Paper under double-blind review

ABSTRACT

We study methods for efficiently aligning large language models (LLMs) with human preferences given budgeted online feedback. We first formulate the LLM alignment problem in the frame of contextual dueling bandits. This formulation, subsuming recent paradigms such as online RLHF and online DPO, inherently quests for sample-efficient algorithms that incorporate *online active exploration*. Leveraging insights from bandit theory, we introduce a unified algorithm based on **Thompson sampling** and highlight its applications in two distinct LLM alignment scenarios. The practical agent that efficiently implements this algorithm, named **SEA** (Sample-Efficient Alignment), is empirically validated through extensive experiments across three model scales (1B, 2.8B, 6.9B) and three preference learning algorithms (DPO, IPO, SLiC). The results demonstrate that **SEA** achieves highly sample-efficient alignment with oracle's preferences, outperforming recent active exploration methods for LLMs. We will release our codebase to hopefully accelerate future research in this field.

Figure 1: Win rate comparison of model responses against reference responses on the TL;DR task, judged by the preference oracle. All compared methods use the same optimization method (DPO). (Left) Performance improvements at convergence over SFT models achieved by offline (Offline DPO), passively online (Online DPO), and our *active exploration* (SEA DPO) methods. (Right) The number of queries required by the passively online method (Passive) versus that by different active exploration methods to attain various levels of win rates. SEA achieves the best sample efficiency for online alignment compared to XPO and APL.

039 1 INTRODUCTION 040

Aligning LLMs with human preferences is a crucial step to elicit various desirable behaviors, e.g., helpfulness and harmlessness (Bai et al., 2022). Moreover, it holds the potential to create superhuman capabilities with only human-level feedback, as verifying is believed to be easier than synthesizing novel behaviors. By iteratively generating massive new candidates and asking for human feedback, LLMs could learn to reinforce good behaviors and may eventually surpass human capabilities.

Existing methods, either via reinforcement learning from human feedback (RLHF) (Stiennon et al., 2020; Ouyang et al., 2022) or direct alignment from preferences (DAP) (Rafailov et al., 2023; Azar et al., 2024), typically require a large amount of human annotations to achieve effective alignment. As a result, the volume of human feedback becomes a major bottleneck in practical alignment scenarios. This poses a challenging and under-explored research question:

How to align LLMs sample-efficiently?

To seek answers, in Section 2, we formalize LLM alignment as a contextual dueling bandit (CDB) (Yue et al., 2012; Dudík et al., 2015), where the agent (i.e., the learner and decision maker, in

our case the LLM) interacts with the environment (i.e., human) to collect experience for improving its policy. This formulation naturally calls for two key properties for alignment algorithms to be sample-efficient:

Property 1 (Online interaction). Interacting and learning *online* allows the agent to act with the latest learned policy and then use that experience to immediately improve the policy.

Property 2 (Active exploration). An *actively exploring* agent strategically selects actions such that the collected experience leads to maximal policy improvement.

062 Since the CDB formulation is general and almost subsumes all existing LLM alignment methods, it provides us a lens to scrutinize prior methods on the axes of Properties 1 and 2. In Section 3, we 063 thoroughly discuss prior alignment approaches, ranging from offline learning (Rafailov et al., 2023; 064 Azar et al., 2024) and passive learning with iterative (Christiano et al., 2017; Dong et al., 2024) or on-065 line interaction (Guo et al., 2024), to active exploration for learning preference models (Dwaracherla 066 et al., 2024) or aligning LLMs (Muldrew et al., 2024; Zhang et al., 2024a; Xie et al., 2024). As will 067 be revealed, most prior methods (partially) fail to satisfy the two properties, resulting in inferior sam-068 ple efficiency. Moreover, through the CDB formulation, we identify two LLM alignment scenarios, 069 namely aligning from online users' feedback (e.g., ChatGPT (2024)) and aligning from crowdsourc-070 ing (Christiano et al., 2017; Ouyang et al., 2022), and shed light on their correspondences to two 071 bandit settings (explore & exploit and best arm identification). Understanding their differences is 072 important for designing efficient alignment algorithms for respective scenarios. We detail these two 073 settings in Section 2 and discuss how prior works approach them in Section 3.

074 Leveraging algorithmic insights from bandit theory, our answer to the research question above is a 075 principled alignment algorithm based on Thompson sampling (TS) (Thompson, 1933). Our method 076 fulfills Properties 1 and 2 to enhance sample efficiency, and it solves either of the two settings de-077 pending on practical scenarios (Section 4.1). We incorporate techniques including *epistemic reward* 078 model, policy-guided search and mixed preference learning to implement the proposed TS algo-079 rithm (Section 4.2), yielding a practical agent which we call SEA (Sample-Efficient Alignment). In addition, we develop and open source a highly efficient, distributed learning system for studying 080 online LLM alignment methods (Section 5), eliminating barriers to *fair* empirical comparisons of 081 different alignment algorithms. Through extensive experiments (Section 6), SEA shows strong empirical results (see Figure 1), consistently achieving higher win rates and improved sample efficiency 083 compared to baseline approaches across three model scales. We will open source the codebase to 084 hopefully accelerate future research in this field. 085

2 LLM ALIGNMENT AS CONTEXTUAL DUELING BANDITS

We first review the definitions and two typical objectives of *Contextual Dueling Bandits* (Section 2.1), then translate them into the language of *LLM alignment* (Section 2.2). The tight connection between them, as we will see, allows us to leverage insights from bandit algorithms to design efficient alignment algorithms for LLMs.

092 2.1 CONTEXTUAL DUELING BANDITS

087

Contextual dueling bandits (CDB) (Yue et al., 2012; Dudík et al., 2015) is proposed to study online 094 learning problems where the feedback consists of relative pairwise comparisons. A CDB problem 095 can be characterized by a tuple $(\mathcal{C}, \mathcal{A}, \mathbb{P})$, where \mathcal{C} is the context space, \mathcal{A} is the action space, and \mathbb{P} : 096 $\mathcal{A} \times \mathcal{A} \times \mathcal{C} \mapsto [0,1]$ denotes the unknown *preference oracle*. An agent learns by iteratively interacting 097 with the environment (i.e., the preference oracle \mathbb{P}) as follows. At each round t of the learning 098 process, a context $c_t \sim p_c$ is presented to the agent, who needs to take two actions $a_t, a'_t \in A$ for 099 a "dueling" comparison. The agent then receives stochastic feedback in the form of a comparison 100 result $z_t \sim \text{Ber}\left(\mathbb{P}\left(a_t \succ a_t' | c_t\right)\right)$ from the environment, where $\text{Ber}(\cdot)$ is the Bernoulli distribution and \succ denotes that the first action is preferred. 101

Regret. The quality of the dueling actions selected by the agent is measured by the *immediate* regret: $R_t = \mathbb{P}(\mathbf{a}_t^* \succ \mathbf{a}_t | \mathbf{c}_t) + \mathbb{P}(\mathbf{a}_t^* \succ \mathbf{a}_t' | \mathbf{c}_t) - 1$, where \mathbf{a}_t^* is the best action¹ the agent would take at round t if it had complete knowledge of \mathbb{P} . Intuitively, if the agent has learned how to act optimally from round t onwards, it would no longer suffer any regret since its actions would be indistinguishable from the best action ($\mathbb{P}(\mathbf{a}_\tau^* \succ \mathbf{a}_\tau | \mathbf{c}_\tau) = \frac{1}{2}$ hence $R_\tau = 0$ for $\tau \ge t$).

2

genera1:polished these two paragraphs

fdaL

¹We assume that a best action a^* in the sense that $\mathbb{P}(a^* \succ a | c) \geq \frac{1}{2}, \forall a \in \mathcal{A}$ exists for all context $c \in C$.

Figure 2: (Left) A typical offline RLHF pipeline consists of three stages: collecting preference dataset, training a reward model to serve as a proxy "environment", and running RL to optimize the LLM policy inside the proxy "environment". (Middle) DAP simplifies RLHF by merging the last two stages of RLHF into a single step of contrastive supervised learning. (Right) Unlike prior two offline approaches, online alignment employs a CDB interface, where the agent directly interacts with the preference oracle (e.g., humans) online, learning to produce *good* responses satisfying either E&E or BAI objectives. [genera1,fdaL: use fig.2 to provide a clearer comparison between our CDB formulation and RLHF/DPO.]

Optimal policy. A policy $\pi \in \Delta_{\mathcal{A}}^{\mathcal{C}\,2}$ associates each context $c \in \mathcal{C}$ with a probability distribution $\pi(\cdot|c) \in \Delta_{\mathcal{A}}$ over the action space. The *total preference* of policy π over policy μ given a context sampling distribution $p_{\mathcal{C}} \in \Delta_{\mathcal{C}}$ and a preference oracle \mathbb{P} is defined as

$$P_{p_{\mathcal{C}},\mathbb{P}}(\pi \succ \mu) = \mathbb{E}_{\boldsymbol{c} \sim p_{\mathcal{C}}} \left[\mathbb{E}_{\boldsymbol{a} \sim \pi(\cdot|\boldsymbol{c})} \mathbb{E}_{\boldsymbol{a}' \sim \mu(\cdot|\boldsymbol{c})} \left[\mathbb{P}(\boldsymbol{a} \succ \boldsymbol{a}'|\boldsymbol{c}) \right] \right].$$
(1)

We adopt the *von Neumann winner* (Dudík et al., 2015) as the solution concept, which requires the optimal policy π^* to satisfy that

$$\forall \pi' \in \Delta_{\mathcal{A}}^{\mathcal{C}}, \ P_{p_{\mathcal{C}}, \mathbb{P}}(\pi^* \succ \pi') \ge \frac{1}{2}.$$
(2)

fdaL

In words, the von Neumann winner policy should beat or tie with every policy (i.e., is zero-regret) on average.

140 Learning objectives. The goal of bandit agents is to learn an optimal policy through interactions 141 with the environment. There are two subtypes of objectives that focus on different learning sce-142 narios. The first type considers the conventional *explore and exploit* (E&E) setting (Robbins, 1952; Auer et al., 2002), where the agent learns fully **online** and tries to minimize the cumulative regret 143 over T rounds: $\sum_{t=1}^{T} R_t$. The second type of objective concerns the best arm identification (BAI) 144 setting (Bubeck et al., 2009; Audibert & Bubeck, 2010), where the agent is only evaluated offline on 145 its average performance, possibly at any round (a.k.a., anytime regret), and tries to learn the optimal 146 policy with minimum interaction. Both settings call for effective online exploration strategies that 147 satisfy Properties 1 and 2. Their differences will be made clearer with real scenarios in Section 2.2. 148

149 2.2 ONLINE ALIGNMENT AS CDB 150

Online LLM alignment can be framed as a CDB problem as illustrated in Figure 2 (Right). Specifically, at time t a text prompt (cf. context) $x_t \in \mathcal{X}$ is sampled from a prompt distribution $p_{\mathcal{X}}$. Then, two distinct responses (cf. actions), $y_t, y'_t \in \mathcal{Y}$, are chosen by the agent, and presented to human annotators (cf. the environment) for preference ranking. The winning and losing responses are labeled as (y_t^+, y_t^-) based on a binary stochastic feedback $z_t \sim \text{Ber}(\mathbb{P}(y_t \succ y'_t | x_t))$. The agent is expected to produce good responses satisfying either E&E or BAI objectives, with knowledge learned from the experience accumulated so far: $\mathcal{D}_t = \{(x_\tau, y_\tau^+, y_\tau^-)\}_{\tau=1}^t$. A standard assumption is that human preferences follow the Bradley-Terry (BT) model (Bradley & Terry, 1952):

161

133

$$\mathbb{P}(\boldsymbol{y}_t \succ \boldsymbol{y}_t' | \boldsymbol{x}_t) = \frac{\exp\left(r^{\star}(\boldsymbol{x}_t, \boldsymbol{y}_t)\right)}{\exp\left(r^{\star}(\boldsymbol{x}_t, \boldsymbol{y}_t)\right) + \exp\left(r^{\star}(\boldsymbol{x}_t, \boldsymbol{y}_t')\right)} = \sigma(r^{\star}(\boldsymbol{x}_t, \boldsymbol{y}_t) - r^{\star}(\boldsymbol{x}_t, \boldsymbol{y}_t')), \quad (3)$$

¹⁵⁸ 159

²We denote by $\Delta_{\mathcal{A}}^{\mathcal{C}}$ the set of all mappings $\mathcal{C} \mapsto \Delta_{\mathcal{A}}$, where $\Delta_{\mathcal{A}}$ denotes the set of all probability distributions over \mathcal{A} .

179

195

196

208

Figure 3: Different paradigms to solve online LLM alignment in the CDB interface (Figure 2 (Right)). The CDB agent is shaded in gray. We use colors to denote learnable components, RL optimizer, direct optimizer, and active exploration. r_{ϕ} denotes a point estimate of human's implicit reward, while \mathcal{R}_{Φ} refers to an uncertainty-aware reward model. Please see Section 3 for detailed comparisons with references to prior works. [fdaL: updated fig.3 to highlight the differences between (b) and (d).]

173 where σ is the sigmoid function and r^* encodes human's implicit reward. The immediate regret of 174 LLM alignment can be rewritten as $R_t = r^*(\boldsymbol{x}_t, \boldsymbol{y}_t^*) - (r^*(\boldsymbol{x}_t, \boldsymbol{y}_t) + r^*(\boldsymbol{x}_t, \boldsymbol{y}_t'))/2$ with the BT 175 assumption (Saha, 2021; Li et al., 2024), where \boldsymbol{y}_t^* is the best response for prompt \boldsymbol{x}_t given human's 176 implicit reward, i.e., $r^*(\boldsymbol{x}_t, \boldsymbol{y}_t^*) \ge r^*(\boldsymbol{x}_t, \boldsymbol{y}), \forall \boldsymbol{y} \in \mathcal{Y}$. The von Neumann winner policy is also 177 redefined as

$$\pi^{\star} \in \underset{\pi \in \Delta_{\mathcal{V}}^{\mathcal{X}}}{\operatorname{arg\,max}} J(\pi), \text{ where } J(\pi) = \mathbb{E}_{\boldsymbol{x} \sim p_{\mathcal{X}}} \mathbb{E}_{\boldsymbol{y} \sim \pi(\cdot | \boldsymbol{x})}[r^{\star}(\boldsymbol{x}, \boldsymbol{y})] \text{ is the objective,}$$
(4)

by substituting Eq. (3) into Eq. (1) and maximizing $P_{p_{\mathcal{X}},\mathbb{P}}(\pi \succ \pi^*)$ towards 1/2.

The two settings in bandits have their respective applications in LLM alignment. (1) The E&E 182 setting applies to the scenario of serving an LLM-based application online and aligning it continually 183 with users' preferences. In this setting, the agent needs to balance exploration with exploitation, thus the cumulative regret is of interest because the quality of *every* response matters. In fact, 185 commercial systems like ChatGPT would strategically ask users to make a dueling comparison, while upholding the quality of both responses. Please see Figure 12 in Appendix G for an example. 187 (2) The BAI setting corresponds to the other scenario where annotators are paid to provide human 188 feedback (Christiano et al., 2017; Ouyang et al., 2022). The desideratum in this scenario is to align 189 the LLM at the minimum labeling cost, while the quality of the dueling responses is not important 190 as long as the experience helps sample-efficiently learn the von Neumann winner policy. 191

After formalizing LLM alignment in the framework of CDB and uncovering their tight connections, we next thoroughly discuss existing alignment methods in the CDB framework and reveal the sources of their sample inefficiencies.

3 HOW PRIOR WORKS (PARTIALLY) SOLVE LLM ALIGNMENT AS CDB

We first align the notations and terminology used in CDB with commonly referred ones in the LLM 197 community. Previously, we used the term "agent" to denote the learner and decision maker, and 198 referred to its overall behavior as the "policy" π (as in Eq. (4)), following the standard abstraction in 199 RL (Sutton & Barto, 2018; Sutton et al., 2022). However, in the LLM literature, "policy" typically 200 refers to the generative language model alone, excluding components like reward models (RMs) that 201 the agent might additionally build (see Figure 2 (Right)). To avoid confusion, from now on we use 202 π_{θ^t} to denote the generative language model (policy) and r_{ϕ^t} to denote the (optional) RM at time t, 203 both of which are learned from preference data \mathcal{D}_t collected up to time t. We will omit t when the 204 time-indexing is not applicable (i.e., no online interaction) or not important in the context.

RLHF and DAP. Commonly adopted RLHF pipelines (Christiano et al., 2017; Stiennon et al., 2020; Bai et al., 2022; Ouyang et al., 2022) first learn a proxy RM with a negative log-likelihood loss:

$$\mathcal{L}_{r}(\phi|\mathcal{D}) = -\mathbb{E}_{(\boldsymbol{x},\boldsymbol{y}^{+},\boldsymbol{y}^{-})\sim p_{\mathcal{D}}}\left[\log\sigma\left(r_{\phi}\left(\boldsymbol{x},\boldsymbol{y}^{+}\right) - r_{\phi}\left(\boldsymbol{x},\boldsymbol{y}^{-}\right)\right)\right],\tag{5}$$

where \mathcal{D} is collected by querying human annotators using a behavior policy π_{ref} (typically the supervised fine-tuned policy π_{sft}). Afterwards, *offline RL*³ (Lange et al., 2012; Levine et al., 2020) fdaL is conducted to learn π_{θ} with respect to the learned reward r_{ϕ} internally within the agent (Figure 3a). However, the learned model π_{θ} might be inaccurate at regions out of the distribution (o.o.d.) of π_{ref} because little training data can be collected. An effective remedy is to incorporate a pessimistic term to combat the distributional shift, leading to a reformulation of the von Neumann winner

$$= \underset{\boldsymbol{x} \sim p_{\mathcal{X}}}{\mathbb{E}} \left[\underset{\boldsymbol{y} \sim \pi_{\theta}(\cdot | \boldsymbol{x})}{\mathbb{E}} \left[r_{\phi}(\boldsymbol{x}, \boldsymbol{y}) \right] - \beta D_{\mathrm{KL}}(\pi_{\theta}(\cdot | \boldsymbol{x}) || \pi_{\mathrm{ref}}(\cdot | \boldsymbol{x})) \right],$$
(7)

(6)

223 which converts an online objective regarding the human's implicit reward r^* to an offline objective 224 regarding the proxy reward r_{ϕ} . The KL penalty in Eq. (7) is widely used for language model 225 fine-tuning (Jaques et al., 2020; Xiong et al., 2024), and PPO (Schulman et al., 2017) has become a 226 default *RL optimizer* to maximize the KL-regularized reward. However, the performance of RLHF 227 is guaranteed only if the preference data D induced by π_{ref} adequately covers π^* (Zhu et al., 2023), 228 which is often approximated by updating π_{ref} with the latest (improved) π_{θ} for re-sampling a batch 229 of online experience and repeating Eq. (5) and (7). Prior works typically focus on offline (Figure 2 230 (Left)) or iterative online (with only a few iterations) settings (Xiong et al., 2024; Dong et al., 231 2024), which may compromise sample efficiency (Property 1).

 $J(\pi_{\theta}) = \mathbb{E}_{\boldsymbol{x} \sim p_{\mathcal{X}}} \mathbb{E}_{\boldsymbol{y} \sim \pi_{\theta}(\cdot | \boldsymbol{x})} \left[\underbrace{r_{\phi}(\boldsymbol{x}, \boldsymbol{y})}_{\boldsymbol{x} \sim \boldsymbol{x}_{\theta}(\cdot | \boldsymbol{x})} - \underbrace{\beta \log \frac{\pi_{\theta}(\boldsymbol{y} | \boldsymbol{x})}{\pi_{\mathrm{ref}}(\boldsymbol{y} | \boldsymbol{x})}}_{\boldsymbol{x} \sim \boldsymbol{x}_{\theta}(\cdot | \boldsymbol{x})} \right]$

232 True online RLHF is difficult due to the complexity and instability of RL optimizers. For example, 233 Huang et al. (2024) openly reproduces offline RLHF scaling behaviors but requires many imple-234 mentation tricks for training, highlighting the difficulties of an online counterpart. Fortunately, the 235 introduction of DAP (or *direct optimizers*) largely simplifies and stabilizes fine-tuning by conducting 236 contrastive supervised learning directly on \mathcal{D} (Figure 3b). While most DAP works focus on learning from a fixed offline preference dataset (Figure 2 (Middle), including Zhao et al. (2023); Rafailov 237 et al. (2023); Azar et al. (2024); Meng et al. (2024); Zhang et al. (2024b)), iterative DPO (Xu et al., 238 2023) observes improved results when allowing iterative online interaction. Guo et al. (2024) fur-239 ther propose OAIF to make DAP faithfully online, satisfying Property 1, and demonstrate that online 240 learning prevents over-fitting and yields continual performance improvement. Nevertheless, it still 241 employs passive exploration strategies (using $y, y' \sim \pi_{\theta}$), hindering sample efficiency (Property 2). 242

Online exploration in LLMs. A line of recent works (Mehta et al., 2023; Das et al., 2024; Melo 243 et al., 2024; Dwaracherla et al., 2024) adopts the fully online bandit formulation and incorporates ac-244 tive exploration with uncertainty-aware RMs for response selection (Figure 3c). In particular, Mehta 245 et al. (2023) consider the E&E setting and develop a UCB-style (Auer et al., 2002) algorithm; Das 246 et al. (2024) instead select the dueling responses with the most uncertain preference estimate, target-247 ing the BAI setting in a pure exploration way; unlike the above, Melo et al. (2024) view the problem 248 from the angle of pool-based active learning and propose an acquisition function based on both en-249 tropy and epistemic uncertainty; finally, the work by Dwaracherla et al. (2024) is the closest to ours 250 in the sense that they apply double Thompson sampling (DTS) (Wu & Liu, 2016) for exploration, 251 but DTS is designed for the E&E setting while they evaluate anytime average performance as in 252 the BAI setting. We will show in Appendix E.1 that pure exploration by Das et al. (2024) is not 253 the best choice for BAI, and the objective mismatch in Dwaracherla et al. (2024) could lead to suboptimal performance in respective settings. Meanwhile, all these works primarily focus on learning 254 uncertainty-aware RMs online without updating LLM policies. Therefore, all responses are sampled 255 from a fixed proposal policy π_{β} (or even a fixed dataset), making the data coverage a critical concern. 256

257 Another line of research updates LLMs online while incorporating exploration. Zhang et al. (2024a) 258 and Xie et al. (2024) independently propose to learn an optimistic RM to encourage exploration. 259 They leverage the property of DPO (Rafailov et al., 2023) to reparameterize RM with policy and conclude with an extra optimistic term in the DPO loss function. Thus, their learning processes are 260 like Figure 3b but with an optimistic direct optimizer. Muldrew et al. (2024) adopt the vanilla DPO 261 loss but utilize the implicit reward margin to actively select dueling responses. Yet, these methods are 262 tightly coupled with DPO and not compatible to other direct optimizers. Their experiments are also 263 limited to a few online iterations, possibly due to the implementation difficulty of a faithfully online 264 learning system. Given their relevance to our approach, we will reproduce them in a fully online 265 manner for fair comparisons in Section 6.1. We summarize prior works in Table 3 in Appendix G.

266 267 268

4 **SEA**: SAMPLE-EFFICIENT ALIGNMENT FOR LLMS

In this section we present our online exploration agent **SEA** (Figure 3d). We first introduce a principled Thompson sampling algorithm inspired by bandit theory (Section 4.1), and then derive **SEA** as

286 287

289 290

291

	Input: Prompt distribution $p_{\mathcal{X}}$, unknown but queryable preference of	pracle \mathbb{P} .
1:	Initialize experience $\mathcal{D}_0 \leftarrow \emptyset$.	
2:	for $t = 1, \ldots, T$ do	
3:	Receive a prompt $\boldsymbol{x}_t \sim p_{\mathcal{X}}$.	
4:	Sample $r \sim p_r(\cdot \mathcal{D}_{t-1})$ and set $\boldsymbol{y}_t \leftarrow \arg \max_{\boldsymbol{b} \in \mathcal{Y}} r(\boldsymbol{x}_t, \boldsymbol{b})$.	// Select 1st response $y.$
	<pre>// E&E objective: aligning an online system.</pre>	
5:	repeat	
	Sample $r \sim p_r(\cdot \mathcal{D}_{t-1})$ and set $y'_t \leftarrow \arg \max_{b \in \mathcal{Y}} r(x_t, b)$.	// Select 2nd response $oldsymbol{y}'$.
	until $oldsymbol{y}_t' eq oldsymbol{y}_t$	
	<pre>// BAI objective: labeling via crowdsourcing.</pre>	
6:	Set $\boldsymbol{y}_t' \leftarrow \arg \max_{\boldsymbol{b} \in \mathcal{Y}} \mathbb{V} \left[\sigma \left(r(\boldsymbol{x}_t, \boldsymbol{y}_t) - r(\boldsymbol{x}_t, \boldsymbol{b}) \right) \right]$	// OR select 2nd response $m{y}'.$
	where $\mathbb{V}[\cdot]$ computes variance over the posterior $p_r(\cdot \mathcal{D}_{t-1})$.	
7:	Query \mathbb{P} to label $\{y_t, y_t'\}$, and update experience $\mathcal{D}_t \leftarrow \mathcal{D}_{t-1}$	$ \{(x_t, y_t^+, y_t^-)\}.$
8:	end for	
	// S	ee Algorithm 2 for a practical version.

its practically efficient implementation (Section 4.2). Interestingly, **SEA** can also be viewed as an 288 instantiation of a classical model-based RL architecture called Dyna (Sutton, 1990), for which we defer the discussion to Appendix B.

4.1 THOMPSON SAMPLING FOR LLM ALIGNMENT

Thompson sampling (TS) (Thompson, 1933) is widely adopted for solving bandit problems at scale 292 due to its efficiency and strong empirical performance in general online learning problems (Chapelle 293 & Li, 2011; Russo et al., 2018). A bandit agent using Thompson sampling typically maintains and 294 incrementally updates a posterior distribution of the oracle reward p(r|D). Meanwhile, the agent 295 takes actions following a greedy policy with respect to a sampled RM: $a_t = \arg \max_a r(a)$ with 296 $r \sim p_r(\cdot | \mathcal{D})$. This simple yet effective algorithm naturally balances exploration and exploitation: 297 when the agent has limited knowledge about the environment, the posterior estimate exhibits high 298 uncertainty so that the sampled RM could guide the greedy policy to explore; after sufficient ex-299 perience is gathered, the sampled RM approximates the oracle more closely, allowing the agent to 300 exploit near-optimal policies. 301

In the context of LLM alignment, we leverage the BT assumption (Eq. (3)) to replace the preference 302 oracle \mathbb{P} with human's implicit reward r^* . This substitution enables us to model the reward posterior 303 $p(r|\mathcal{D})$ in the standard TS framework, preserving the probabilistic structure necessary for effective 304 posterior sampling. Inspired by prior works (Wu & Liu, 2016; González et al., 2017) on non-305 contextual K-arm bandits and preferential Bayesian optimization problems, we generalize them for 306 LLM alignment and develop a unified algorithm as shown in Algorithm 1. Note that we assume for 307 now the LLM agent can be fully described by the posterior $p(r|\mathcal{D})$, and we defer practical reward 308 (r_{ϕ}) and policy (π_{θ}) learning to Section 4.2.

309 As Algorithm 1 presents, the first response of the duel is always selected via standard TS (Line 4). 310 The selection of the second response varies across different settings. Line 5 will be used for scenarios 311 where preference feedback is collected from online users (the E&E setting). The dueling responses 312 selected in this case will both try to maximize a sampled RM, so that the online user experience 313 is warranted with best effort. However, such algorithm can have poor asymptotic performance for 314 BAI problems (Russo, 2016), because sub-optimal responses with confidently high rewards might 315 be tried for a long time at the expense of not exploring other potentially better choices. In light of this, Line 6 provides an alternative for scenarios where we could hire annotators for feedback 316 and low-quality but exploratory responses are safe to try. Specifically, Line 6 selects the second 317 response as the one that maximizes the variance of the preference (Eq. (3)) over the first response 318 y_t . This variance quantifies the *epistemic uncertainty* of the RM, pointing the agent to the maximally 319 informative direction to explore for better sample efficiency. 320

321 However, Algorithm 1 is yet to be practical for LLM alignment for three main reasons. First, computing and sampling from a reward posterior is intractable for nearly all RMs at LLM scale, which 322 are mostly based on large transformers (Lambert et al., 2024). Second, even if we managed to ap-323 proximate the reward posterior, the $\arg \max$ operations for response selection are still intractable since the search space \mathcal{Y} is discrete and massive for token sequences of arbitrary length. Last but not least, an LLM agent (Achiam et al., 2023; Touvron et al., 2023) typically consists in a generative model π_{θ} (e.g., a transformer (Vaswani et al., 2017)), while the algorithm above is centered around a reward posterior $p(r|\mathcal{D})$ that cannot be easily converted into a generative model. We next detail how SEA practically addresses the three aforementioned issues.

4.2 PRACTICAL IMPLEMENTATION

331 4.2.1 EPISTEMIC REWARD MODEL FOR POSTERIOR SAMPLING

To implement active exploration with TS, we seek an efficient way to maintain and incrementally update the reward posterior p(r|D). We consider *deep ensemble* for our purpose, due to its capability to model epistemic uncertainty (Lakshminarayanan et al., 2017) and provable results when applied to TS in linear bandits (Qin et al., 2022). Specifically, we update a set of plausible RMs independently and online, using the preference data and a regularized negative log-likelihood loss:

337 338

339

347

367 368

$$\mathcal{L}_{\mathcal{R}}(\Phi^t | \mathcal{D}_t) = \sum_{k=1}^K \left(\mathcal{L}_r(\phi_k^t | \mathcal{D}_t) - \lambda || \phi_k^t - \phi_k^0 || \right),$$
(8)

RtS4

fdaL

where \mathcal{L}_r is defined in Eq. (5), $\Phi^t = \{\phi_k^t\}_{k=1}^K$ contains the weights of the ensemble of size K, and λ controls the regularization towards individual initial weights ϕ_k^0 . Each ensemble member is initialized independently with random weights, and then trained with regularization to maintain the diversity across ensemble members (Dwaracherla et al., 2024). Randomly picking a ϕ_k^t from Φ^t would approximate the posterior sampling $(r \sim p_r(\cdot|\mathcal{D}_t))$ for the RM (Lu & Van Roy, 2017; Gustafsson et al., 2020). In practice, we train K MLP heads on top of a pretrained and frozen transformer. We refer to the ensemble as the Epistemic Reward Model (ERM, denoted as \mathcal{R}_{Φ}).

348 4.2.2 POLICY-GUIDED SEARCH TO APPROXIMATE arg max

349 With the ERM approximating the reward posterior, we need to further approximate the response selection steps (Lines 4 to 6) which generally take the form of $\arg \max_{b \in \mathcal{Y}} U(b)$, where U absorbs the 350 351 sampled prompt, the sampled RM, and optionally the selected first response (for BAI, Line 6). To obtain the maximum, bandit algorithms for large action spaces typically resort to an action optimiza-352 tion oracle (Katz-Samuels et al., 2020; Zhu et al., 2022), but they assume a linear structure of U with 353 respect to b, which might be impractical for LLMs. Therefore, we instead replace the optimization 354 over \mathcal{Y} with sampling from a policy-guided distribution conditioned on U, $\pi_{\text{prior}}(\cdot|\boldsymbol{x}) \exp(U(\cdot)/\eta)$, 355 which is appropriate since it favors responses y that approximately maximize U(y). In practice, for 356 a given prompt x_t , we sample M candidate responses from the prior policy $\pi_{\text{prior}}(\cdot|x_t)$ to construct 357 a proposal set $S_t = \{y_t^i\}_{i=1}^M$. We then conduct a greedy search in S_t (taking $\eta \to 0$) to identify the 358 response y_t (or y'_t) that locally maximizes the utility function U, which is subsequently used in the 359 duel. We also reuse the same S_t for different U functions at time t to save computation. The choice 360 of π_{prior} will be discussed in the next section. 361

362 4.2.3 ONLINE POLICY LEARNING FROM MIXED PREFERENCES

We finally resolve two remaining questions: (Q1) how to choose a sensible π_{prior} at each time t and (Q2) how to get a good generative policy online. To this end, we propose a simple approach to approximately address both questions simultaneously. That is, we can utilize any direct optimizer to learn the policy $\pi_{\theta t}$ online with the following loss and use the latest online policy as π_{prior} :

$$\mathcal{L}_{\pi}(\theta^{t}|\mathcal{B}_{t}, \pi_{\mathrm{ref}}, F) = \mathbb{E}_{(\boldsymbol{x}, \boldsymbol{y}^{+}, \boldsymbol{y}^{-}) \sim p_{\mathcal{B}^{t}}} \left[F_{\theta^{t}}(\boldsymbol{x}, \boldsymbol{y}^{+}, \boldsymbol{y}^{-}, \pi_{\mathrm{ref}}) \right],$$
(9)

where \mathcal{B}_t is a batch of preference data labeled by the oracle wherein the responses are proposed by π_{prior} and selected by \mathcal{R}_{Φ^t} , *F* could be any DAP loss (see Appendix A for some examples), and π_{ref} is chosen to be π_{sft} . Note that we use π_{θ^t} as π_{prior} at any time *t*, thus \mathcal{B}^t is a batch of on-policy data. By *contrastive training* on these *on-policy* data, we leverage their orthogonal benefits to achieve maximal policy improvement (Tajwar et al., 2024; Tang et al., 2024).

Now that optimizing Eq. (9) yields a good online policy π_{θ^t} (answering Q2), we need to assess whether π_{θ^t} can serve as a suitable π_{prior} for approximating the arg max in TS (Q1). If we optimize π_{θ^t} with oracle preference data, S_t will be biased towards responses with high oracle reward r^* . Bias towards high- r^* region is generally helpful because it aligns with $\arg \max_{b \in \mathcal{Y}} r(x, b)$ that seeks high-reward responses. However, optimizing π_{θ^t} only with oracle data can average out the 378 epistemic uncertainty of \mathcal{R} , hindering the exploration efficiency. To mitigate this issue, we further 379 align π_{θ^t} with \mathcal{R}_{Φ^t} using the same direct optimizer to encourage π_{θ^t} to propose high- r_{ϕ^t} responses 380 for individual $r_{\phi_{k}^{t}}$, leading to better approximation of $\arg \max_{\boldsymbol{b} \in \mathcal{Y}} r(\boldsymbol{x}, \boldsymbol{b})$ for any sampled r. To 381 implement, we optimize Eq. (9) over a mixture distribution $p_{\mathcal{B}_{t}^{\text{mix}}} = \gamma p_{\mathcal{B}_{t}} + (1 - \gamma) p_{\mathcal{B}_{t}^{\text{ERM}}}$, where 382 $\gamma \in [0,1]$ controls the mixture ratio and $\mathcal{B}_t^{\text{ERM}} = \{(\boldsymbol{x}_i, \tilde{\boldsymbol{y}}_i^+, \tilde{\boldsymbol{y}}_i^-)\}_{i=1}^b$ consists of preference data labeled by randomly sampled individual ensemble members $r_{\phi_k^t}$. Interestingly, learning from mixed 383 384 preferences further boosts sample efficiency because it utilizes the internal ERM to get pseudo labels 385 instead of querying humans. This relates closely to model-based RL, for which we discuss further 386 in Appendix B. We summarize our practical algorithm (Algorithm 2) in Appendix A. 387

388 5 EXPERIMENTAL SETUP

In this section, we elaborate the experimental setup employed to validate our algorithm and ensure fair comparisons with other online alignment baselines. We start by introducing the distributed learning system designed for experimenting with online LLM alignment using simulated human preferences (Section 5.1). Then, we provide key experimental details in Section 5.2, with a full description available in Appendix D.

3943955.1 DISTRIBUTED LEARNING SYSTEM

396 The interactive nature of LLM alignment necessitates an integrated online learning system that simu-397 lates the interface depicted on the right of Figure 2. The absence of a performant open-source online alignment system has restricted many existing works to only a few iterations of batch learning (Mul-398 drew et al., 2024; Dong et al., 2024; Chen et al., 2024; Zhang et al., 2024a; Xie et al., 2024), which 399 creates a mismatch with their theories that typically require a large number of online interaction 400 rounds. Even worse, such absence also makes the comparison between different LLM exploration 401 methods difficult, often restricting evaluations to the simplest iterative DAP baselines (Zhang et al., 402 2024a; Xie et al., 2024). 403

To fill this gap, we build a highly efficient learning system for exper-404 imenting with online LLM alignment algorithms. We notice that the 405 computational bottleneck lies in online response sampling (i.e., au-406 toregressive generation) and preference labeling (e.g., human, large 407 RMs, or large LLMs), which mirrors the slow actor-environment 408 interaction seen in RL systems. Inspired by distributed deep RL 409 systems which spawn many actors or environments in parallel (Es-410 peholt et al., 2018; Weng et al., 2022), we design an Actor-Learner-411 Oracle architecture for online LLM alignment, which is depicted in 412 Figure 4. The three types of workloads (i.e., actor, learner and ora-413 cle) are heterogeneous and require different optimization. In partic-414 ular, we adopt vLLM (Kwon et al., 2023) for the actor to accelerate the autoregressive response generation. We also use DeepSpeed's 415

Figure 4: The learning system for experimenting online LLM alignment algorithms.

ZeRO (Rasley et al., 2020; Rajbhandari et al., 2020) strategies to enhance the memory efficiency of
 the learner. The updated model weights are broadcasted from the learner master to all actors after
 every optimizer step efficiently via NCCL, similar to Hu et al. (2024). Furthermore, to improve the
 scalability, we wrap the oracle RM as a service using Mosec (Yang et al., 2021b), which supports
 dynamic batching and parallel processing, to minimize preference query latency. Finally, we lever age DeepMind Launchpad (Yang et al., 2021a) to compose all workloads into a distributed program
 and adopt Plasma (Philipp & Robert, 2017) to efficiently transfer data across process boundaries.

We benchmark our system's efficiency against a concurrent implementation of online DPO by HuggingFace⁴, which utilizes only DeepSpeed for memory optimization. Our system achieves up to 2.5 × latency reduction compared to this counterpart, demonstrating its computational efficiency. Due to space constraints, detailed benchmarking methods and results are presented in Appendix F.

5.2 Settings

We adopt SFT models tuned on TL;DR (Stiennon et al., 2020) from Huang et al. (2024), which cover three scales (1B, 2.8B, 6.9B) of the Pythia family (Biderman et al., 2023), as starting points

430 431

427

428

⁴https://huggingface.co/docs/trl/main/en/online_dpo_trainer.

451 Figure 5: Win rate comparison of different algorithms against their initial SFT models across three scales and452 three direct optimizers.

454 for our experiments. We use a strong scalar RM (Liu et al., 2024a)⁵ to simulate the preference 455 oracle. To verify the effectiveness of SEA, we employ three direct optimizers: DPO (Rafailov et al., 456 2023), IPO (Azar et al., 2024), and SLiC (Zhao et al., 2023) to serve as F in Eq. (9). Besides, two 457 LLM exploration methods built on DPO, APL (Muldrew et al., 2024) and XPO (Xie et al., 2024), are fairly compared when using DPO as the optimizer. Our experiments primarily focus on the BAI 458 setting (crowdsourcing labeling), where we report the win rate of learned models against initial 459 SFT models. All experiments are repeated three times to ensure statistical significance. Please see 460 Appendix D for more details. 461

6 EMPIRICAL STUDIES

We next present our empirical studies highlighting four results: (1) Comparisons with baselines across various direct optimizers and model scales demonstrate SEA's superior *sample efficiency* (Section 6.1). (2) Ablations confirm that both *online policy learning* and *active exploration* contribute to sample-efficient alignment, and using the learned ERM for Best-of-N sampling further improves the performance (Section 6.2). (3) Different exploration strategies (Line 5 or Line 6 in Algorithm 1) are verified to work best in respective settings. (4) SEA robustly outperforms baselines when GPT40-mini is used as a judge to simulate human feedback. Results for (3-4) are deferred to Appendices E.1 and E.2 due to space constraints.

471 472 6.1 OVERALL COMPARISON

473 We first compare **SEA** with all baselines across three model scales and three direct optimizers. 474 APL and XPO are only compared when DPO is used as the direct optimizer, because they are incompatible with IPO or SLiC. Figure 5 shows the win rate curves versus the number of query 475 steps. Across all settings, Online agents consistently improve sample efficiency over their Offline 476 counterparts, validating the necessity of Property 1 for alignment algorithms. Focusing on the first 477 row, we observe that among prior active exploration methods, XPO gives a small improvement in 478 final performance over Online (passive) at the 1B scale, but falls short for larger scales. On the 479 other hand, APL shows a significant sample efficiency boost at the 1B scale, but this advantage 480 diminishes when scaling up and it performs almost the same as Online at 6.9B scale. Our method, 481 **SEA**, outperforms both offline and online passive methods across all scales and all direct optimizers, 482 confirming the critical role that Property 2 plays for sample-efficient alignment. Meanwhile, in the 483 special case of using DPO as the direct optimizer, SEA also shows superior performance to prior 484 online active exploration methods including APL and XPO. We invite readers to revisit Figure 1,

 Table 1: Decomposition of different driving factors of online active alignment algorithms.

where we show that **SEA** not only attains significantly improved final performance (Left) but also achieves $2-5 \times$ better sample efficiency (Right).

Additionally, we note that the choice of direct optimizer matters for both online learning and active exploration. When comparing different optimizers at 1B scale (the first column), all Offline agents demonstrate comparable learning efficiency and reach the same level of final performance (around 70% win rate), but SLiC Online agent deliver slightly less improvement than DPO and IPO Online agents. Besides, when incorporating active exploration, the SEA agent using DPO shows much larger improvement than the other two. This suggests that selecting the most suitable policy optimizer coupled with active exploration would yield the best agent.

504 505 6.2 ABLATION ANALYSIS

486

496

497

Next, we decompose SEA into distinct components to evaluate their individual contributions. Table 1 shows the three axes we dissect SEA on, including inference methods, exploration strategies, and learning components. We construct seven agent variants from different combinations, which cover two closely related baselines (Guo et al., 2024; Dwaracherla et al., 2024). We show in Figure 6 the performance curves of each variant, all trained with DPO on 1B scale.

The left plot compares variants that di-511 rectly use the policy for inference. It 512 clearly shows the benefits of learning 513 ERM for active exploration (Variant-2) 514 and aligning π_{θ^t} with \mathcal{R}_{Φ^t} (Variant-3). 515 Since a reward model is learned within 516 the agent, we can further incorporate 517 inference-time alignment via Best-of-N 518 (BoN) sampling (Nakano et al., 2021; 519 Touvron et al., 2023). This also facilitates 520 a direct comparison between SEA and 521 Dwaracherla et al. (2024), which learns a similar ERM for both exploration and 522

Figure 6: Win rate comparison of different agent variants when using (Left) policy and (Right) Best-of-N sampling for inference.

BoN but does not align the LLM policy. Results in the right plot of Figure 6 suggest a similar trend that Variant-6 \succ Variant-5 \succ Variant-4. The Variant-7 (Dwaracherla et al., 2024), however, ceases to improve after ERM converges due to the limited capability of its fixed policy.

7 CONCLUSION

In this paper, we study the problem of LLM alignment through the lens of contextual dueling ban-528 dits and propose a Thompson sampling-based algorithm to achieve sample-efficient alignment. We 529 incorporate three techniques, including epistemic reward model, policy-guided search and mixed 530 preference learning to yield a practically efficient online alignment method. Extensive empirical 531 evaluation demonstrates the superior sample efficiency of our method compared to existing base-532 lines. To our knowledge, this is the first work to study active exploration for online LLM alignment with fully online experimental verification. We hope our positive empirical results, along with the 534 open-sourced codebase, will encourage future research in this direction, ultimately enabling LLMs 535 to achieve superhuman intelligence with an affordable amount of human feedback.

repeat

6:

9:

10:

While Algorithm 1 presents our Thompson sampling algorithm for LLM alignment, it is intractable and centered around the reward posterior modeling. We next present a practical sample-efficient alignment agent that learns both an LLM policy and an epistemic reward model online.

genera1:adddetails

fdaL

// Reward learning

// Policy learning.

Algorithm 2 Sample-efficient alignment (SEA) for LLMs

Input: Reference policy π_{ref} , DAP loss function F, prompt distribution $p_{\mathcal{X}}$, unknown but queryable preference oracle \mathbb{P} , mixture ratio γ . 1: Initialize experience $\mathcal{D}_0 \leftarrow \emptyset$, policy $\pi_{\theta^0} \leftarrow \pi_{ref}$, and ERM weights $\Phi^0 = \{\phi_k^0\}_{k=1}^K$ randomly. 2: for $t = 1, \ldots, T$ do 3: Receive a prompt $x_t \sim p_{\mathcal{X}}$. 4: Sample M responses $y_t^i \sim \pi_{\theta^{t-1}}(\cdot | x_t)$ to construct $\mathcal{S}_t = \{y_t^i\}_{i=1}^M$. 5: Sample $\phi \sim \text{Uniform}(\Phi^{t-1})$ and set $y_t \leftarrow \arg \max_{b \in \mathcal{S}_t} r_{\phi}(x_t, b)$. // Select 1st response y. // E&E objective: aligning an online system.

Sample $\phi \sim \text{Uniform}(\Phi^{t-1})$ and set $y'_t \leftarrow \arg\max_{b \in S_t} r_{\phi}(x_t, b)$. **until** $y'_t \neq y_t$ // Select 2nd response y'. BAI objective: labeling via crowdsourcing. 7: Set $y'_t \leftarrow \arg\max_{b \in S_t} \mathbb{V}_{\phi} [\sigma(r_{\phi}(x_t, y_t) - r_{\phi}(x_t, b))]$, where $\mathbb{V}_{\phi} [\cdot]$ computes variance across ensemble members of Φ^{t-1} . 8: **if** $g < \gamma$ for $g \sim \text{Uniform}(0, 1)$ **then** Label $\{y_t, y'_t\}$ with \mathbb{P} to obtain $\mathcal{B}_t = \{(x_t, y^+_t, y^-_t)\}$ and update experience $\mathcal{D}_t \leftarrow \mathcal{D}_{t-1} \bigcup \mathcal{B}_t$. **else**

 $\Phi^{t} \leftarrow \Phi^{t-1} - \alpha_{\mathcal{R}} \nabla_{\Phi} \mathcal{L}_{\mathcal{R}} (\Phi^{t-1} | \mathcal{D}_{t}).$

 $\theta^t \leftarrow \theta^{t-1} - \alpha_{\pi} \nabla_{\theta} \mathcal{L}_{\pi}(\theta^{t-1} | \mathcal{B}_t, \pi_{\mathrm{ref}}, F).$

Use $\mathcal{R}_{\Phi^{t-1}}$ to get synthetic labels and obtain $\mathcal{B}_t = \{(\boldsymbol{x}_i, \tilde{\boldsymbol{y}}_i^+, \tilde{\boldsymbol{y}}_i^-)\}.$ end if

Update ERM with the regularized NLL loss (Eq. (8)):

Update policy with the direct optimizer (Eq. (9)):

842 In Algorithm 2, we describe an online setting where a single example is processed at each time t (batch size b = 1). This is mainly for notational convenience, while in implementation we set b to be the training batch 843 size (e.g., 128). We instantiate the reward posterior with an epistemic reward model, which allows for efficient 844 incremental update and sampling. We also replace the global optimization ($\arg \max_{b \in \mathcal{Y}}$) with a policy-guided 845 local search among proposals sampled from the latest online policy $\pi_{\theta^{t-1}}$. At each time t, we update ERM 846 weights Φ with m gradient steps with randomly sampled batches from the experience \mathcal{D}_t . We find setting 847 m = 5 suffices to achieve a reasonable accuracy. The policy parameters θ are updated using mixed preference data, with a γ proportion being the real environment experience and the remaining $(1 - \gamma)$ from the ERM's 848 synthetic experience. Note that the synthetic experience is not added into \mathcal{D}_t to ensure reward learning always 849 uses ground truth environment data. 850

851 We consider the following three direct optimizers in our experiments:

• DPO (Rafailov et al., 2023):

$$F_{\theta}(\boldsymbol{x}, \boldsymbol{y}^{+}, \boldsymbol{y}^{-}, \pi_{\mathrm{ref}}) = -\log \sigma \left(\beta \log \frac{\pi_{\theta} \left(\boldsymbol{y}^{+} | \boldsymbol{x}\right) \pi_{\mathrm{ref}} \left(\boldsymbol{y}^{-} | \boldsymbol{x}\right)}{\pi_{\mathrm{ref}} \left(\boldsymbol{y}^{+} | \boldsymbol{x}\right) \pi_{\theta} \left(\boldsymbol{y}^{-} | \boldsymbol{x}\right)}\right)$$
(10)

• IPO (Azar et al., 2024):

$$F_{\theta}(\boldsymbol{x}, \boldsymbol{y}^{+}, \boldsymbol{y}^{-}, \pi_{\mathrm{ref}}) = \left(\log \left(\frac{\pi_{\theta} \left(\boldsymbol{y}^{+} | \boldsymbol{x} \right) \pi_{\mathrm{ref}} \left(\boldsymbol{y}^{-} | \boldsymbol{x} \right)}{\pi_{\mathrm{ref}} \left(\boldsymbol{y}^{+} | \boldsymbol{x} \right) \pi_{\theta} \left(\boldsymbol{y}^{-} | \boldsymbol{x} \right)} \right) - \frac{1}{2\beta} \right)^{2}$$
(11)

• SLiC (Zhao et al., 2023):

$$F_{\theta}(\boldsymbol{x}, \boldsymbol{y}^{+}, \boldsymbol{y}^{-}, \pi_{\mathrm{ref}}) = \max\left(0, 1 - \beta \log \frac{\pi_{\theta}\left(\boldsymbol{y}^{+} | \boldsymbol{x}\right) \pi_{\mathrm{ref}}\left(\boldsymbol{y}^{-} | \boldsymbol{x}\right)}{\pi_{\mathrm{ref}}\left(\boldsymbol{y}^{+} | \boldsymbol{x}\right) \pi_{\theta}\left(\boldsymbol{y}^{-} | \boldsymbol{x}\right)}\right)$$
(12)

where β controls the rate of deviation of π_{θ} from π_{ref} .

864 **ON CONNECTIONS WITH SINGLE-STEP RL** В 865

866 By viewing contextual dueling bandits as single-step preference-based RL (PbRL) (Busa-Fekete et al., 2014; 867 Wirth et al., 2017) problems, we can interpret paradigms shown in Figure 3 from the RL perspective.

868 RLHF approaches (Figure 3a) are instances of offline model-based RL (Kidambi et al., 2020; Yu et al., 2021; fdaL Schrittwieser et al., 2021; Liu et al., 2023; Tajwar et al., 2024), where they learn a reward model (no need for 870 a transition model since the prompt-response interaction is single-step) of the environment from a batch of offline collected data, and train a policy (i.e., LLM) to maximize the return (i.e., expected one-step reward) 871 with respect to the *learned* reward. 872

873 In contrast, DAP methods (Figure 3b) are similar to policy-based model-free RL algorithms, e.g., REIN-FORCE (Williams, 1992) which conducts policy gradient update: 874

880

899

900

901

902

907

908

910 911

912

$$\mathbb{E}_{\boldsymbol{x}\sim\mathcal{X}}\mathbb{E}_{\boldsymbol{y}\sim\pi_{\theta}(\cdot|\boldsymbol{x})}\left[R(\boldsymbol{x},\boldsymbol{y})\nabla_{\theta}\log\pi_{\theta}(\boldsymbol{y}|\boldsymbol{x})\right],\tag{13}$$

876 where R(x, y) is the return (i.e., cumulative reward) of the trajectory. To connect with DAP, we could set R as 877 arbitrary scalar values based on the binary preference outcomes, e.g., $R(x, y^+) = \zeta$ and $R(x, y^-) = -\zeta$ for 878 preference triplet $\{x, y^+, y^-\}$. In this way we could rewrite Eq. (13) as 879

$$\mathbb{E}_{\boldsymbol{x}\sim\mathcal{X}}\mathbb{E}_{\boldsymbol{y},\boldsymbol{y}'\sim\pi_{\theta}}(\cdot|\boldsymbol{x})\mathbb{E}_{(\boldsymbol{y}^{+}\succ\boldsymbol{y}^{-})\sim\mathbb{P}}\left[\zeta\left(\nabla_{\theta}\log\pi_{\theta}(\boldsymbol{y}^{+}|\boldsymbol{x})-\nabla_{\theta}\log\pi_{\theta}(\boldsymbol{y}^{-}|\boldsymbol{x})\right)\right],\tag{14}$$

881 by repeating action sampling twice and querying the oracle for preference labeling. This matches the gradient direction of contrastive DAP losses (e.g., see Section 4 of DPO (Rafailov et al., 2023)) if we optimize them 882 online (Guo et al., 2024). 883

884 Additionally, active reward learning from behavior policy's data distribution (Figure 3c) can be regarded as inverse RL (Ng & Russell, 2000), which tries to recover environment's reward function given expert 885 trajectories. In the context of LLM alignment, the preference data $\{x, y^+, y^-\}_{i=1}^N$ directly encodes human's 886 implicit reward r*, which can be inversely learned with assumptions such as the BT model (Bradley & Terry, 887 1952). However, existing methods belonging to this paradigm mostly rely on a fixed (and suboptimal) behavior policy for response sampling, whose coverage inherently limits the quality of the recovered reward function.

Last but not least, SEA depicted in Figure 3d resembles a class of online model-based RL algorithms, known 890 as Dyna (Sutton, 1990; Janner et al., 2019), that learns a world model from environment experience and 891 trains a base agent (consisting of reactive policies and value functions) from both environment experience and 892 model experience. Compared to model-free methods, Dyna naturally enables more sample-efficient learning 893 by planning with the learned world model to update the base agent. In SEA, we learn the reward model online and update the LLM (i.e., the reactive policy) with model-planing experience by mixed preference learning (Section 4.2.3). Online model-based RL algorithms could suffer from catastrophic forgetting in the 895 face of nonstationary data (Liu et al., 2024b), and we leave it for future work. Overall, this model-based RL 896 formulation is powerful and explains popular LLM techniques, e.g., Best-of-N sampling (Touvron et al., 2023) 897 can be viewed as planning for acting, which trades compute for performance. We believe it is a promising path 898 leading us to unlock superhuman capabilities of LLMs.

С **BASELINE METHODS**

fdaL

We review four baseline methods that are relevant to this work and used for comparisons in our experiments.

903 Offline DAP. We review DPO (Rafailov et al., 2023), which is a representative work in the direction of Direct Alignment from Preferences (DAP). It simplifies the two-stage pipeline of offline RLHF (Figure 2 (Left)) as a 904 single step of supervised learning (Figure 2 (Middle)) by leveraging the closed-form solution (Peters & Schaal, 905 2007; Peng et al., 2019) of the RL objective in Eq. (7): 906

$$\pi_r(\boldsymbol{y}|\boldsymbol{x}) = \frac{1}{Z(\boldsymbol{x})} \pi_{\text{ref}}(\boldsymbol{y}|\boldsymbol{x}) \exp(\frac{1}{\beta}r(\boldsymbol{x},\boldsymbol{y})),$$
(15)

909 where $Z(\mathbf{x})$ normalizes such that $\Sigma_{\mathbf{y}} \pi_r(\mathbf{y}|\mathbf{x}) = 1$, to reparametrize r as a function of π :

$$(\boldsymbol{x}, \boldsymbol{y}) = \beta \log \frac{\pi_r(\boldsymbol{y}|\boldsymbol{x})}{\pi_{\text{ref}}(\boldsymbol{y}|\boldsymbol{x})} + \beta \log Z(\boldsymbol{x}).$$
(16)

Consequently, plugging Eq. (16) into the reward model loss (Eq. (5)) yields a contrastive loss that directly 913 optimizes the policy: 914

915
916
$$\min_{\pi_{\theta}} \mathbb{E}_{(\boldsymbol{x},\boldsymbol{y}^{+},\boldsymbol{y}^{-}) \sim p_{\mathcal{D}}} \left[-\log \sigma \left(\beta \log \frac{\pi_{\theta} \left(\boldsymbol{y}^{+} | \boldsymbol{x} \right) \pi_{\mathrm{ref}} \left(\boldsymbol{y}^{-} | \boldsymbol{x} \right)}{\pi_{\mathrm{ref}} \left(\boldsymbol{y}^{+} | \boldsymbol{x} \right) \pi_{\theta} \left(\boldsymbol{y}^{-} | \boldsymbol{x} \right)} \right) \right],$$
(17)

where \mathcal{D} is a pre-collected offline preference dataset.

947 948 949

958

959

963

964

965

966

971

918 We also experiment different DAP methods⁶ besides DPO, such as IPO (Azar et al., 2024) and SLiC (Zhao 919 et al., 2023), whose loss functions are shown in Eq. (11) and (12).

920 Online DAP (Guo et al., 2024). In contrast to the conventional DAP methods that learn a policy from a 921 fixed dataset \mathcal{D} , online DAP proposes to collect on-policy preference data to update the policy online. It first 922 samples responses from the current policy $(y, y') \sim \pi_{\theta_t}$, then acquires preference labels to form a batch 923 $\mathcal{B}_t = \{(x, y^+, y^-)\}_{i=1}^b$. One gradient step minimizing the DAP loss over this data batch to get $\pi_{\theta_{t+1}}$, which 924 is used for the next iteration. Such approach not only mitigates the over-fitting issue faced by offline DAP methods (Guo et al., 2024), but also facilitates online interaction (Property 1) with the environment, falling into 925 the second paradigm of CDB solution algorithms (Figure 3b). 926

Active Preference Learning (APL) (Muldrew et al., 2024). APL follows the online DAP paradigm, but is 927 restricted to DPO due to its reliance on DPO implicit rewards. Two techniques are proposed by APL to actively 928 select both prompts and dueling responses for querying the preference oracle: 929

- 1. Predictive entropy (PE) for selecting prompts. In this step APL computes a Monte-Carlo estimate of PE for each prompt as $\mathcal{H}_{\pi_{\theta}}(\boldsymbol{y}|\boldsymbol{x}) \approx -\sum_{n=1}^{N} \log \pi_{\theta}(\boldsymbol{y}_n|\boldsymbol{x})/N$, where $\boldsymbol{y}_n \sim \pi_{\theta}(\cdot|\boldsymbol{x})$ and $\log \pi_{\theta}(\boldsymbol{y}_n | \boldsymbol{x})$ is the summation of log probabilities of each token. Then, APL filters a subset of prompts with high PE to form \mathcal{X}_S .
 - 2. Preference model certainty for selecting dueling responses. For prompts in \mathcal{X}_S , APL generates many responses for each prompt, then selects the pair with largest reward margin measured as $|\hat{r}(\boldsymbol{x}_i, \boldsymbol{y}_i) - \boldsymbol{x}_i|$ $\hat{r}(\boldsymbol{x}_i, \boldsymbol{y}'_i)$, where \hat{r} is the DPO implicit reward $\hat{r}(\boldsymbol{x}, \boldsymbol{y}) = \beta(\log \pi_{\theta}(\boldsymbol{y}|\boldsymbol{x}) - \log \pi_{\mathrm{ref}}(\boldsymbol{y}|\boldsymbol{x}))$.

937 By above two steps, APL actively explores more uncertain prompts and responses in an online DPO paradigm, 938 satisfying both Properties 1 and 2.

939 Exploratory Preference Optimization (XPO) (Xie et al., 2024). XPO studies LLM alignment in the frame-940 work of token-level MDP, and leverages the property that DPO conducts implicit Q*-approximation (Rafailov 941 et al., 2024), so that

$$\beta \log \frac{\pi^{\star}(\boldsymbol{y}|\boldsymbol{x})}{\pi_{\mathrm{ref}}(\boldsymbol{y}|\boldsymbol{x})} = r^{\star}(\boldsymbol{x}, \boldsymbol{y}) - V^{\star}(\boldsymbol{x}) \quad \forall \boldsymbol{y},$$
(18)

944 where V^* is the optimal value function depending only on the prompt x. XPO incorporates the *implicit* (global) optimism for exploration by overestimating the value $V_{\pi_{\theta}}(\boldsymbol{x}) = r^{\star}(\boldsymbol{x}, \boldsymbol{y}) - \beta \log \frac{\pi_{\theta}(\boldsymbol{y}|\boldsymbol{x})}{\pi_{\text{ref}}(\boldsymbol{y}|\boldsymbol{x})}$. This is achieved 945 946 by optimizing the policy with a modified DPO loss:

$$\min_{\pi_{\theta}} \mathbb{E}_{(\boldsymbol{x},\boldsymbol{y}^{+},\boldsymbol{y}^{-},\boldsymbol{y}^{\mathrm{ref}}) \sim p_{\mathcal{B}^{t}}} \left[\alpha \log \pi_{\theta}(\boldsymbol{y}^{\mathrm{ref}} | \boldsymbol{x}) - \log \sigma \left(\beta \log \frac{\pi_{\theta}(\boldsymbol{y}^{+} | \boldsymbol{x}) \pi_{\mathrm{ref}}(\boldsymbol{y}^{-} | \boldsymbol{x})}{\pi_{\mathrm{ref}}(\boldsymbol{y}^{+} | \boldsymbol{x}) \pi_{\theta}(\boldsymbol{y}^{-} | \boldsymbol{x})} \right) \right], \quad (19)$$

950 where $y^{\text{ref}} \sim \pi_{\text{ref}}(\cdot | x)$ and \mathcal{B}^t is an on-policy data batch in the same vein as online DPO. Intuitively, the 951 first term in Eq. (19) biases the policy toward a large value estimation such that $V_{\pi_{\theta}} \gtrsim V^{\star}$, implementing 952 the optimism in the face of uncertainty (OFU) for exploration. Theoretically, Xie et al. (2024) also prove the sample complexity bound of XPO, making it a promising algorithm for online LLM alignment. 953

954 Self-exploring language model (SELM) (Zhang et al., 2024a) is a concurrent work of Xie et al. (2024) that 955 proposes nearly the same theoretic algorithm to achieve OFU. However, the practical implementation of SELM cF2f involves offline preference dataset for training, making it hard to benchmark in an online alignment setting like 956 ours. Therefore, we will keep XPO as our baseline while omitting the comparison with SELM. 957

D FULL EXPERIMENTAL DETAILS

960 In the main text we focus on the task of summarization using the TL;DR dataset. This provides a lightweight 961 and clean setting to extensively study different algorithmic designs with affordable computational resources. 962 Appendix D.1 provides the full details of this setting.

To further validate the sample efficiency of **SEA** in aligning LLMs to perform general tasks, we adopt the UltraFeedback dataset (Cui et al., 2023) and evaluate trained LLMs on AlpacaEval 2.0 (Li et al., 2023). Appendix D.2 provides more details of this setting.

D.1 DETAILS OF TL; DR TASK 967

968 Models. We experiment three model scales (1B, 2.8B, 6.9B) from the Pythia family (Biderman et al., 2023). 969 We take pretrained SFT models from Huang et al. (2024) as π_{ref} for the starting model in all experiments. 970 Except in Section 6.1, we use 1B model for other experiments to save computation.

z8J2

⁶We use "DAP method" and "direct optimizer" interchangeably.

972 Preference oracle. We simulate the process of human feedback with a strong scalar RM and refer it as preference oracle. We choose Skywork-Reward-Llama-3.1-8B⁷ (Liu et al., 2024a), which is top-ranked in RewardBench leaderboard (Lambert et al., 2024), as the preference oracle.

Epistemic reward model. We build ERM on top of a pretrained 0.4B transformer (Jiang et al., 2023), by removing its head and adding an ensemble of MLPs. The size of ensemble is set to K = 20, and all MLPs contain 2 hidden layers of 128 nodes. Note that the ERM is chosen to be much smaller than the preference oracle following Dwaracherla et al. (2024), which reflects the fact that human preferences can be more complex than what the agent can model. The regularization coefficient λ is fixed to be 0.5 after a coarse hyperparameter search.

Data. We employ the widely adopted TL; DR dataset (Stiennon et al., 2020) for our experiments. It consists of
 Reddit posts as prompts, and the agent is required to give summaries that align with human preferences. We fix
 50k prompts for training and limit the query budget to 50k as well.

DAP methods. We adopt three DAP methods (direct optimizers) to thoroughly validate our algorithm, including DPO (Rafailov et al., 2023), IPO (Azar et al., 2024) and SLiC (Zhao et al., 2023). Except in Section 6.1, all experiments are done with DPO as the direct optimizer.

fdaL

Baselines. Similar to Guo et al. (2024), we include the offline and online variants of different DAP methods as
baselines. Additionally, we compare with two active exploration baselines built on online DPO: APL (Muldrew et al., 2024) and XPO (Xie et al., 2024). A detailed review of all baselines can be found in Appendix C.

989 **Metrics.** We use the win rate of agent's responses against reference responses judged by the preference oracle as the performance metric. This metric can reflect both the agent's cumulative regret and anytime regret (i.e., av-990 erage performance). In the E&E setting, we measure the "online" win rate of the agent's dueling responses that 991 are executed during experience collection and take the average. In the BAI setting, we measure the "offline" win 992 rate by evaluating the latest agent's responses given a fixed set of 1000 holdout prompts periodically. We mainly 993 focus on the BAI setting because crowdsourcing seems a major scenario for most practitioners, and present one 994 set of experiments for comparing different exploration strategies in both settings. When the comparison is only made within a model scale, we report the relative win rate against the initial STF models. When the comparison 995 is across scales (Figure 1 Left), we report the absolute win rate against the ground truth responses in the dataset. 996

997 Hyperparameters. We set $\beta = 0.1$ for DPO and $\beta = 0.2$ for SLiC and find they are robust for all scales. **998** We tune β from {0.2, 0.3, 0.5, 1.0} for IPO across scales and report the best performing results. We sample **999** M = 20 on-policy responses with a temperature $\eta = 0.7$ during training, and use greedy decoding for offline evaluation (BAI's metric). We use the Adam optimizer with learning rate of 5×10^{-7} and cosine scheduling, and set the batch size to be 128. We initialize the mixture ratio γ of **SEA** to be 1 and adjust it to 0.7 after a burn-in period of 1k samples.

1002 All hyperparameters are kept the same for offline and online baselines, except that online methods update the 1003 sampling policy after every gradient step as the latest π_{θ_t} . For APL and XPO, we keep the learning rate and 1004 DPO's β the same for apple-to-apple comparisons. Specifically for APL, we initially sample 1024 prompts per batch and use the predictive entropy to filter a subset of 128 prompts. Then, we sample 8 responses per prompt and use the preference model certainty to finalize two responses for the duel. Specifically for XPO, we follow the their recommended optimism coefficient to set $\alpha = 5 \times 10^{-6}$.

Statistical significance. There are various factors to introduce randomness during online learning. We thus
 launch 3 independent runs for every experiment with different random seeds. All the results are reported with
 mean and standard error to indicate their statistical significance.

Computational resources. Experiments at all scales are conducted on a single machine with 8 A100 GPUs to run the learner and actors. We additionally host a separate remote server with workers spawned on 16 A100 GPUs for the oracle RM⁸, so that it can be queried by all concurrently running experiments. All experiments conducted for this research consume about 2 A100 GPU years.

1015 D.2 DETAILS OF GENERAL TASKS

z8J2,RtS4,fdaL

1017 Model. Following Meng et al. (2024); Zhang et al. (2024a), we employ Llama3-8B-Instruct⁹ as our initial model π_{ref} .

Preference oracle. We follow Meng et al. (2024) to adopt ArmoRM-Llama3-8B-v0.1¹⁰ (Wang et al., 2024) as the preference oracle to provide online preference feedback.

1021

1014

Figure 7: (Left and Middle) Win rate comparison of different exploration strategies measured in E&E and BAI settings. (Right) Win rate comparison of different agents when using GPT4o-mini to simulate human feedback via LLM-as-a-judge.

Data. We take the UltraFeedback dataset (Cui et al., 2023), which is widely used for LLM alignment in the literature. We filter out samples whose prompt is longer than 1800 tokens and result in 61k samples. We extract prompts from the filtered dataset while excluding the responses. The prompt set are collected from multiple sources and cover diverse domains, making it suitable to improve LLM's capability on general tasks.

1043 DAP method and baselines. We employ the state-of-the-art DAP method, SimPO (Meng et al., 2024), as our direct optimizer. Since SimPO is originally an offline algorithm, we extend it to Online SimPO and take both offline and online variants as baselines.

Evaluation. We evaluate SEA and baselines using AlpacaEval 2.0 (Li et al., 2023). It consists of 805 test prompts, and uses GPT4-Turbo to judge the quality of model responses against reference responses generated by GPT-4-Turbo. We follow the standard protocol to report both the win rate (WR) and the Length-Controlled win rate (LC) (Dubois et al., 2024).

Hyperparameters. We follow SimPO's recommended hyperparameters to set $\beta = 10$ and $\gamma/\beta = 0.3$. We use a learning rate of 8×10^{-7} and batch size of 128. The decoding temperature is set to be 0.9 for generating evaluation outputs. The same hyperparameters apply to baselines and our method. Configurations of **SEA** are kept the same as those in the TL; DR task (Appendix D.1).

1054 E EXTENDED EMPIRICAL STUDIES

1055

We present additional empirical studies in this section, including investigation on different exploration strate gies (Appendix E.1) and preference oracles (Appendix E.2) on the TL;DR task, as well as the performance comparison on AlpacaEval 2.0 for general tasks (Appendix E.3).

1059 E.1 CHOICE OF EXPLORATION STRATEGIES 1060

1061 Recalling that different LLM alignment scenarios (online system or crowdsourcing) require different exploration strategies to meet their respective learning objectives (Section 2.2). We investigate three strategies based 1062 on posterior sampling and compare them on both online and offline performance. The first strategy (Uncer-1063 tainty) focuses on pure exploration with information maximization. It seeks the pair of dueling responses that 1064 exhibits the largest epistemic uncertainty, which is implemented by selecting the pair whose logits difference has the largest variance across ensemble members. The second (E&E-TS) and the third (BAI-TS) strategies 1066 follow the principles in Algorithm 1, and their differences are between Line 5 and Line 6. The comparison results are shown in Figure 7 (Left and Middle). Focusing on the left plot, we observe that E&E-TS strategy 1067 achieves the best online performance, which is within our expectation. In contrast, Uncertainty shows the 1068 worst online performance because it tries to maximize the information gain but does not prioritize reward 1069 maximization. On the other hand, conclusions are interestingly different when taking the offline performance as 1070 the metric. In this case, BAI-TS and Uncertainty both exhibit more efficient offline performance improvement 1071 than E&E-TS. This can be attributed to that exploration for uncertainty minimizing helps to identify more informative responses to train the LLM policy. Moreover, BAI-TS > Uncertainty indicates exploration with 1072 both reward and information maximization is better than exploration with only information maximization. 1073 E&E-TS, however, always chooses two responses with similarly high quality to exploit. This can not only lead 1074 to less efficient exploration, but also result in less efficient policy learning due to smaller DAP loss gradients. 1075

1076 E.2 ALIGNING LLMS WITH A HUMAN SIMULATOR

Results presented so far are based on experimenting LLM alignment with the preference oracle being a scalar reward model, which is deterministic and does not capture the potential randomness of the choice by real humans. To test different agents in a more realistic setting, we use generative models as human simulator in an LLM-as-a-judge (Bubeck et al., 2023; Zheng et al., 2023) manner. In particular, we directly query the OpenAI

1093 API and use gpt-4o-mini-2024-07-18 as the judge to provide preference feedback. We use a similar prompt template to Li et al. (2023)'s, which is shown in Figure 11. We also randomly swap the order of two responses 1094 to mitigate the known position bias of LLM judges. The results are shown in Figure 7 (Right). We can observe 1095 the performance curves generally exhibit higher variance, possibly due to the randomness introduced in the 1096 feedback process, which puts more stringent requirements for learning algorithms. The two active exploration 1097 methods demonstrate opposite results to those in Section 6.1—APL learns fast initially but is eventually out-1098 performed by Online, while XPO improves over Online after stabilizing its training and delivers a better final performance. Our agent, SEA, is shown to offer the best sample efficiency as well as asymptotic performance, 1099 further validating the importance of online learning and well-designed active exploration mechanism. 1100

1101 E.3 PERFORMANCE ON GENERAL TASKS

1103 We investigate the generalizability of **SEA** by training with the prompt set from UltraFeedback (Cui et al., 1104 2023) and evaluating the model performance on AlpacaEval 2.0 (Li et al., 2023). Figure 8 shows the Length-Controlled (LC) win rate of different models against GPT-4-Turbo. The left plot compares the sample efficiency 1105 (in terms of the number of queries) of offline, online and SEA SimPO. The results suggest that enabling online 1106 interaction does not improve the sample efficiency over the offline counterpart. Such observation is in stark 1107 contrast to what we have seen in the TL; DR task, where the online agent always improves over the offline ones. 1108 We hypothesize that this is due to the different coverage of π_{ref} in these two tasks. For TL;DR, which is a 1109 much easier task, the initial SFT models already have good coverage, permitting online DAP with only passive exploration to work reasonably well; however, for more challenging tasks, the insufficient coverage of $\pi_{\rm ref}$ 1110 would lead to sample complexity exponential in $\frac{1}{\beta}$ (Xie et al., 2024), which necessitates *deliberate exploration*, 1111 such as Thompson sampling proposed in this work. The above claim is justified by observing that SEA largely 1112 improves the sample efficiency over the online and offline variants. 1113

Attentive readers may have noticed that comparing query budget could be advantageous to **SEA** because pseudo labels are used in mixed preference learning (Section 4.2.3), which results in more gradient steps given the same query budget. In the right plot of Figure 8, we show the performance versus gradient step. We can observe **SEA** has the steepest learning curve, verifying that it explores more informative samples to yield faster improvement.

Last but not least, in Table 2, we show the AlpacaEval 2.0 LC win rates of XPO and SELM (as reported in their papers), along with ours and several cutting-edge LLMs. SEA is agnostic to direct optimizers, thus it can leverage the state-of-the-art SimPO to achieve a high LC of 47.4%. On the other hand, XPO and SELM can only be applied to DPO, restricting their potential to incorporate future advances in direct optimization algorithms.

- 1122
- 1123 F SYSTEM BENCHMARKING
- 1124

We conduct a rigorous benchmarking comparison on the efficiency of online DPO training using our learning system, alongside the trl's implementation¹¹.

Settings. In alignment with the examples provided by tr1, we use the TL;DR (Stiennon et al., 2020) dataset and evaluate training efficiency at three model scales: 1B, 2.8B and 6.9B parameters for both SFT-ed LLMs¹²

is recommended for synchronization over GLOO, it requires older vLLM packages (prior to version 0.4.3),
which may lack support for newer LLM architectures. Moreover, NCCL is incompatible with config 1 due to
its restriction on the learner master process establishing two separate process groups (one for DeepSpeed, the
other for weight synchronization). In summary, we recommend future researchers prioritize the config 2 and
employ NCCL when feasible.

G SUPPLEMENTARY MATERIALS

In this section, we include a comparison of prior works (Table 3), the prompt template we use for LLM-as-a-judge (Figure 11), and an example showing ChatGPT actively explores (Figure 7).

LLM-as-a-Judge Prompt Template I require a leaderboard for various large language models. I'll provide you with prompts given to these models and their corresponding outputs. Your task is to assess these responses, and select the model that produces the best output from a human perspective. ## Instruction {instruction} ## Model Outputs Here are the unordered outputs from the models. Each output is associated with a specific model, identified by a unique model identifier. "model_identifier: "0", "output": {response0} "model_identifier: "1", "output": {response1} ## Task Evaluate the models on the basis of the quality and relevance of their results, and select the model that generated the best result. Reply with the identifier of the best model. Our evaluation will only take into account the first character of your answer, so make sure it contains only one of the identifiers and nothing else (no quotation marks, no spaces, no new lines, ...). Figure 11: We provide the prompt with two responses and ask GPT to choose the preferred one. We parse the first token's logits of "0" and "1" and apply the BT model to obtain the relative preference.
