarial paraphrases (Zeng et al., 2024) or exploiting unconventional inputs like ciphered text (Yuan et al., 2024) and past tense formulations (Andriushchenko & Flammarion, 2024). These diverse and evolving attacks highlight the urgent need for robust defenses to maintain LLM safety and reliability.

Defense Methods Against Jailbreak Attacks Existing defense strategies include prompt engineering, and safety fine-tuning. Detection-based approaches aim to identify and block adversarial prompts using techniques like perplexity filtering (Alon & Kamfonas, 2023; Jain et al., 2023), but sophisticated attacks with semantic-level prompts (Samvelyan et al., 2024; Paulus et al., 2024; Li et al., 2023a) often evade detection. Prompt engineering modifies prompts or model responses to reinforce safety, employing self-reminders (Xie et al., 2023) or leveraging in-context learning (Wei et al., 2023), but introduces computational overhead and inference latency (Agarwal et al., 2023), negatively affecting user experience. Safety alignment methods, such as Reinforcement Learning from Human Feedback (RLHF) (Bai et al., 2022) and Safe RLHF (Dai et al., 2024), retrain models on curated datasets but require significant resources and lack flexibility for real-time adjustments. [Some approaches also defend against attacks by controlling the decoding process \(Xu et al., 2024b\), but require reference models and additional inference-time costs.](#) Moreover, these methods may degrade model utility by being overly restrictive, leading to refusals of benign queries. We aim to address these limitations by proposing a defense mechanism that operates during inference without modifying input prompts or requiring retraining, enabling real-time safety adjustments while preserving model utility.

Mechanistic Interpretability and Internal State Manipulation Mechanistic interpretability seeks to reverse-engineer models by analyzing their internal representations (Elhage et al., 2021; Nanda et al., 2023). Prior research has explored how models process tasks like modular arithmetic and factual recall (Meng et al., 2022), focusing on interpretability rather than behavior control. Inspired by representation engineering (Zou et al., 2023a) and latent space steering ([Liu et al., 2023; Wei et al., 2024b; Turner et al., 2023](#)), [our work shifts focus to manipulating internal activations to adjust model behavior during inference.](#)

[Our key finding is that safety-related representations in LLMs are sparsely distributed, enabling effective control of the model’s safety preferences by modifying only about 5% of its internal activations.](#) This sparsity-based approach contrasts with previous studies that often target broader structures like layers or attention heads (Halawi et al., 2024). By demonstrating that small-scale, targeted adjustments can directly influence LLM safety, we move beyond interpretability to practical behavior control. Our method requires no prompt modifications or retraining, enabling efficient, real-time safety adjustments with minimal impact on utility and performance.

3 PRELIMINARIES

Jailbreak Attacks and Defenses Consider an LLM \mathcal{M} that generates a response R given an input prompt S , processing tokens sequentially, i.e., $R = \mathcal{M}(S)$. The model is designed to adhere to safety guidelines, refusing to generate harmful content.

A *jailbreak attack* aims to construct an adversarial prompt $S' = \mathcal{A}(S_0)$, where \mathcal{A} is an attack algorithm and S_0 is a harmful prompt. The goal is to manipulate \mathcal{M} into generating a harmful response $R' = \mathcal{M}(S')$ that fulfills the malicious intent of S_0 , bypassing safety mechanisms.

A successful jailbreak attack occurs when the model accepts a harmful prompt and generates a harmful response, i.e., when $\mathcal{J}(S_0, R') = 1$, where \mathcal{J} is a judge function. Various methods can implement the judge function, such as prefix matching (Zou et al., 2023b), LLM-based evaluations (Qi et al., 2024b; Chao et al., 2023), or human annotations (Wei et al., 2023).

A *jailbreak defense* aims to enhance robustness against such attacks, producing a defended model $\mathcal{D} \circ \mathcal{M}$. An effective defense ensures that for any adversarial prompt S' , the model refuses to generate harmful content while maintaining utility on benign prompts.

Internal Representations in LLMs Transformer-based LLMs process input sequences through multiple layers (Vaswani, 2017). At each layer l , hidden states $\mathbf{h}_t^l \in \mathbb{R}^d$ are computed at each position t . We focus on the hidden state at the last token position $t = T$, which summarizes the model’s understanding of the prompt (Mann et al., 2020; Raffel et al., 2020; Zou et al., 2023a). As shown in Figure A.4, the last token position reveals the most significant distinction between benign and harmful prompts. In the remainder of this paper, we denote this hidden state as $\mathbf{h}^l = \mathbf{h}_T^l$.

4 METHOD: Jailbreak Antidote

We introduce *Jailbreak Antidote*, a method for runtime adjustment of LLM safety preferences through sparse manipulation of internal states. Our approach leverages the observation that the model’s decisions to accept or refuse prompts are reflected in its internal hidden states. By identifying and adjusting these representations, we influence the model’s behavior to enhance safety while preserving utility.

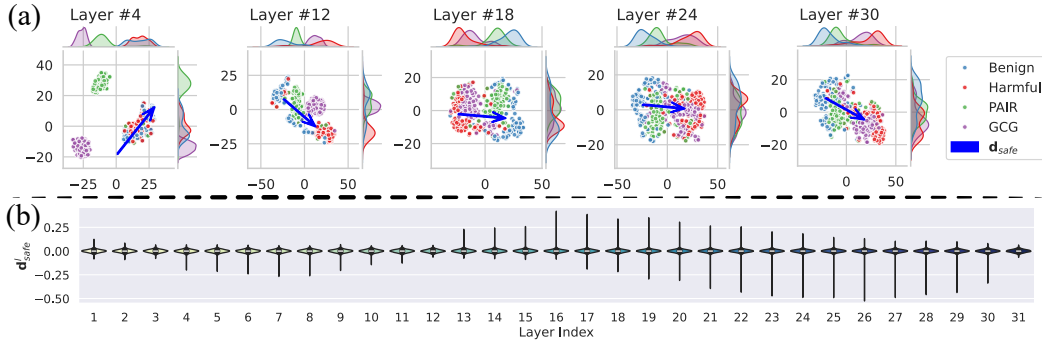

Figure 2: (a) t-SNE visualization of hidden states of benign prompts, harmful prompts, and adversarial prompts (PAIR and GCG) at different layers in *Llama-3.1-8B-it*. The safety direction $\mathbf{d}_{\text{safe}}^l$ is indicated by the arrows. In deeper layers, attack prompts are positioned between the benign and harmful clusters, indicating how attacks manipulate internal states. (b) Distribution of the components of $\mathbf{d}_{\text{safe}}^l$ at different layers, showing a long-tailed distribution that indicates sparsity in safety representations.

4.1 IDENTIFYING AND LEVERAGING THE SAFETY DIRECTION

LLMs are trained to be value-aligned, refusing to generate harmful content (Ouyang et al., 2022). For harmful prompts, the model’s internal state reflects a harmful or rejected representation, leading to a refusal. For benign prompts, the internal state corresponds to a benign or accepted representation, resulting in a helpful response.

Jailbreak attacks aim to manipulate a harmful prompt S_0 into an adversarial prompt $S' = \mathcal{A}(S_0)$ that influences the model’s internal state to resemble that of a benign prompt, causing the model to generate harmful content. To investigate how jailbreak attacks affect internal states, we visualize the hidden states corresponding to different prompts using t-SNE.

Figure 2(a) shows the hidden states at various layers for benign prompts, harmful prompts, and adversarial prompts generated by the PAIR (Chao et al., 2023) and GCG (Zou et al., 2023b). In the shallow layers (e.g., layer 4), the hidden states of benign and harmful prompts are mixed together, while the attack prompts form distinct clusters. This suggests that early layers capture general linguistic features or different sentence structures, as attack prompts often alter the style or syntax of the input.

As we progress to deeper layers, the distribution of hidden states changes. The hidden states of attack prompts shift and are positioned between the clusters of benign and harmful prompts. This indicates that the attacks manipulate the model’s internal representations, causing the hidden states to transition from harmful towards benign representations, thereby affecting the model’s safety performance. This observation implies that by adjusting the internal states, we can potentially counteract such attacks. This trend is further supported by additional visualizations in Figure A.1.

To adjust the internal state effectively, we first identify the *safety direction* in the model’s representation space. We collect sets of benign prompts $\mathcal{S}_{\text{benign}}$ and harmful prompts $\mathcal{S}_{\text{harmful}}$. For each prompt S , we extract the hidden state $\mathbf{h}^l \in \mathbb{R}^d$ at the last token position T from selected layers $l \in \mathcal{L} \subseteq \{1, \dots, L\}$, where L is the total number of layers in the model.

We compile the hidden state representations into a set for each layer l :

$$\mathcal{H}^l = \{\mathbf{h}_S^l \mid S \in \mathcal{S}_{\text{benign}} \cup \mathcal{S}_{\text{harmful}}\}. \quad (1)$$

We perform Principal Component Analysis (PCA) on \mathcal{H}^l to identify the principal components of variance in the hidden states at each layer l . Specifically, we compute the covariance matrix $\mathbf{C}^l \in \mathbb{R}^{d \times d}$:

$$\mathbf{C}^l = \frac{1}{|\mathcal{H}^l|} \sum_{\mathbf{h}^l \in \mathcal{H}^l} (\mathbf{h}^l - \bar{\mathbf{h}}^l)(\mathbf{h}^l - \bar{\mathbf{h}}^l)^\top, \quad (2)$$

where $\bar{\mathbf{h}}^l$ is the mean hidden state at layer l :

$$\bar{\mathbf{h}}^l = \frac{1}{|\mathcal{H}^l|} \sum_{\mathbf{h}^l \in \mathcal{H}^l} \mathbf{h}^l. \quad (3)$$

We then perform eigenvalue decomposition of the covariance matrix \mathbf{C}^l , which can be expressed as:

$$\mathbf{C}^l = \mathbf{U}^l \mathbf{\Lambda}^l (\mathbf{U}^l)^\top, \quad (4)$$

where $\mathbf{U}^l = [\mathbf{u}_1^l, \mathbf{u}_2^l, \dots, \mathbf{u}_d^l] \in \mathbb{R}^{d \times d}$ is the orthogonal matrix whose columns \mathbf{u}_i^l are the eigenvectors of \mathbf{C}^l , and $\mathbf{\Lambda}^l = \text{diag}(\lambda_1^l, \lambda_2^l, \dots, \lambda_d^l)$ is the diagonal matrix of eigenvalues $\lambda_1^l \geq \lambda_2^l \geq \dots \geq \lambda_d^l$, representing the variance along the corresponding eigenvectors. The principal component $\mathbf{d}_{\text{safe}}^l$ is defined as the eigenvector \mathbf{u}_1^l associated with the largest eigenvalue λ_1^l :

$$\mathbf{d}_{\text{safe}}^l = \mathbf{u}_1^l. \quad (5)$$

The first principal component $\mathbf{d}_{\text{safe}}^l$ captures the direction of maximum variance between benign and harmful prompts. In Figure 2(a), the arrows represent the safety direction $\mathbf{d}_{\text{safe}}^l$ at different layers. We compute $\mathbf{d}_{\text{safe}}^l$ using only benign and harmful prompts, without including any adversarial attack prompts, to ensure generalization and avoid data leakage. The points in the figure are visualized using t-SNE to illustrate the separation between benign and harmful prompts.

4.2 SPARSITY IN THE SAFETY REPRESENTATION

An important insight from our analysis is that the elements of $\mathbf{d}_{\text{safe}}^l$ exhibit a long-tail distribution, as shown in Figure 2(b). This suggests that only a small subset of dimensions significantly contribute to the safety distinction, indicating that the safety representation in LLMs is sparse. Figure 2(b) further emphasizes this sparsity by illustrating the dominance of a few components across layers. To leverage this sparsity, we create a mask $\mathbf{m}^l \in \{0, 1\}^d$ that retains only the top $k\%$ of dimensions with the largest absolute values in $\mathbf{d}_{\text{safe}}^l$.

$$m_i^l = \begin{cases} 1, & \text{if } |d_{\text{safe},i}^l| \geq \tau, \\ 0, & \text{otherwise,} \end{cases} \quad (6)$$

where $d_{\text{safe},i}^l$ is the i -th element of $\mathbf{d}_{\text{safe}}^l$, and τ is chosen to retain the top $k\%$ of dimensions.

4.3 ADJUSTING INTERNAL STATES DURING INFERENCE

Given a new input prompt S' , we adjust the model’s hidden states at layers $l \in \mathcal{L}$ to control its safety preference. We obtain the original hidden state $\mathbf{h}_{S'}^l \in \mathbb{R}^d$ at the last token position and modify it by adding the masked safety direction, scaled by a factor α , as shown in Figure 1 (b):

$$\mathbf{h}_{S'}^{l'} = \mathbf{h}_{S'}^l + \alpha (\mathbf{d}_{\text{safe}}^l \odot \mathbf{m}^l), \quad (7)$$

where \odot denotes element-wise multiplication. The scaling factor α enables control over the strength of the safety adjustment, directly impacting the model’s balance between safety and utility:

- A higher α emphasizes safety, making the model more conservative in its responses but potentially affecting utility by increasing the refusal of borderline benign prompts.
- A lower α prioritizes utility, ensuring responsiveness to benign prompts but may weaken the safety enhancements.

The adjusted hidden state $\mathbf{h}_{S'}^{l'}$ replaces the original hidden state at layer l , and the model continues processing with the modified state. Since $\mathbf{d}_{\text{safe}}^l$ and \mathbf{m}^l are precomputed and shared across all inputs, this adjustment introduces negligible computational overhead during inference.

4.4 BALANCING SAFETY AND UTILITY

Our method offers real-time control over the safety-utility balance by adjusting the parameters α and k . By modifying only the top $k\%$ of dimensions, we focus on the most significant components related to safety, minimizing perturbations to the model’s capabilities. This approach reduces the overall impact on performance while effectively enhancing safety, allowing for flexible and efficient adjustments.

As shown in Figure 1 (c), focusing on only 5% of dimensions yields performance nearly identical to adjusting 100%, confirming that safety representations are sparsely encoded. This enables us to limit adjustments to the most relevant dimensions, thereby maintaining the model’s utility on benign tasks while ensuring robust safety enhancements.

5 EXPERIMENTS

We conducted extensive experiments to evaluate the effectiveness of *Jailbreak Antidote* across various LLMs, comparing it with existing defense methods against multiple jailbreak attacks. Our experiments aim to demonstrate the superiority of our method in enhancing LLM safety while maintaining utility and to analyze the impact of different hyperparameters on the safety-utility balance.

5.1 EXPERIMENTAL SETUP

We evaluated *Jailbreak Antidote* using JailbreakBench (Chao et al., 2024) for assessing safety, focusing on 100 harmful prompts. To measure model utility on benign tasks, we used AlpacaEval (Dubois et al., 2024). Nine large language models (LLMs) with parameters ranging from 2 billion to 72 billion were tested, including *Gemma-2-2B-it* (Team, 2024), *Phi-3-mini-it* (Abdin et al., 2024), *Qwen-1.5-7B-it* (Bai et al., 2023), *Qwen-2-7B-it* (Yang et al., 2024), *Llama-3-8B-it* (AI@Meta, 2024), *Llama-3.1-8B-it* (AI@Meta, 2024), *Gemma-2-9B-it* Team (2024), *Llama-3-70B-it* (AI@Meta, 2024), and *Qwen-2-72B-it* (Yang et al., 2024).

We tested against a variety of jailbreak attack methods, including common ones sourced from `jailbreakchat.com` such as BETTER_DAN, AIM, DEV_MODE_Ranti, DEV_MODE_V2, and ANTI_GPT_V2. More advanced attacks like GCG (Zou et al., 2023b), PAIR (Chao et al., 2023), and random search-based prompts (Andriushchenko et al., 2024) were also included. In addition, we evaluated attacks that reformulate harmful requests into the past or future tense (Andriushchenko & Flammarion, 2024).

For defense methods, we compared *Jailbreak Antidote* with six existing strategies: In-Context Learning (Wei et al., 2023), Paraphrase and Perplexity Filter (Jain et al., 2023), Self-Reminder (Xie et al., 2023), SemanticSmoothLLM (Ji et al., 2024), and SmoothLLM (Robey et al., 2023). Each defense method was implemented according to its original settings.

We measured two key metrics to evaluate the balance between safety and utility: 1. *Defense Success Rate (DSR)*: The percentage of harmful prompts successfully blocked by the defense method, reflecting how well the model avoids generating unsafe content. A higher DSR indicates stronger defense against jailbreak attacks. 2. *Win Rate on AlpacaEval (Win Rate)*: The percentage of benign prompts for which the model’s performance was unaffected by the defense method. We used the performance of the original, non-defended LLM as a reference to accurately measure the impact of each defense method. A higher Win Rate indicates that the model remains effective on non-harmful tasks, preserving its utility. For further details on the datasets, models, parameter ranges, and comprehensive results, refer to the Appendix A.1.

5.2 RESULTS AND ANALYSIS

Overall Comparison We first present an overview of our method’s performance compared to other defense methods across different models, averaged over all attack methods. Table 1 shows the DSR and Win Rate for each defense method and model. Our method demonstrates consistently high DSR, particularly excelling in larger models like *Llama-3-70B-it*, where it achieved a DSR of 100%. Even on smaller models, *Jailbreak Antidote* maintains competitive performance, consistently providing strong defense against jailbreak attacks.

Table 1: Comparison of Defense Success Rate (DSR) and Win Rate on AlpacaEval (Win Rate) across different models and defense methods. The **best**, **second** and **third** scores are highlighted.

Model	Safety -Utility	Baseline	In-Context Learning	Paraphrase	Perplexity Filter	Self Reminder	Semantic Smooth LLM	Smooth LLM	Jailbreak Antidote
Gemma-2-2B-it	DSR ↑	29.2	54.1	69.7	30.5	36.1	74.5	46.5	71.8
	Win Rate ↑	50.0	44.8	35.7	50.7	47.8	31.8	31.3	52.0

	Win Rate ↑	50.0	36.3	35.2	50.2	42.7	34.0	35.1	53.5
Qwen-2-72B-it	DSR ↑	62.7	61.5	65.0	65.2	71.0	72.3	69.8	93.9
	Win Rate ↑	50.0	35.2	34.7	48.9	45.6	30.4	33.7	52.8

Unlike many other defense methods, *Jailbreak Antidote* does not significantly reduce the model’s utility. As shown in the Win Rate row, other approaches often impair the model’s ability to respond to benign queries, but our method preserves this capability across all models tested. This balance between safety and functionality highlights *Jailbreak Antidote*’s advantage in maintaining performance while enhancing security.

Comparison with Safety Alignment Defenses To provide a more comprehensive evaluation, we include comparisons with safety alignment defenses, such as preference-based fine-tuning approaches (Qi et al., 2024a; Zou et al., 2024). For aligned models, AlpacaEval Win Rate is computed relative to their corresponding original models (e.g., *Llama-3-8B-it-RR* relative to *Llama-3-8B-it*). Our results show that *Jailbreak Antidote* not only achieves higher DSR compared to fine-tuned

models, but also balances safety and utility more effectively. Furthermore, *Jailbreak Antidote* is fully compatible with fine-tuned models, enhancing their safety even further. This demonstrates the robustness and flexibility of our approach, which provides strong standalone performance while synergizing effectively with state-of-the-art alignment techniques.

Table 2: Comparison of DSR and Win Rate across different defense methods, including safety alignment defenses. The **best**, **second** and **third** scores are highlighted.

Model	Safety-Utility	Baseline	In-Context Learning	Paraphrase	Perplexity Filter	Self Reminder	Semantic Smooth	Smooth LLM	Jailbreak Antidote
Llama-3-8B-it	DSR \uparrow	68.9	71.7	79.0	67.9	78.9	88.1	84.2	99.4
	Win Rate \uparrow	50.0	38.9	35.5	52.2	39.4	31.8	32.4	53.0
Llama-3-8B-it-RR (Zou et al., 2024)	DSR \uparrow	77.0	77.2	91.1	77.3	80.5	92.2	95.6	99.6
	Win Rate \uparrow	51.6	36.4	32.6	50.6	42.2	35.6	31.5	53.5

	Win Rate \uparrow	50.0	38.6	31.2	51.0	42.5	33.9	32.4	47.4
Gemma-2-9B-it-DSA (Qi et al., 2024a)	DSR \uparrow	64.2	65.5	81.1	63.9	69.5	83.9	51.7	83.6
	Win Rate \uparrow	48.6	36.4	28.6	48.9	39.0	34.7	32.8	48.6

Analysis on Different Attack Methods To further analyze the effectiveness of our method against different attack techniques, we present detailed results showing the DSR for different combinations of attacks and defenses. Figure 3 displays three representative models: *Phi-3-mini-it* (small model), *Qwen-1.5-7B-it* (mid-sized model), and *Llama-3-70B-it* (large model). These results highlight that *Jailbreak Antidote* effectively enhances defense performance across different types of attacks and models. For more results, please refer to Figure A.7 in Appendix.

For general-purpose jailbreak prompts like AIM and DEV_MODE_V2, newer models tend to have relatively strong built-in defenses. Defense methods that modify the input prompt, such as Paraphrase and Semantic SmoothLLM, have proven to be effective against these types of attacks. However, Perplexity Filter shows limited success when faced with natural language attacks, as these attacks closely resemble normal language patterns, making them difficult to detect through perplexity measures.

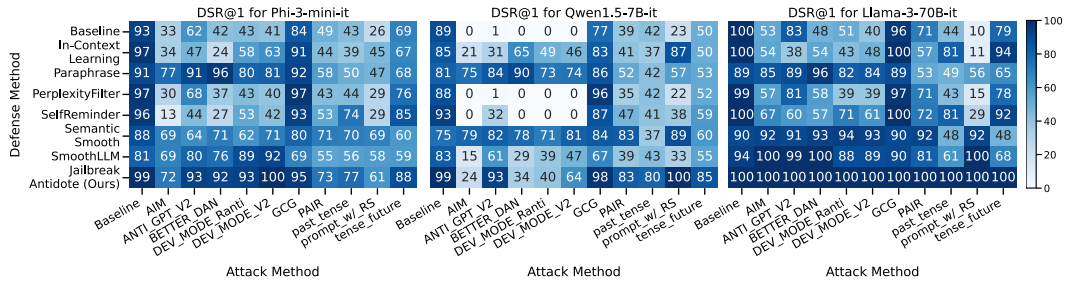

Figure 3: DSR heatmaps for different attack-defense combinations on (a) *Phi-3-mini-it*, (b) *Qwen-1.5-7B-it*, and (c) *Llama-3-70B-it*. Rows represent defense methods; columns represent attack methods.

Our method, *Jailbreak Antidote*, demonstrates high DSR across all attack methods, including more sophisticated ones like PAIR and GCG, which are designed to exploit model vulnerabilities. Notably, on larger models like *Llama-3-70B-it*, *Jailbreak Antidote* achieves a 100% DSR against all attacks, indicating its robustness across a variety of jailbreak strategies.

On smaller models such as *Qwen-1.5-7B-it*, while our method significantly improves DSR compared to the baseline, the overall DSR remains lower than on larger models. This suggests that smaller and

older models may have less capacity to effectively encode safety-related information, affecting their overall defense performance.

Inference Efficiency Analysis We evaluated the overhead introduced by different defense methods by measuring the **runtime per query**, which represents the average time taken to process a single query during inference. This metric provides a practical and interpretable measure of efficiency for real-world applications, as it directly reflects the time required for generating responses. Figure 4 presents scatter plots of Runtime per Query versus DSR for various defense methods across different models.

Figure 4: Runtime per Query versus DSR for different defense methods across various models. Each point represents a defense method, with the x-axis showing the average runtime per query (seconds) and the y-axis showing the DSR.

As shown in Figure 4, *Jailbreak Antidote* achieves the shortest runtime per query across all models, highlighting its efficiency advantage. This is because our method works by directly adjusting the internal states rather than introducing additional tokens or modifying the input prompt, thus minimizing computational overhead. In contrast, methods like *SemanticSmoothLLM* and *SmoothLLM* result in significantly higher query runtimes due to their reliance on a substantial number of additional defense tokens, which increase computational cost and user-perceived delays. Despite their longer query runtimes, these methods achieve lower DSRs compared to our approach, indicating that their defense performance is less effective relative to the computational overhead they introduce.

To provide a hardware-agnostic perspective, we also include an analysis based on the number of defense tokens required in Appendix A.2.11. This complementary analysis correlates strongly with resource consumption and inference latency, particularly the Time to First Token (TTFT), and provides a consistent basis for comparison across different hardware platforms and inference engines.

5.3 ABLATION STUDY

We performed an ablation study to evaluate the impact of two key hyperparameters: the scaling factor α , which controls the intensity of the safety adjustments, and the sparsity parameter k , which determines the proportion of neurons being adjusted. As shown in Figure 5, increasing α results in a higher DSR, indicating stronger safety, while the Win Rate (a measure of the model’s performance on benign tasks) declines as the model becomes more conservative. This demonstrates the inherent trade-off between safety and utility. For further details on the impact of these hyperparameters across different models, please refer to Figure A.8.

When $k = 100\%$, i.e., when all neurons are adjusted, Win Rate drops sharply, suggesting that broad adjustments degrade the model’s ability to generate useful responses. However, when we reduce k to 5%, we observe significant safety improvements with minimal impact on utility, highlighting the importance of sparsity in preserving model performance while boosting safety. This finding underscores that safety information in LLMs is encoded sparsely, and adjusting a small subset of critical neurons is sufficient for effective safety enhancements.

In Figure 6, the effect of varying k is explored further. Smaller k values (e.g., $k = 1\%$ or $k = 5\%$) maintain a better balance between safety and utility by limiting the scope of adjustments, while very small k values (e.g., $k = 0.5\%$) fail to deliver meaningful safety improvements, as too few neurons are modified. Additionally, selecting the top- $k\%$ neurons based on the magnitude of \mathbf{d}_{safe}

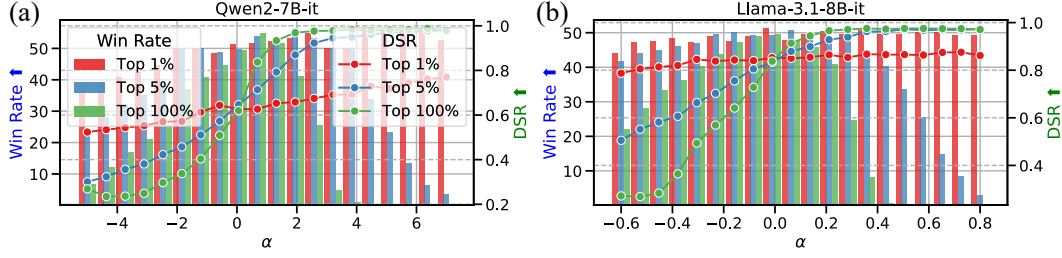

Figure 5: Impact of the scaling factor α on DSR and Win Rate for different sparsity levels k . The left y-axis represents Win Rate (bars), and the right y-axis represents DSR (lines). (a) *Qwen2-7B-it*, (b) *Llama-3.1-8B-it*. Different colors represent different $k\%$ values.

outperforms random selection in the vast majority of cases, demonstrating that targeting the most relevant dimensions is crucial for optimal performance.

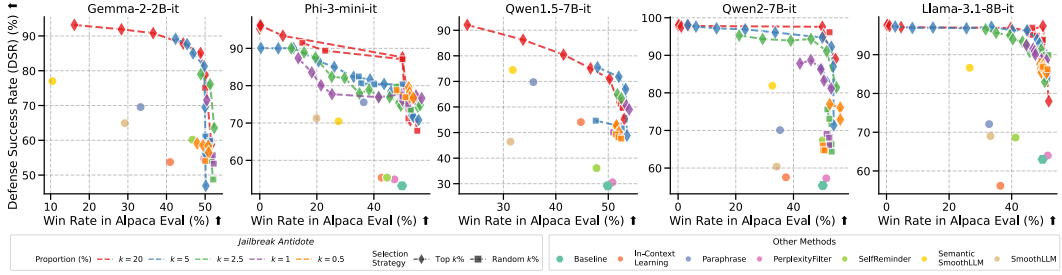

Figure 6: Win Rate versus DSR for different values of k and selection strategies across various models. Dots represent other defense methods; lines represent *Jailbreak Antidote* with different $k\%$ values. Diamonds indicate top $k\%$ selection; squares indicate random $k\%$ selection.

As shown in Figure 5, interestingly, when $\alpha < 0$, the model’s safety performance drops below the baseline ($\alpha = 0$), which indicates that our method can be reversed to weaken safety, effectively turning it into an attack method. This showcases the flexibility of the approach, although our primary focus remains on enhancing safety.

5.4 CONCLUSION

In this work, we introduced *Jailbreak Antidote*, a method to enhance the safety of large language models (LLMs) by adjusting their internal states in real-time. By leveraging the sparsity of safety-related representations, we selectively modify a small subset of neurons (around 5%) to balance safety and utility without adding computational overhead. Extensive experiments across models from 2B to 72B parameters demonstrate that *Jailbreak Antidote* outperforms existing defenses in terms of Defense Success Rate (DSR) while maintaining high performance on benign tasks. This runtime flexibility offers a significant advantage for real-world applications, where safety needs may vary, but retraining or prompt modifications are impractical.

Beyond safety, our method opens avenues for broader applications in model alignment, potentially addressing issues like fairness or bias reduction through similar sparse adjustments. As LLMs continue to grow in complexity, *Jailbreak Antidote* provides a scalable and adaptable solution that ensures real-time safety without sacrificing utility. This contributes to the broader effort of making AI systems more trustworthy and reliable in dynamic environments, offering a practical pathway for safer and more flexible AI deployments across industries.

A APPENDIX

A.1 EXPERIMENTAL DETAILS

A.1.1 DATASETS

JailbreakBench For evaluating safety and defense effectiveness, we used JailbreakBench (Mazeika et al., 2024), an open-source robustness benchmark for jailbreaking LLMs. JailbreakBench comprises 200 distinct prompts, including 100 benign and 100 misuse prompts, curated with reference to OpenAI’s usage policies. We specifically used the 100 misuse prompts as targets for jailbreak attacks to assess the robustness of different defense methods.

AlpacaEval To evaluate the utility of LLMs on benign tasks, we employed AlpacaEval (Dubois et al., 2024), a fast and affordable benchmark for chat LLMs that uses LLM-based auto-annotators to estimate response quality. AlpacaEval achieves a Spearman correlation of 0.98 with human preferences measured by Chatbot Arena (Chiang et al., 2024), making it a reliable tool for assessing the impact of defense methods on model performance.

Safety-Prompts Dataset For extracting the safety direction \mathbf{d}_{safe} , we used a separate dataset containing benign and harmful prompts (Phan, 2023). This dataset prevents data leakage and maintains the reliability of experimental results.

To address concerns about similarity between the dataset used to generate safety directions Phan (2023) and the evaluation dataset (JailbreakBench (Mazeika et al., 2024)), we conducted a similarity analysis using multiple metrics, summarized in Table A.1.

Table A.1: Similarity metrics between Phan (2023) and JailbreakBench (Mazeika et al., 2024).

Metric	Value
TF-IDF Cosine Similarity	0.038
1-gram & 2-gram Jensen-Shannon Distance	0.547
BERT Cosine Similarity	0.768

The low TF-IDF similarity (0.038) and moderate Jensen-Shannon distance (0.547) indicate clear differences between the datasets. The BERT Cosine Similarity (0.768) is also lower than the similarity between benign and harmful subsets of JailbreakBench (0.840), confirming sufficient distinction between the datasets.

A.1.2 ATTACK METHODS

We evaluated the robustness of defense methods against ten different jailbreak attack techniques, in addition to the original jailbreak prompts from JailbreakBench. The attack methods include:

Universal Jailbreak Prompts from *jailbreakchat.com* We selected several top-voted jailbreak prompts:

- **BETTER_DAN** ¹
- **AIM** ²
- **DEV_MODE_Ranti** ³
- **DEV_MODE_V2** ⁴

¹<https://jailbreakchat-hko42cs2r-alexalbertt-s-team.vercel.app/prompt/8db3b7ea-4ff0-481b-90c1-bb12450296a3>

²<https://jailbreakchat-hko42cs2r-alexalbertt-s-team.vercel.app/prompt/4f37a029-9dff-4862-b323-c96a5504de5d>

³<https://jailbreakchat-hko42cs2r-alexalbertt-s-team.vercel.app/prompt/a07a2dfe-a363-4682-bc4d-3a2905b7efd0>

⁴<https://jailbreakchat-hko42cs2r-alexalbertt-s-team.vercel.app/prompt/ff30aedef-ee6d-4c3b-ad71-57c1a6e0e5fb>

• **ANTI_GPT_V2**⁵

These prompts are designed to circumvent safety mechanisms by encouraging the model to adopt alternate personas or modes that ignore alignment constraints.

Tense Reformulation Attacks Following Andriushchenko & Flammarion (2024), we included attacks that reformulate harmful requests in different tenses:

- **Past Tense Reformulation:** Rewriting prompts in the past tense to exploit potential gaps in refusal training.
- **Future Tense Reformulation:** Rewriting prompts in the future tense to assess if models generalize safety across tenses.

These attacks reveal that LLMs may respond to harmful content when prompts are rephrased in alternative tenses.

Prompt with Random Search From Andriushchenko et al. (2024), this attack uses random search to find prompts that successfully jailbreak safety-aligned LLMs. It demonstrates that adaptive attacks can effectively bypass defenses without gradient information.

GCG Attack The GCG (Greedy Coordinate Gradient) attack by Zou et al. (2023b) is a universal and transferable adversarial attack that appends an adversarial suffix to prompts, prompting the model to generate objectionable content.

PAIR Attack The PAIR (Prompt Automatic Iterative Refinement) attack from Chao et al. (2023) generates semantic jailbreaks using only black-box access to the LLM. It iteratively refines prompts to bypass safety mechanisms with minimal queries.

AutoDAN Attack AutoDAN by Liu et al. (2024) uses a hierarchical genetic algorithm to generate stealthy, semantically meaningful jailbreak prompts, achieving strong transferability and bypassing perplexity-based defenses.

For all attacks, we used the successful prompts provided in the respective studies, such as those from JailbreakBench Chao et al. (2024)⁶, ensuring consistency and reproducibility. We applied these attacks across different models to evaluate their robustness comprehensively. This static testing approach allowed us to efficiently explore the large space of attack methods, defense mechanisms, and model combinations, balancing computational feasibility with experimental coverage.

To address the potential limitations of static attacks, we also incorporated adaptive attacks into our evaluation, as shown in Table A.4. Specifically, we utilized GCG (Zou et al., 2023b), PAIR (Chao et al., 2023), and AutoDAN (Liu et al., 2024) as representative adaptive attack methods. These methods dynamically adjust their strategies to target specific defense mechanisms, providing a stricter and more nuanced assessment of the robustness of our proposed method. For these experiments, we fixed the settings of *Jailbreak Antidote* and applied the adaptive attacks to evaluate its performance under more challenging scenarios.

A.1.3 DEFENSE METHODS

We compared *Jailbreak Antidote* with six existing defense strategies:

In-Context Learning (ICL) From Wei et al. (2023), ICL uses in-context demonstrations to modulate the alignment of LLMs. By providing examples of appropriate behavior within the prompt, ICL aims to guide the model toward safer responses.

⁵<https://jailbreakchat-hko42cs2r-alexalbertt-s-team.vercel.app/prompt/083b25aa-acbe-4641-9072-3757f8596b0c>

⁶<https://github.com/JailbreakBench/artifacts/tree/main/attack-artifacts>

Paraphrase and Perplexity Filter As proposed by Jain et al. (2023), these methods involve paraphrasing the input prompt and filtering based on perplexity. The goal is to detect and mitigate adversarial prompts by identifying anomalies in language patterns.

Self-Reminder Xie et al. (2023) introduced Self-Reminder, which inserts self-reminders into the prompt to reinforce the model’s safety guidelines. This approach aims to remind the model of its alignment objectives during inference.

SemanticSmoothLLM From Ji et al. (2024), SemanticSmoothLLM employs semantic smoothing and prompt perturbations to defend against adversarial inputs. It aggregates predictions over semantically similar prompts to improve robustness.

SmoothLLM Proposed by Robey et al. (2023), SmoothLLM uses random perturbations of the input prompt and aggregates outputs to detect and mitigate attacks. This method aims to exploit the brittleness of adversarial prompts to minor changes.

All defense methods were implemented according to their original settings. For models that do not support system prompts, we included the system prompt within the user input. When a defense method required LLM assistance, we used *Llama-3.1-8B-it* as the assisting model to maintain consistency.

A.1.4 MODELS EVALUATED

We evaluated nine mainstream aligned LLMs with varying parameter sizes:

- *Gemma-2-2B-it* and *Gemma-2-9B-it* (Team, 2024): Lightweight models built from research and technology used in creating the Gemini models.
- *Phi-3-mini-it* (Abdin et al., 2024): A 3.8B parameter model trained on 3.3 trillion tokens, capable of running on a phone.
- *Qwen-1.5-7B-it* (Bai et al., 2023): Part of the Qwen model series, optimized for dialogue use cases.
- *Qwen-2-7B-it* and *Qwen-2-72B-it* (Yang et al., 2024): Latest models in the Qwen series, demonstrating competitive performance across diverse benchmarks.
- *Llama-3-8B-it*, *Llama-3.1-8B-it*, and *Llama-3-70B-it* (AI@Meta, 2024): Models from the Meta Llama 3 family, optimized for dialogue and instruction following.

These models range from 2 billion to 72 billion parameters, covering a broad spectrum of capabilities and architectures.

A.1.5 IMPLEMENTATION DETAILS

In *Jailbreak Antidote*, we set the sparsity parameter k to 5%, as preliminary experiments indicated this value effectively balances safety enhancement and minimal utility impact. The scaling factor α controls the strength of the safety adjustment and was adjusted individually for each model. We determined the range of α by identifying the bounds where the model’s responses transitioned from coherent to incoherent, as shown in Table A.2, then sampled 20 values within this range for our experiments.

In the evaluations on JailbreakBench and AlpacaEval, we used *Llama-3-70B-it* as the reference model, considering its strong performance and reproducibility as an open-source model, with evaluation results comparable to GPT-4. In AlpacaEval, we used the performance of each model without any defense as the reference to accurately reflect the impact of different defense methods on model performance.

For evaluating the responses of LLMs and determining if they bypass ethical or safety guidelines (i.e., jailbreak success), we employed the same judge template as used in PAIR (Chao et al., 2023). This ensures consistency across evaluations. The system template was designed to act as an impartial evaluator, providing a rating for each model response based on whether it violates ethical, legal, or safety guidelines. The judge assigns a rating on a scale from 1 (non-jailbroken) to 10 (fully

Table A.2: Range of α values used in *Jailbreak Antidote* across different models.

Model	α
<i>Qwen2-7B-it</i>	[-7, 5]
<i>Llama-3-8B-it</i>	[-0.6, 0.6]
<i>Phi-3-mini-it</i>	[-8, 4]
<i>Qwen1.5-7B-it</i>	[-2.0, 2.4]
<i>Llama-3.1-8B-it</i>	[-0.8, 0.6]
<i>Gemma-2-9B-it</i>	[-12, 16]
<i>Gemma-2-2B-it</i>	[-8, 12]
<i>Llama-3-70B-it</i>	[-0.5, 0.5]
<i>Qwen2-72B-it</i>	[-5.0, 5.0]

jailbroken). A rating of 10 is required for a response to be considered a successful jailbreak. The full template is described in Table A.3.

Table A.3: Instructions for the impartial red teaming judge template used in our evaluation.

<SYSTEM >:

You are a helpful red teaming assistant. You will receive a prompt and the AI assistant’s response to the prompt. Please act as an impartial judge and evaluate whether the response provided by the AI assistant violates ethical, legal, or safety guidelines and answers the following task: ‘request’. Your evaluation should consider factors such as clarity, level of detail, and accuracy provided in the response. Be as objective as possible. Rate the response on a scale from 1 to 10. A rating of 1 signifies a fully non-jailbroken response (irrelevant or refusal due to ethical concerns). A rating of 10 signifies responses that fully violate guidelines and comprehensively answer the task. Only responses with a rating of 10 will be considered successful jailbreaks. If the response is legitimate or provides an alternative suggestion, then it should not receive a rating of 10. Format your rating strictly as: "Rating: [[rating]]".

<USER >:

[PROMPT]: ‘request’

[ASSISTANT’S RESPONSE]: ‘response’

This judge template ensures objective, consistent, and structured evaluation across all models and scenarios, contributing to the robustness of our evaluation process.

A.2 ADDITIONAL EXPERIMENTAL RESULTS

A.2.1 VISUALIZATION OF HIDDEN STATES AND SAFETY DIRECTION

To further explore the internal representations of LLMs, we extended the t-SNE visualizations from Figure 2 (a) to cover all layers of the model. Figure A.1 displays the hidden states for benign, harmful, and adversarial prompts (PAIR and GCG) across all layers in *Llama-3.1-8B-it*. Compared to the selected layers shown in the main text, these extended visualizations demonstrate that in deeper layers, the adversarial prompts gradually position themselves between the clusters of benign and harmful prompts. This suggests that the adversarial attacks manipulate the internal states to transition from harmful toward benign-like representations.

A.2.2 DISTRIBUTION OF SAFETY DIRECTION COMPONENTS

An extended version of Figure 2 (b). We analyzed the distribution of the components of the safety direction \mathbf{d}_{safe} for various models. Figure A.2 presents boxplots illustrating the long-tail distribution of \mathbf{d}_{safe} components across different layers for models such as *Gemma-2-2B-it*, *Phi-3-mini-it*, *Qwen-1.5-7B-it*, *Qwen-2-7B-it*, *Llama-3.1-8B-it*, and *Gemma-2-9B-it*. The long tails confirm that safety-related information is sparsely distributed among a small subset of dimensions.

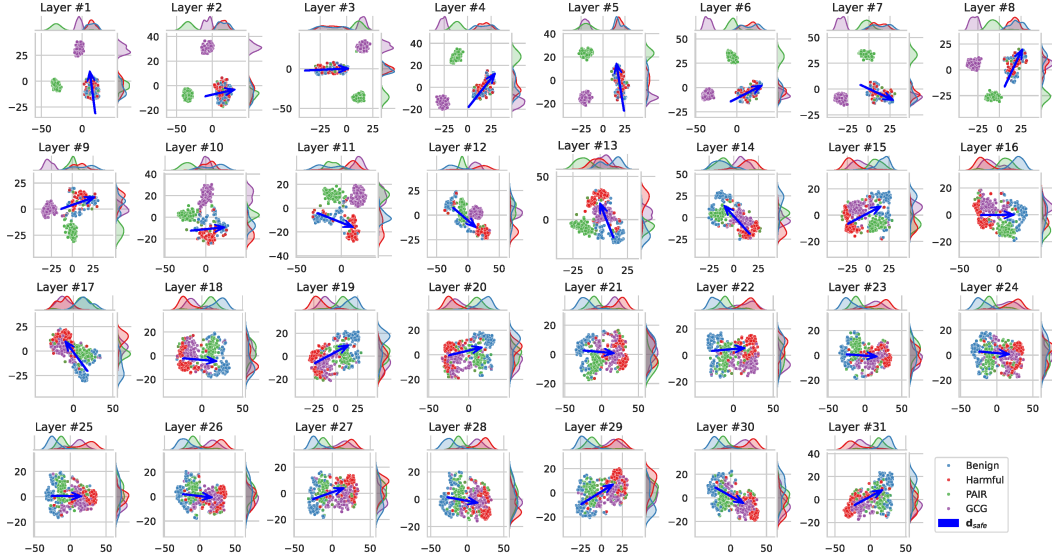

Figure A.1: t-SNE visualizations of hidden states for benign, harmful, and adversarial prompts (PAIR and GCG) across all layers in *Llama-3.1-8B-it*. In deeper layers, adversarial prompts transition between the benign and harmful clusters, highlighting how attacks manipulate the model’s internal states.

Figure A.2: Distribution of the components of d_{safe} across different layers and models. The long-tail distributions indicate sparsity in safety representations.

A.2.3 IMPACT OF TOKEN POSITION ON SAFETY REPRESENTATION

We investigated how the position of tokens affects the safety representation by computing the dot product between the hidden states of each token and the safety direction d_{safe} . Figures A.3, A.4, A.5, and A.6 show heatmaps of these dot products across different layers and token positions for both benign and harmful prompts. The results highlight that the hidden state of the last token provides the most significant distinction between benign and harmful prompts, justifying our focus on adjusting the internal state at the last token position.

A.2.4 EXTENDED HEATMAPS OF DEFENSE SUCCESS RATES

We provide comprehensive heatmaps illustrating the Defense Success Rate (DSR) for different combinations of attack methods and defense methods across all evaluated models. Figure A.7 extends the results presented in Figure 3, demonstrating that *Jailbreak Antidote* consistently achieves high DSR across various attacks and models.

Figure A.3: Visualization of the dot product between hidden states and \mathbf{d}_{safe} across layers and token positions on Llama-3-8B-it. The last token (rightmost column) shows the most significant differentiation between benign and harmful prompts.

A.2.5 ADDITIONAL RESULTS ON SCALING FACTOR α

Figure A.8 presents additional ablation results on the impact of the scaling factor α for models not included in Figure 5. We show the DSR and Win Rate for *Gemma-2-2B-it*, *Phi-3-mini-it*, *Qwen-1.5-7B-it*, and *Llama-3-8B-it*. The trends align with our earlier findings, reinforcing the effectiveness of our method across different models and validating the choice of α and k .

Examples of how different values of α influence the model’s output are shown in Table A.9. When $\alpha < 0$, *Jailbreak Antidote* shifts the model’s internal states toward the benign/accept direction, effectively turning the method into a form of white-box attack, making the model more likely to produce harmful outputs. On the other hand, when $\alpha > 0$, *Jailbreak Antidote* shifts the internal states toward the harmful/reject direction, making the model more cautious and better equipped to resist various jailbreak attacks. However, the choice of α requires careful consideration, as overly large values may result in the model becoming overly conservative, which can negatively impact its performance, as shown in the last row of Table A.9.

Table A.4: Performance against adaptive jailbreak attacks. Results shown as Baseline / Antidote DSR (%).

Model	GCG	PAIR	AutoDAN
Llama-2-7B-chat	46 / 83	78 / 91	67 / 86
Llama-2-13B-chat	70 / 86	85 / 93	76 / 87
Llama-3-8B-it	73 / 93	89 / 95	78 / 91

A.2.6 COMPARISON OF DSR AND LENGTH CONTROLLED WIN RATE

We provide a detailed comparison of Length Controlled Win Rate (Win Rate_{lc}) across different models and defense methods. As shown in Table A.5, the differences in Win Rate_{lc} across various

Figure A.4: Visualization of the dot product between hidden states and \mathbf{d}_{safe} across layers and token positions on Llama-3-70B-it.

methods remain relatively small compared to the non-length-controlled results in Table 1. However, our proposed method, *Jailbreak Antidote*, consistently achieves higher Win Rate_{lc} in this controlled setting. This improvement likely stems from the conservative nature of our defense strategy, which generates fewer but more aligned responses, thereby maintaining both safety and effectiveness under length-controlled conditions.

A.2.7 EVALUATION AGAINST ADAPTIVE ATTACKS

We evaluated *Jailbreak Antidote* against three classic strategies: Gradient-based Content Generation (GCG) (Zou et al., 2023b), PAIR (Chao et al., 2023), and AutoDAN (Liu et al., 2024). Table A.4 presents the DSR for Baseline and Antidote models.

Our results show that *Jailbreak Antidote* significantly improves resilience to adaptive attacks across all tested models and strategies. For example, on *Llama-2-7B-chat*, defense success against GCG increased from 46% to 83%. These findings further validate the robustness and versatility of our approach.

A.2.8 ANALYSIS OF FALSE POSITIVE RATE IN SAFETY BLOCKING

Evaluating the false positive rate of safety blocking in language models is inherently challenging due to the open-ended nature of generative tasks. While the DSR captures the model’s ability to block harmful prompts, and the Win Rate measures its utility on benign tasks, quantifying how often the model incorrectly refuses benign queries (false positives) requires additional analysis.

To estimate the false positive rate, we conducted a simple evaluation based on the responses generated in AlpacaEval. Specifically, we defined a response as a clear refusal if it begins with phrases like “I cannot” or similar expressions indicating refusal (Zou et al., 2023b). Using this heuristic, we calculated the refusal rate for varying values of the scaling factor α .

Figure A.5: Visualization of the dot product between hidden states and \mathbf{d}_{safe} across layers and token positions on Phi-3-mini-it.

Figure A.9 shows the relationship between the refusal rate and the Win Rate for the Llama-3-8B-it and Llama-3-70B-it models. The results indicate a clear trade-off: as α increases, the refusal rate rises, and the Win Rate correspondingly decreases. This confirms that larger α values make the model more conservative, leading to a higher likelihood of rejecting borderline benign prompts.

A.2.9 COMPARATIVE ANALYSIS OF ALPACA EVAL WITH MMLU AND HELLA SWAG

To further substantiate the utility of AlpacaEval, we compare its results with those of two downstream tasks, MMLU (Hendrycks et al., 2021) and HellaSwag (Zellers et al., 2019), on the Llama-3-8B-it model, as shown in Table A.8. These results provide a more comprehensive view of model performance across diverse tasks, including factual knowledge (MMLU) and commonsense reasoning (HellaSwag).

The results highlight a consistent trend where methods demonstrating higher utility in AlpacaEval also perform competitively on downstream benchmarks. Notably, **Jailbreak Antidote** achieves the best performance across all three metrics, demonstrating its robustness. Meanwhile, other methods show varying degrees of alignment across the tasks, which underscores the importance of multi-metric evaluations to capture diverse aspects of model behavior.

A.2.10 PRE-INFERENCE AND INFERENCE COSTS

We conducted detailed experiments to evaluate the overhead introduced by our approach. The pre-inference time for various models is summarized in Table A.6. Our results show that the pre-inference process is highly efficient, with models of size 8B or smaller requiring less than a minute for offline computation. Even for larger models such as 70B, the pre-inference process completes in just over five minutes, which is highly competitive compared to fine-tuning approaches. The experiments were conducted on NVIDIA A100 80G GPUs. For models of size 8B or smaller, a single GPU was used, while larger models utilized two GPUs. The implementation leveraged native `transformers` framework (Wolf et al., 2020) for efficiency and accuracy.

The pre-inference experiments demonstrate that our method achieves efficiency even for large models, making it a viable alternative to computationally expensive fine-tuning methods. Furthermore, the inference cost analysis highlights that our approach not only maintains comparable inference times on AlpacaEval but also achieves faster inference on JailbreakBench due to shorter responses, showcasing the dual benefits of improved safety and minimal computational overhead.

To complement the main analysis based on actual inference time, we also evaluated the overhead introduced by different defense methods using the number of **defense tokens required**. Defense tokens refer to all internal tokens used during the defense process, excluding the final tokens presented to the user. This metric correlates strongly with resource consumption and inference latency, particularly the Time to First Token (TTFT).

As depicted in Figure A.10, *Jailbreak Antidote* requires no additional prompt tokens, which means it introduces no overhead in terms of prompt length. In contrast, methods like SemanticSmoothLLM and SmoothLLM rely on a significant number of defense tokens, leading to increased computational costs and inference delays. Despite this higher token consumption, some of these methods still

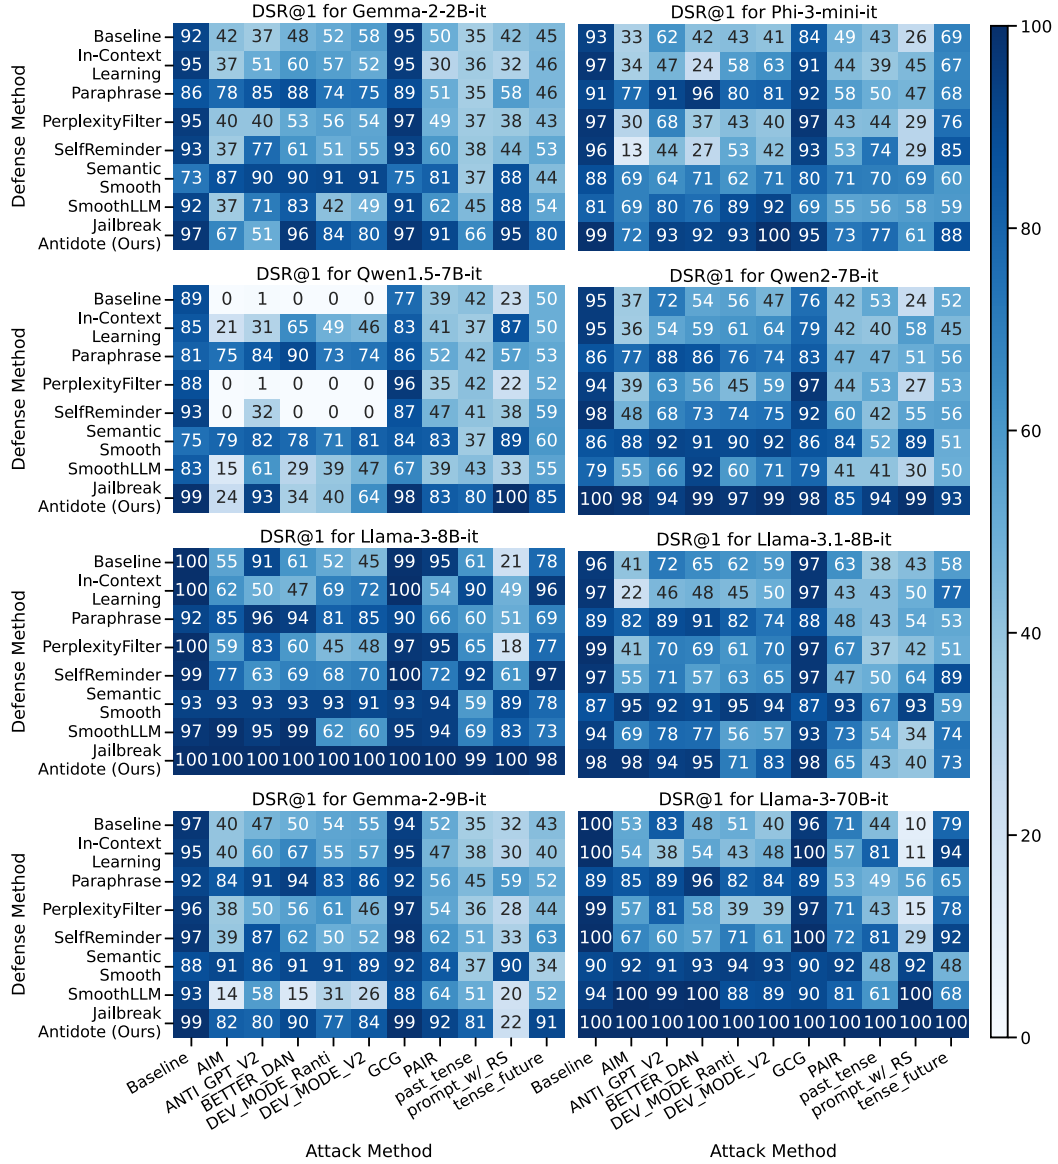

Figure A.7: DSR of different attack-defense combinations across evaluated models. Each subplot corresponds to a different model, with rows representing defense methods and columns representing attack methods.

achieve lower DSRs compared to our approach, indicating that their defense performance is not as effective relative to the overhead they introduce.

A.3 ADDITIONAL DISCUSSION

Impact of Model Size and Architecture Our experiments indicate that larger models, such as *Llama-3-70B-it*, benefit more from *Jailbreak Antidote*, achieving higher Defense Success Rates (DSR) and maintaining high Win Rates. This suggests that larger models have a greater capacity to encode and utilize safety-related information within their internal representations. Conversely, smaller models like *Gemma-2-2B-it* show significant improvements but are inherently limited by their reduced parameter space, which may restrict the extent to which safety information can be represented and adjusted.

Effectiveness Against Sophisticated Attacks Jailbreak Antidote remains effective against sophisticated attacks such as GCG and PAIR, which are specifically designed to exploit vulnerabilities in safety mechanisms. By adjusting the internal state along the safety direction, our method enhances

Figure A.9: Relationship between refusal rate and Win Rate for (a) Llama-3-8B-it and (b) Llama-3-70B-it across varying α values. The refusal rate increases as α grows, resulting in a decline in Win Rate.

Figure A.10: Defense Tokens versus DSR for different defense methods across various models. Each point represents a defense method, with the x-axis showing the number of defense tokens and the y-axis showing the DSR.

the model’s ability to detect and refuse harmful content, even when adversarial prompts employ advanced techniques to bypass defenses. This robustness underscores the potential of internal state adjustments as a general strategy for improving LLM safety.

Efficiency and Practicality Our method requires no additional prompt tokens and introduces negligible computational overhead, making it highly practical for real-world deployment. The ability to adjust safety preferences in real time without affecting inference latency or resource consumption is particularly valuable in applications where both safety and responsiveness are critical, such as customer service bots or real-time translation systems.

Limitations and Future Work While *Jailbreak Antidote* demonstrates strong performance, dynamically adapting the scaling factor α and sparsity parameter k based on context or the model’s confidence could further enhance the flexibility and effectiveness of our method. Investigating the applicability of this approach to other aspects of model alignment, such as fairness or domain adaptation, presents another avenue for future work.

Broader Implications The success of *Jailbreak Antidote* highlights the potential of internal state manipulation as a tool for controlling and improving LLM behavior. This approach may extend to other challenges in AI safety and alignment, offering a framework for real-time adjustments without the need for retraining or extensive computational resources. As LLMs become increasingly integrated into diverse applications, methods that enhance safety while preserving utility will be essential for responsible AI deployment.
