Visual Chain-of-Thought Diffusion Models

William Harvey 1  Frank Wood 1

Abstract
Recent progress with conditional image diffusion models has been stunning, and this holds true whether we are speaking about models conditioned on a text description, a scene layout, or a sketch. Unconditional image diffusion models are also improving but lag behind, as do diffusion models which are conditioned on lower-dimensional features like class labels. We propose to close the gap between conditional and unconditional models using a two-stage sampling procedure. In the first stage we sample an embedding describing the semantic content of the image. In the second stage we sample the image conditioned on this embedding and then discard the embedding. Doing so lets us leverage the power of conditional diffusion models on the unconditional generation task, which we show improves FID by 25−50% compared to standard unconditional generation.

1. Introduction
Recent text-to-image diffusion generative models (DGMs) have exhibited stunning sample quality (Saharia et al., 2022) to the point that they are now being used to create art (Oppenlaender, 2022). Further work has explored conditioning on scene layouts (Zhang & Agrawala, 2023), segmentation masks (Zhang & Agrawala, 2023; Hu et al., 2022), or the appearance of a particular object (Ma et al., 2023). We broadly lump these methods together as “conditional” DGMs to contrast them with “unconditional” image DGMs which sample an image without dependence on text or any other information. Relative to unconditional DGMs, conditional DGMs typically produce more realistic samples (Ho & Salimans, 2022; Bao et al., 2022; Hu et al., 2022) and work better with few sampling steps (Meng et al., 2022). Furthermore our results suggest that sample realism grows with "how much" information the DGM is conditioned on: as hinted at in Figure 1 an image is likely to be more realistic if conditioned on being “an aerial photograph of a road between green fields” than if it is if simply conditioned on being “an aerial photograph.” This gap in performance is problematic. Imagine trying to generate a dataset of synthetic aerial photos for testing a computer vision system. A researcher doing so would currently have to either (a) make up a scene description before generating each dataset image, and ensure these cover the entirety of the desired distribution, or (b) accept the inferior image quality gleaned by conditioning just on each image being “an aerial photograph”.

To close this gap, we take inspiration from “chain of thought” reasoning (Wei et al., 2022) in large language models (LLMs). Consider using an LLM to answer a puzzle: Roger has 5 tennis balls. He buys 2 more cans of tennis balls. Each can has 3 tennis balls. How many tennis balls does he have now? If the LLM is prompted to directly state the answer, it must perform all reasoning and computation in a single step. If instead it is prompted to explain its reasoning as it computes an answer, it can first conclude that the answer is given by the expression $5 + 2 \times 3$, and then output an answer conditioned on it arising from such an expression. Printing this expression in an intermediate step dramatically improves accuracy (Wei et al., 2022).

2We used the prompt “Aerial photography of a patchwork of small green fields separated by brown dirt tracks between them. A large tarmac road passes through the scene from left to right.”
Let us imagine an image generative model along these lines. When prompted to sample "an aerial photograph", it may start by sampling a more detailed description: "an aerial photograph of a patchwork of small green fields [...]". Given this detailed description, it can leverage the full power of a conditional DGM to generate a high-quality image. Our approach follows these lines but, instead of operating on language, our intermediate space consists of a semantically-meaningful embedding from a pretrained CLIP embedder (Radford et al., 2021). Specifically we train a DGM to model the distribution of CLIP embeddings of images in our dataset. From this we achieve improved unconditional image generation by first sampling a CLIP embedding and then feeding this CLIP embedding into a conditional image DGM. Note that, while this technique is related to text-conditional image generation, we are instead applying it to improved unconditional image generation. We call the resulting model a Visual Chain-of-Thought Diffusion Model (VCDM) and release code at https://github.com/plai-group/vcdm.

3. Conditional vs. unconditional DGMs

What does it mean to say that conditional DGMs beat unconditional DGMs? A standard procedure to evaluate unconditional DGMs is to start by sampling a set of $N$ images independently from the model: $x^{(1)}, \ldots, x^{(N)} \sim p_{\theta}(\cdot)$. We can then compute the Fréchet Inception distance (FID) (Heusel et al., 2017) between this set and the dataset.

If the generative model matches the data distribution well, the FID will be low. For conditional DGMs the standard procedure has one extra step: we first independently sample $y^{(1)}, \ldots, y^{(N)} \sim p_{\text{data}}(\cdot)$. Then, as in the unconditional case, we compute the FID between the set of images $x_1, \ldots, x_N$ and the dataset, without reference to $y_1, \ldots, y_N$. Even though it does not measure alignment between $x, y$ pairs, conditional DGMs beat comparable unconditional DGMs on this metric in many settings: class-conditional CIFAR-10 generation (Karras et al., 2022), segmentation-conditional generation (Hu et al., 2022), or bounding box-conditional generation (Hu et al., 2022).

**Why do conditional DGMs beat unconditional DGMs?**

Conditional DGMS “see” more data during training than their unconditional counterparts because updates involve

---

**Figure 2.** CLIP-conditional samples on AFHQ/FFHQ. Each row shows three samples conditioned on the same CLIP embedding.

**Figure 3.** FID versus dimensionality of $y$ on AFHQ (Choi et al., 2020) and FFHQ (Karras et al., 2018). With small training budgets (brown), it is harmful when $y$ is too informative. With larger training budgets (purple), it is helpful to make $y$ high dimensional.
We have established that conditioning on CLIP embeddings improves DGMs. We now introduce VCDM which leverages this phenomenon to benefit the unconditional setting (in which the user does not wish to specify any input to condition on) and the “lightly-conditional” setting in which the input is low-dimensional, e.g. a class-label. We will denote any such additional input $a$ (letting $a$ be a null variable in the unconditional setting) and from now on always use $y := e_i(x)$ to refer to a CLIP embedding. VCDM approximates the target distribution $p_{data}(x|a)$ as

$$p_{data}(x|a) = \mathbb{E}_{p_{data}(y|a)}[p_{data}(x|y,a)]$$  \hspace{1cm} (2)

$$\approx \mathbb{E}_{p_y(y|a)}[p_{\phi}(x|y,a)]$$  \hspace{1cm} (3)

where $p_y(y|a)$ is a second DGM modeling the CLIP embeddings. We can sample from this distribution by sampling $y \sim p_y(y|a)$ and then leveraging the conditional image DGM to sample $x \sim p_\phi(x|y,a)$ before discarding $y$. From now on we will call $p_\phi(x|y,a)$ the conditional image model and $p_y(y|a)$ the auxiliary model. In our experiments the auxiliary model uses a small architecture relative to the conditional image model and so adds little extra cost.\(^\text{3}\)

**Auxiliary model** Our auxiliary model is a conditional DGM targeting $p_{data}(y|a)$, where $y$ is a 512-dimensional CLIP embedding. We follow the architectural choice of Ramesh et al. (2022) and use a DGM with a transformer architecture. It takes as input a series of 512-dimensional input tokens: an embedding of $\sigma$; an embedding of $a$ if this is not null; an embedding of $a_{y_1}$; and a learned query. These are passed through six transformer layers and then the output corresponding to the learned query token is used as the output. Like Ramesh et al. (2022), we parameterize the DGM to output an estimate of the denoised a instead of estimating the added noise as is more common in the diffusion literature. On AFHQ and FFHQ we find that data augmentation is helpful to prevent the auxiliary model overfitting. We perform augmentations (including rotation, flipping and color jitter) in image space and feed the augmented image through $c_i(\cdot)$ to obtain an augmented CLIP embedding. Following Karras et al. (2022), we pass a label describing the augmentation into the transformer as an additional input token so that we can condition on there being no augmentation at test-time.

**Conditional image model** Our diffusion process hyperparameters and samplers build on those of Karras et al. (2022). For AFHQ and FFHQ, we use the U-Net architecture originally proposed by Song et al. (2020). For ImageNet, we use the slightly larger U-Net architecture proposed by Dhariwal & Nichol (2021). We match the data augmentation scheme to be the same as that of Karras et al. (2022) on each dataset. There are established conditional variants of both archite-
tures (Dhariwal & Nichol, 2021; Karras et al., 2022), which incorporate y via a learned linear projection that is added to the embedding of the noise standard deviation σ. Our conditional image model needs to additionally incorporate a; we can do so by simply concatenating it to y and learning a projection for the resulting vector.

5. Experiments

We experiment on three datasets: AFHQ (Choi et al., 2020), FFHQ (Karras et al., 2018) and ImageNet (Deng et al., 2009), all at 64 × 64 resolution. We target unconditional generation for AFHQ and FFHQ, and class-conditional generation for ImageNet. As well as training networks from scratch on each dataset, we report results with the model checkpoints released by Karras et al. (2022) on AFHQ and FFHQ, which we finetune to be conditional on the CLIP embedding. To do so, we simply add a learnable linear projection of the CLIP embedding and initialize its weights to zero. Figure 4 reports the FID on each setting and dataset throughout the training of the conditional image model.4 In each case, the auxiliary model is trained for one day on one V100 GPU. We compare VCDM to three other approaches: EDM (Karras et al., 2018) is a standard DGM directly modeling pdata(x|a). VCDM with oracle uses our conditional image model but uses the ground-truth y for each test instead of sampling from the learned auxiliary model, i.e. it is the performance that VCDM would achieve with a perfect auxiliary model. Class-cond is an ablation that applies to unconditional tasks where a is null. It uses discrete y (as on the right of Figure 3) so that pdata(y|a) = pdata(y) is a simple categorical distribution which we can sample from exactly, but is outperformed by VCDM.

VCDM consistently outperforms unconditional generation after 1-2 GPU-days and this performance gap continues for as long as we train the networks. Comparing VCDM’s performance with and without the oracle we see that they are close. For networks trained from scratch we show in Section 5 that VCDM always has an improvement over EDM at least 80% as large as that of VCDM with an oracle, indicating that p0(y|a) is a good approximation of pdata(y|a). We can therefore leverage almost the full power of conditional DGMs for unconditional sampling.

6. Related work

Several existing image generative models leverage CLIP embeddings for better text-conditional generation (Nichol et al., 2021; Ramesh et al., 2022). We differ by suggesting that CLIP embeddings are not only useful for text-conditioning, but also as a general tool to improve the realism of generated images. We demonstrate this for unconditional and class-conditional generation. Our work takes inspiration from Weilbach et al. (2022), who show improved performance in various approximate inference settings by modeling problem-specific auxiliary variables (like y) in addition to the variables of interest (x) and observed variables (a). We apply these techniques to the image domain and incorporate pretrained CLIP embedders to obtain auxiliary variables. VCDM also relates to methods which perform diffusion in a learned latent space (Rombach et al., 2022): our auxiliary model p0(y|a) is analogous to a “prior” in a latent space and our conditional image model p0(x|a,y) to a “decoder". Such methods typically use a near-deterministic decoder and so their latent variables must summarize all information about the image. Our conditional DGM decoder on the other hand will function reasonably however little information is stored in y and so VCDM provides an additional degree of freedom in terms of what to store. This is an interesting design space for future exploration. Classifier (Song et al., 2020) and classifier-free guidance (Ho & Salimans, 2022) are two alternative methods for conditional sampling from DGMs. Both have a “guidance strength” hyperparameter to trade fidelity to pdata(x|y) against measures of alignment between x and y. A possible extension to VCDM could parameterize p0(x|y, a) with either of them.

7. Discussion and conclusion

We have presented VCDM, a method for unconditional or lightly-conditional image generation which harnesses the impressive performance of conditional DGMs. A massive unexplored design space remains: there are almost certainly more useful quantities that we could condition on than CLIP embeddings. It may also help to condition on multiple quantities, or “chain” a series of conditional DGMs together. An alternative direction is to simplify VCDM’s architecture by, for example, learning a single diffusion model over the joint space of x and y instead of generating them sequentially.

---

4 Each FID is estimated using 20,000 images, each sampled with the SDE solver proposed by Karras et al. (2022) using 40 steps, Strue = 50, Snoise = 1.007, and other parameters set to their default values.
