## ABSTRACT

027  
028 Classification of electroencephalogram (EEG) and electrocorticogram (ECoG)  
029 signals obtained during motor imagery (MI) has substantial application potential,  
030 including for communication assistance and rehabilitation support for patients with  
031 motor impairments. These signals remain inherently susceptible to physiologi-  
032 cal artifacts (e.g., eye blinking, swallowing), which pose persistent challenges.  
033 Although Transformer-based approaches for classifying EEG and ECoG signals  
034 have been widely adopted, they often struggle to capture fine-grained depen-  
035 dencies within them. To overcome these limitations, we propose Cortical-SSM, a  
036 novel architecture that extends deep state space models to capture integrated de-  
037 pendencies of EEG and ECoG signals across temporal, spatial, and frequency  
038 domains. We validated our method across three benchmarks: 1) two large-scale  
039 public MI EEG datasets containing more than 50 subjects, and 2) a clinical MI  
040 ECoG dataset recorded from a patient with amyotrophic lateral sclerosis. Our  
041 method outperformed baseline methods on the three benchmarks. Furthermore,  
042 visual explanations derived from our model indicate that it effectively captures  
043 neurophysiologically relevant regions of both EEG and ECoG signals. Our project  
044 page is available at <https://cortical-ssm-u90sg.kinsta.page/>  
045

046 Figure 1: Task overview. The input is EEG or ECoG signals recorded while the subject imagines  
047 actions (e.g., elbow extension), and the model’s output are predictions of the corresponding actions.  
048 The model also provides explicit interpretability across temporal, spatial, and frequency domains.  
049

## 1 INTRODUCTION

050 Brain-Computer Interfaces (BCIs) hold transformative potential across various domains, including  
051 the diagnosis of neurodegenerative diseases, advanced brain function mapping, robotic control, and  
052 the development of immersive gaming devices (Wolpaw, 2013; Hramov et al., 2021). Among the  
053 various BCI paradigms, motor imagery (MI) BCIs decode intentionally modulated neural activity  
054 resulting from conscious cognitive effort, making them especially promising for developing assistive  
055 communication systems and neurorehabilitation protocols for patients with severe motor impair-  
056 ments (Hramov et al., 2021). Furthermore, BCI implementations leverage various techniques for  
057 recording brain activity, including electroencephalography (EEG), electrocorticography (ECoG),  
058 functional magnetic resonance imaging, and functional near-infrared spectroscopy (Ramadan &  
059 Vasilakos, 2017). Among these modalities, BCIs based on EEG and ECoG are particularly promising  
060 for real-world applications because of their high temporal resolution and superior portability.

061 In this study, we focus on brain activity occurring during motor imagery (MI) and tackle a classifica-  
062 tion task for imagined actions using both EEG and ECoG signals. Figure 1 presents a representative  
063 example of the task. In this case, the input comprises EEG and ECoG signals recorded while the

054 subject imagines an elbow extension. As its response, the model outputs predicted probabilities for  
 055 each corresponding actions. Despite intensive research, the accurate decoding of MI EEG and ECoG  
 056 signals is still non-trivial. For instance, binary classification task using MI EEG signals from the  
 057 OpenBMI (Lee et al., 2019) dataset, a representative model (e.g., Lawhern et al. (2018)), demonstrates  
 058 an error rate of approximately 22%.

059 Recent approaches have used Transformers to capture subject-agnostic dependencies in EEG and  
 060 ECoG signals (Song et al., 2022; Wang et al., 2024a;d). However, to address the exponential growth  
 061 in computational cost associated with longer time series, these methods patchify and compress the  
 062 input EEG or ECoG signals along the temporal dimension, which may result in fine-grained temporal  
 063 dependencies being lost. Moreover, while these approaches offer interpretability in spatio-temporal  
 064 domains, they do not directly provide insights into the frequency domain, leaving the contributions of  
 065 neurophysiologically significant frequency bands (e.g., mu band (Pfurtscheller et al., 2006)) unclear.  
 066 Therefore, we propose Cortical-SSM, an extension of Deep SSM that captures integrated EEG  
 067 and ECoG dependencies across temporal, spatial, and frequency domains. This design enables the  
 068 modeling of temporal dependencies in EEG and ECoG signals without compressing them. Moreover,  
 069 it provides direct visual explanations in each of the time, spatial, and frequency domains.

070 In Cortical-SSM, we extend a deep state space model (Deep SSM (Gu et al., 2022; Smith et al., 2023;  
 071 Gu & Dao, 2024))—an architecture offering superior computational efficiency than Transformers  
 072 for long sequence modeling—to effectively capture multi-scale temporal dependencies in EEG and  
 073 ECoG signals. Specifically, we introduce the Frequency-SSM module, which extracts spatio-temporal  
 074 dependencies for each frequency component, and the Channel-SSM module, which captures temporal-  
 075 frequency dependencies for each electrode. Furthermore, we introduce a Wavelet-Convolution  
 076 module integrating both deterministic and adaptive frequency features for feature extraction from the  
 077 frequency-domain. The Frequency-SSM and Channel-SSM modules model temporal dependencies  
 078 in EEG and ECoG signals without requiring the patchification employed in prior studies, thereby  
 079 facilitating the capture of fine-grained temporal variations. Moreover, by incorporating the Wavelet-  
 080 Convolution, Cortical-SSM extracts frequency-analyzable features while simultaneously learning  
 081 their representations. Frequency-SSM and Channel-SSM modules explicitly model frequency-wise  
 082 and electrode-wise features derived from the Wavelet-Convolution module, enabling direct visual  
 083 explanations across temporal, spatial, and frequency domains.

084 Our main contributions lie in the following aspects:

- 085 • We propose Cortical-SSM, an extension of Deep SSM that captures integrated EEG and  
 086 ECoG dependencies across temporal, spatial, and frequency domains.
- 087 • For frequency-domain feature extraction, we introduce Wavelet-Convolution, which inte-  
 088 grates deterministically obtained frequency components with adaptively derived frequency  
 089 features. This approach enables the extraction of interpretable features while preserving  
 090 their learnable representations.

## 092 2 RELATED WORK

094 EEG and ECoG decoding methods have been extensively studied, as reviewed in (Abibullaev et al.,  
 095 2023; Altaheri et al., 2023). Additionally, diverse predictive methods for multivariate time series  
 096 signals have been systematically summarized in (Lara-Benítez et al., 2021; Liang et al., 2024).  
 097 Furthermore, deep state space models (Deep SSMs) have emerged as a promising architecture for  
 098 sequence modeling, with recent advances comprehensively documented in (Patro & Agneeswaran,  
 099 2024; Wang et al., 2024c).

100 **EEG and ECoG decoding.** Deep-learning based methods for decoding EEG and ECoG signals  
 101 have been extensively investigated (Wang et al., 2024a; Song et al., 2022), and they demonstrate  
 102 considerable potential for enhancing communication and rehabilitation in patients with physical  
 103 paralysis (Abibullaev et al., 2023; Altaheri et al., 2023). Early attempts rely on convolutional  
 104 architectures (Lawhern et al., 2018; Mane et al., 2021). Nonetheless, the limited receptive field of  
 105 convolutional layers has motivated the exploration of Transformer-based approaches (Song et al.,  
 106 2022; Miao et al., 2023; Jiang et al., 2024; Wang et al., 2024d) to model temporal dependencies in EEG  
 107 and ECoG signals. Medformer (Wang et al., 2024d), for instance, segments input signals into patches  
 108 of varying temporal lengths and then feeds these patches into a Transformer. These Transformer-based

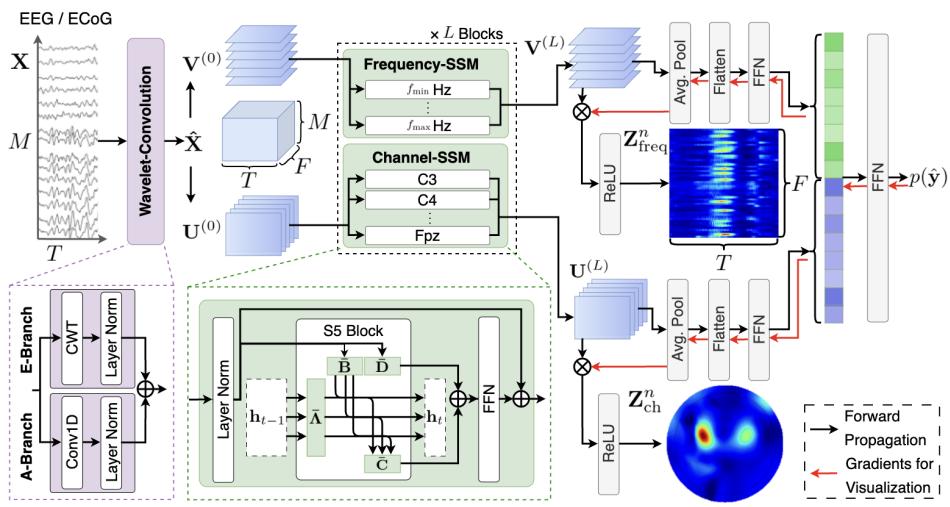

Figure 2: Overview of the proposed Cortical-SSM. Given an EEG or ECoG signal, the Wavelet-Convolution module extracts interpretable frequency features by combining deterministic and adaptive features (left). The Frequency-SSM and Channel-SSM then model spatio-temporal features for each frequency component and temporal-frequency features for each electrode, respectively (middle). Finally, the resulting features  $V^{(L)}$  and  $U^{(L)}$  are fused for action prediction, while providing visual explanations in spatio-temporal and temporal-frequency domains, respectively (right).

approaches typically employ temporal patching strategies prior to Transformer processing to address computational complexity in long-sequence modeling. However, this preprocessing step may disrupt fine-grained temporal dependencies in EEG and ECoG signals.

**Deep state space models.** Although the Transformer architecture has been widely adopted across various domains (Vaswani et al., 2017; Baevski et al., 2020; Dosovitskiy et al., 2021), the quadratic computational complexity  $O(N^2)$  of its attention mechanism with respect to sequence length  $N$  introduces fundamental scalability bottlenecks. This limitation has motivated extensive research into efficient alternative architectures (Ren et al., 2021; Han et al., 2023). Among these alternatives, Deep SSMs (Gu et al., 2022; Nguyen et al., 2022; Smith et al., 2023; Gu & Dao, 2024) have emerged as a promising framework for efficiently capturing long-range dependencies. In line with this trend, EEG classification models (Zhang et al., 2024; Tran et al., 2024; Gui et al., 2025) have also leveraged Deep SSMs to capture temporal dependencies in signals. However, current models predominantly adopt Mamba (Gu & Dao, 2024) as their foundational Deep SSM, leaving the optimal choice for the EEG or ECoG classification task ambiguous. In contrast, our proposed method extends S5 (Smith et al., 2023), a Deep SSM explicitly designed to capture inter-variable dependencies within the state space, to effectively address the intrinsic multivariate nature of EEG and ECoG signals.

Further related studies are discussed in Appendix A.

### 3 METHOD

#### 3.1 CORTICAL-SSM

In this study, we address a classification task for EEG and ECoG signals recorded while subjects engage in motor imagery (MI) tasks. In this task, it is desirable to accurately classify the corresponding EEG or ECoG signals recorded while subjects engage in MI involving  $N$  types of movement. Definitions of the key terminology used in this paper are provided in Appendix B. The input is EEG or ECoG signals recorded while the subjects performed MI, and the output is a predicted probability corresponding to the MI.

Unlike previous studies (Zhang et al., 2024; Tran et al., 2024; Gui et al., 2025), our method simultaneously captures the spatio-temporal features for individual frequency components as well as the temporal-frequency features of individual electrodes. This parallel modeling approach enables the integrated capture of spatial, temporal, and frequency dependencies, providing a more comprehensive representation for EEG and ECoG classification. Our approach, which is designed to capture

162 integrated dependencies among spatial, temporal, and frequency features, is widely applicable to the  
 163 decoding of other endogenous and exogenous stimuli from EEG or ECoG signals.  
 164

165 Figure 2 shows the overall architecture of our proposed Cortical-SSM. The proposed method consists  
 166 of three main modules, Wavelet-Convolution, Frequency-SSM, and Channel-SSM. The input  $\mathbf{X} \in \mathbb{R}^{M \times T}$   
 167 to our model is the recorded EEG or ECoG signal, where  $M$  and  $T$  denote the number of  
 168 electrodes and the sequence length, respectively.  
 169

### 3.2 WAVELET-CONVOLUTION

170 In the Wavelet-Convolution module, we integrate deterministically derived frequency components  
 171 with learned frequency features. Previous models for EEG and ECoG classification widely employed  
 172 one-dimensional convolutional layers to learn frequency features through their kernels (Lawhern et al.,  
 173 2018; Song et al., 2022). Despite the promising results achieved by these models, their black-box  
 174 nature poses challenges for direct interpretability and impedes frequency domain analysis of the  
 175 extracted features. In contrast, the conventional short-time Fourier transform (STFT) and wavelet  
 176 transform extract frequency components in a deterministic manner, thereby yielding inherently  
 177 interpretable features. However, these fixed representations constrain the model’s performance (see  
 178 Subsection 5.3 for details).  
 179

180 To address this trade-off between learnability and interpretability, we propose a module integrating  
 181 deterministically derived frequency components from an Explanation Branch (E-Branch) with train-  
 182 able frequency features from an Adaptation Branch (A-Branch). This architecture maintains both  
 183 the learnability of these representations and the extraction of non-black-box features. Specifically,  
 184 we employ the continuous wavelet transform (CWT) for the E-Branch (first term of Equation 1),  
 185 and a one-dimensional convolutional layer for the A-Branch (second term of Equation 1). Unlike  
 186 existing methods that integrate the wavelet transform within convolutional layers (Fujieda et al., 2018;  
 187 Williams & Li, 2018; Liu et al., 2019), our module processes CWT and 1D convolutional features in  
 188 parallel, thereby enabling effective feature fusion.  
 189

190 Let  $\mathbf{x}_m \in \mathbb{R}^T$  denote the EEG or ECoG signal recorded from the  $m$ -th electrode ( $m = 1 \dots M$ ).  
 191 The module’s output  $\tilde{\mathbf{x}}_m \in \mathbb{R}^{F \times T}$  for each  $\mathbf{x}_m$  is formulated as shown below, yielding  $\tilde{\mathbf{X}} =$   
 192  $\{\tilde{\mathbf{x}}_m \mid m = 1 \dots M\} \in \mathbb{R}^{M \times F \times T}$ :

$$193 \tilde{\mathbf{x}}_m = \frac{1}{2} \text{LayerNorm}(\text{CWT}(\mathbf{x}_m)) + \frac{1}{2} \text{LayerNorm}(\text{Conv1D}(\mathbf{x}_m)), \quad (1)$$

194 where  $\text{Conv1D}(\cdot)$ ,  $\text{CWT}(\cdot)$ , and  $\text{LayerNorm}(\cdot)$  represent one-dimensional convolutional layers,  
 195 CWT, and layer normalization (Ba, 2016), respectively. Additionally,  $F$  represents the dimension in  
 196 the frequency domain. Details of the processing are described below.  
 197

198 First, in  $\text{Conv1D}(\cdot)$ , the kernel length  $K$  is set to  $K = f_{\text{sample}}/2$  following EEGNet (Lawhern et al.,  
 199 2018), and frequency features are extracted. Here,  $f_{\text{sample}}$  represents the sampling frequency.  
 200

201 In  $\text{CWT}(\cdot)$ , a filter bank  $\Psi \in \mathbb{R}^{F \times T}$  is constructed to extract features for individual frequency  
 202 components. For the extraction of frequency components, the Morlet wavelet (Torrence & Compo,  
 203 1998) is employed as the standard mother wavelet. Let  $\psi_f = [\psi_{f,-\frac{T}{2}}, \psi_{f,-\frac{T}{2}+1}, \dots, \psi_{f,\frac{T}{2}}] \in \mathbb{R}^T$   
 204 denote the Morlet wavelet used to extract a frequency component  $f$ .  $\psi_{f,t}$  is defined as follows:  
 205

$$206 \psi_{f,t} = \sqrt{\frac{1}{s}} \pi^{-\frac{1}{4}} e^{i\omega_0 \frac{t}{s}} e^{-\frac{1}{2}(\frac{t}{s})^2}, \quad s = \frac{\omega_0 f_{\text{sample}}}{2\pi f}, \quad (2)$$

207 where  $\omega_0$  and  $s$  denote the center frequency and scaling factor, respectively. Based on the above,  $\Psi$   
 208 is expressed by the following equation:  
 209

$$\Psi = \{\psi_f \mid f = f_{\text{min}} + \alpha(f_{\text{max}} - f_{\text{min}})/F, \alpha = 1 \dots F\}, \quad (3)$$

210 where  $f_{\text{min}}$  and  $f_{\text{max}}$  denote the minimum and maximum  $f$  targeted by the CWT, respectively.  
 211

212 Finally, we employ  $\text{LayerNorm}(\cdot)$  to normalize the features obtained from  $\text{Conv1D}(\cdot)$  and  $\text{CWT}(\cdot)$ .  
 213 In this model,  $\text{LayerNorm}(\cdot)$  is specifically applied along the temporal dimension, as explained  
 214 below. Normalization techniques widely applied in deep learning include batch normalization (Ioffe  
 215 & Szegedy, 2015), group normalization (Wu & He, 2018), and layer normalization across dimensions  
 at a given time step. These methods normalize features across variables. However, in multivariate

time-series, when an arbitrary event occurs across variables and its effects appear at different time steps in the sequence, normalization across variables is known to introduce mutual noise (Liu et al., 2022; Kim et al., 2022; Liu et al., 2024). Similarly, in EEG and ECoG classification tasks, when internal stimuli derived from motor activity are recorded as signal sources via electrodes, these stimuli influence different temporal points within each electrode’s signal. Therefore, we adopt layer normalization along the temporal dimension to address these issues.

### 3.3 FREQUENCY-SSM

The Frequency-SSM module independently captures spatio-temporal feature interactions within individual frequency component. Previous EEG and ECoG studies (Pfurtscheller & Neuper, 2001; Miller et al., 2007) have reported that MI tasks elicit frequency-specific power variations localized to functionally relevant cortical regions. Motivated by these neurophysiological findings, Frequency-SSM explicitly models the spatio-temporal dependencies for each frequency component in an independent manner. This design effectively tracks the power variations of those frequency bands associated with MI. The proposed module comprises  $L$  hierarchically organized blocks, where each block includes layer normalization, a feed-forward network, and a Deep SSM. In the following, we provide a detailed description of the processing steps applied to the input  $\mathbf{U}^{(l)}$  within the  $l$ -th block ( $l = 0, \dots, L$ ), where  $\mathbf{U}^{(0)} = \tilde{\mathbf{X}}$ .

We first normalize  $\mathbf{U}^{(l)}$  along the temporal dimension for each frequency component  $f \in \{1, \dots, F\}$ :

$$\tilde{\mathbf{u}}_f^{(l)} = \text{LayerNorm}(\mathbf{u}_f^{(l)}). \quad (4)$$

Next, we capture the temporal dependencies in  $\tilde{\mathbf{u}}_f^{(l)}$ . In EEG classification tasks, Transformer-based approaches are widely employed to model temporal dependencies (Song et al., 2022; Wang et al., 2024d;a). However, for long-sequence modeling, Deep SSMs have demonstrated superior performance to Transformer (Gu et al., 2022; Gu & Dao, 2024). Therefore, our module incorporates a Deep SSM to capture temporal dependencies in EEG or ECoG signals. Deep SSMs can be broadly categorized into time-invariant (Goel et al., 2022; Smith et al., 2023) and time-varying (Gu & Dao, 2024; Dao & Gu, 2024) systems. Although time-varying Deep SSMs are prevalent in EEG classification (Zhang et al., 2024; Tran et al., 2024; Gui et al., 2025), prior work (Gu & Dao, 2024) suggests that their inherent selection mechanisms can be detrimental for continuous signals, and they have exhibited inferior performance in certain speech synthesis tasks. Therefore, we opt for time-invariant Deep SSMs. Furthermore, Deep SSMs can be classified by their input-output configuration into Single-Input Single-Output (SISO) (Gu et al., 2022; Dao & Gu, 2024) or Multi-Input Multi-Output (MIMO) (Smith et al., 2023; Soydan et al., 2024). Given the multi-electrode nature of EEG and ECoG signals, a MIMO configuration that preserves inter-variable dependencies within the state space is deemed appropriate. For these reasons, we extend S5 (Smith et al., 2023) as the Deep SSM with a time-invariant and MIMO configuration. The detailed mathematical formulation of S5 is provided in Appendix C.

By defining the operation of S5 as  $\text{SSM}(\cdot)$ , the feature  $\mathbf{u}_f^{(l+1)}$  that captures temporal dependencies in  $\tilde{\mathbf{u}}_f^{(l)}$  is obtained as the following equation:

$$\mathbf{u}_f^{(l+1)} = \text{FFN} \left( \text{SSM} \left( \tilde{\mathbf{u}}_f^{(l)} \right) \right) + \tilde{\mathbf{u}}_f^{(l)}, \quad (5)$$

where  $\text{FFN}(\cdot)$  denotes the feed-forward network. Subsequently, the output  $\mathbf{U}^{(l+1)} = [\mathbf{u}_1^{(l+1)}, \mathbf{u}_2^{(l+1)}, \dots, \mathbf{u}_F^{(l+1)}] \in \mathbb{R}^{M \times F \times T}$  of the module at the  $l$ -th block is obtained, capturing temporal dependencies independently for each frequency component.

### 3.4 CHANNEL-SSM

In the Channel-SSM, temporal-frequency features are extracted independently for each electrode. By explicitly modeling electrode-specific dependencies of temporal-frequency features, we capture localized variations in signal intensity associated with MI. This module comprises  $L$  stacked blocks, each incorporating layer normalization, a feed-forward network, and Deep SSM layers hierarchically. The input  $\mathbf{V}^{(l)}$  within the  $L$ -th block ( $l = 0, \dots, L$ ) is modeled as follows, where  $\mathbf{V}^{(0)} = \tilde{\mathbf{X}}$ :

$$\mathbf{v}_m^{(l+1)} = \text{FFN} \left( \text{SSM} \left( \text{LayerNorm} \left( \mathbf{v}_m^{(l)} \right) \right) \right) + \text{LayerNorm} \left( \mathbf{v}_m^{(l)} \right), \quad (6)$$

270 yielding the block’s final output  $\mathbf{V}^{(l+1)} = [\mathbf{v}_1^{(l+1)}, \mathbf{v}_2^{(l+1)}, \dots, \mathbf{v}_M^{(l+1)}] \in \mathbb{R}^{M \times F \times T}$ .  
 271

272 Finally, the outputs  $\mathbf{U}^{(l)}$  and  $\mathbf{V}^{(l)}$  from Frequency-SSM and Channel-SSM, respectively, are integrated as follows, yielding the predicted probability  $p(\hat{\mathbf{y}})$  of action corresponding to  $\mathbf{X}$ :  
 273

$$274 \quad p(\hat{\mathbf{y}}) = \text{FFN} \left( \left[ \text{AvgPool} \left( \mathbf{U}^{(l)} \right); \text{AvgPool} \left( \mathbf{V}^{(l)} \right) \right] \right), \quad (7)$$

275 where  $N$  represents the number of action types. Moreover,  $\text{AvgPool}(\cdot)$  denotes the average pooling  
 276 layer, which aggregates the input features along the temporal dimension following the approach  
 277 proposed in S4 (Gu et al., 2022). Furthermore, we use the cross-entropy loss as the loss function.  
 278

## 279 4 EXPERIMENTS

280 In the experiments, we used EEG and ECoG datasets recorded during MI tasks. For the EEG datasets,  
 281 we used two public MI datasets OpenBMI (Lee et al., 2019) and Stieger2021 (Stieger et al., 2021).  
 282 For the ECoG dataset, we used a clinical dataset collected from a subject diagnosed with amyotrophic  
 283 lateral sclerosis (ALS; hereafter referred to as the ECoG-ALS dataset).  
 284

285 These datasets were selected for the following reasons. Previous research identified domain shifts  
 286 across experimental sessions and subjects in EEG and ECoG signals recorded during MI tasks (Cho  
 287 et al., 2017; Kaya et al., 2018). In the context of EEG, evaluating these two types of domain shifts is  
 288 essential for developing reliable and broadly applicable models. Accordingly, we selected the publicly  
 289 available OpenBMI (Lee et al., 2019) and Stieger2021 (Stieger et al., 2021) datasets, each of which  
 290 comprise EEG signals recorded across multiple sessions from over 50 subjects. In contrast, ECoG  
 291 signal acquisition poses substantial practical limitations because of the requirement for invasive  
 292 craniotomy, making it infeasible to record signals from numerous subjects. Therefore, evaluating  
 293 domain shifts across experimental sessions is the primary concern for ECoG. To this end, we selected  
 294 a clinical dataset that consists of ECoG recordings made across eight experimental sessions from  
 295 a single individual diagnosed with ALS. Furthermore, based on these properties, we adopted a  
 296 cross-subject evaluation paradigm for EEG datasets (OpenBMI and Stieger2021) and a cross-session  
 297 paradigm for the ECoG dataset (ECoG-ALS), employing  $k$ -fold cross-validation ( $k = 8$ ).  
 298

299 For preprocessing, we followed the minimal approach reported by Delorme (2023). We downsampled  
 300 EEG and ECoG signals to 250 Hz and used them directly as model inputs, without applying noise or  
 301 artifact removal across electrodes. Further experimental details are provided in Appendix E.  
 302

## 303 5 RESULTS

### 304 5.1 QUANTITATIVE RESULTS

305 We conducted experiments to compare the performance of our model with baselines on the  
 306 OpenBMI (Lee et al., 2019), Stieger2021 (Stieger et al., 2021), and ECoG-ALS datasets. The  
 307 results for OpenBMI and ECoG-ALS are presented in Table 1, while the results for Stieger2021 can  
 308 be found in Appendix F.1. Values reported in the table represent the mean and standard deviation  
 309 obtained across  $k$ -fold cross-validation ( $k = 8$ ). For the evaluation metrics, we employed accuracy,  
 310 Macro-F1, AUROC (macro-averaged), AUPRC (macro-averaged), and Cohen’s Kappa. We used  
 311 these metrics because they are standard for the classification of EEG and ECoG signals.  
 312

313 This task involves (i) classification of EEG and ECoG signals, and (ii) handling of multivariate time-  
 314 series signals recorded from multiple electrodes. Accordingly, we selected baseline methods from the  
 315 following perspectives: (i) we chose baselines that have been successfully applied to EEG or ECoG  
 316 classification, including ShallowConvNet (Schirrmeister et al., 2017), DeepConvNet (Schirrmeister  
 317 et al., 2017), EEGNet (Lawhern et al., 2018), TSception (Ding et al., 2020), EEG Conformer (Song  
 318 et al., 2022), and Medformer (Wang et al., 2024d), and (ii) given the multivariate nature, we se-  
 319 lected baselines that have demonstrated effectiveness in multivariate time-series forecasting, such as  
 320 Informer (Zhou et al., 2021), Autoformer (Wu et al., 2021), FEDformer (Zhou et al., 2022), Cross-  
 321 former (Zhang & Yan, 2023), DLinear (Zeng et al., 2023), TimesNet (Wu et al., 2023), PatchTST (Nie  
 322 et al., 2023), TimeMixer (Wang et al., 2024b), iTransformer (Liu et al., 2024), Uni-TS (Gao et al.,  
 323 2024), TimeMachine (Ahamed & Cheng, 2024), and S-Mamba (Wang et al., 2025b).  
 324

325 Table 1 presents the performance of our proposed method, which achieved the highest accuracy,  
 326 macro-F1, AUROC, AUPRC, and Cohen’s Kappa on OpenBMI, with values of 81.62%, 81.56%,  
 327

324 Table 1: Performance comparison on OpenBMI (Lee et al., 2019) and ECoG-ALS datasets. **Bold** and  
 325 underlined values indicate the best and second-best performances, respectively.

326	Dataset	Models	Accuracy [%]↑	Macro-F1 [%]↑	AUROC [%]↑	AUPRC [%]↑	Kappa ↑

426</td							

We further examine our proposed method by generating visual explanations, following the procedure described in Appendix D. Figure 3 demonstrates sample-agnostic visual explanations of the proposed method on OpenBMI (Lee et al., 2019). Row (a) depicts temporal-frequency visualizations, whereas Rows (b) illustrate spatio-temporal visualizations. Columns (i) and (ii) show the class-wise average explanations for successful cases, corresponding to left-hand and right-hand grasp imagery, respectively. Specifically, Row (a) visualize  $Z_{\text{freq}}^n$  (introduced in Appendix D), with 0 seconds indicating the onset of MI, while Row (b) visualize  $Z_{\text{ch}}^n$  (also introduced in Appendix D) projected as topographic maps aligned with the 10–20 system (Klem, 1999). As seen in Row (a), the proposed method consistently attends to the mu band (approximately 10 Hz), a frequency range well known to be associated with MI in EEG (Pfurtscheller et al., 2006). Furthermore, Row (b) indicates that regions near electrodes C3 and C4 were strongly attended to. The C3 and C4 electrodes are positioned over the motor cortex and are neurophysiologically linked to hand motor control (Pfurtscheller et al., 2006). Therefore, these results suggest that the proposed method reliably attends to neurophysiologically critical regions in EEG, in a sample-agnostic manner.

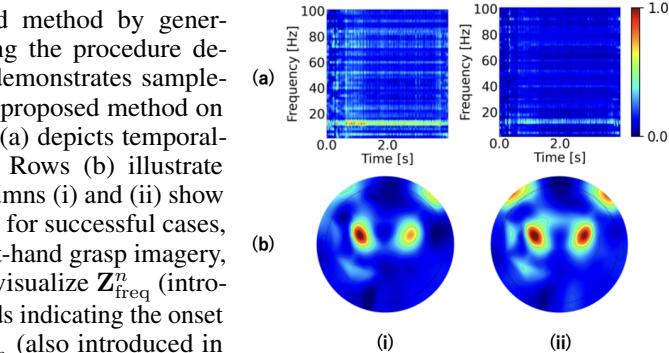

Figure 3: Sample-agnostic visual explanations of our proposed method on OpenBMI (Lee et al., 2019). Rows (a) and (b) display the temporal-frequency and spatio-temporal visual explanations for Subject 02, respectively. Columns (i) and (ii) correspond to left and right hand grasp, respectively.

Next, Figure 4 presents sample-agnostic visual explanations of our proposed method on ECoG-ALS. Columns (i)–(iv) display the class-wise average explanations corresponding to elbow extension, elbow flexion, hand extension, and hand grasp, respectively. Row (a) shows the average  $Z_{\text{freq}}^n$  for successful cases in Session 07, aligned such that 0 seconds denotes the onset of MI. Row (b) visualizes the average  $Z_{\text{ch}}^n$  for the same sessions, projected onto the subject’s electrode configuration (as shown in Figure 5). As seen in Row (a), the proposed method consistently attends to a temporal interval of approximately 0.5 seconds centered around the MI onset. Moreover, Row (b) reveals that regions surrounding 9–25 and 49–60, located in the Hand Knob Area (Yousry et al., 1997) were consistently attended to. Previous studies have demonstrated that MI related to hand movements induces distinct increases in high-frequency components in ECoG signals from these regions. Accordingly, these results suggest that our proposed method effectively attends to neurophysiologically critical regions in a sample-agnostic manner, not only for EEG but also for ECoG.

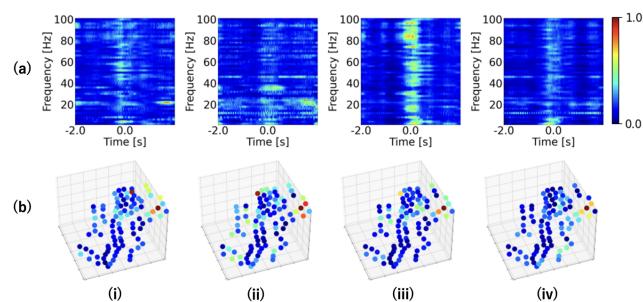

Figure 4: Sample-agnostic visual explanations of our proposed method on ECoG-ALS. Rows (a) and (b) display the temporal-frequency and spatio-temporal visual explanations for Session 07, respectively. Columns (i)–(iv) correspond to the output classes: (i) elbow extension, (ii) elbow flexion, (iii) hand extension, and (iv) hand grasp.

### 5.3 ABLATION STUDY

To investigate the effectiveness of each module, we conducted ablation studies on the following three conditions.

**Wavelet-Convolution ablation.** Table 2 presents the performance of different frequency-domain feature extraction methods in the E-Branch and A-Branch of the Wavelet-Convolution module. We compared five model variants (1-i)–(1-v) with combinations of short-time Fourier transform (STFT)

Table 2: Ablation study on frequency-domain feature extraction methods in the Wavelet-Convolution module. 1D-Conv. denotes 1D convolutional layers.

Model	E-Branch	A-Branch	Accuracy [%] $\uparrow$	
			OpenBMI	ECoG-ALS
(1-i)	STFT	—	71.51 $\pm$ 3.94	45.31 $\pm$ 6.30
(1-ii)	CWT	—	78.86 $\pm$ 5.05	65.55 $\pm$ 9.92
(1-iii)	—	1D-Conv.	80.25 $\pm$ 5.55	73.98 $\pm$ 8.48
(1-iv)	STFT	1D-Conv.	79.46 $\pm$ 5.22	70.00 $\pm$ 9.81
(1-v)	CWT	1D-Conv.	<b>81.62<math>\pm</math>5.20</b>	<b>75.08<math>\pm</math>9.69</b>

432 and continuous wavelet transform (CWT) in the E-Branch, along with 1D convolutional layers in  
 433 the A-Branch. The results reveal that models employing CWT in the E-Branch exhibited markedly  
 434 different performance on OpenBMI (Lee et al., 2019), with the classification accuracy of Model (1-ii)  
 435 being 2.76 points lower than that of Model (1-v). Similarly, when models using 1D convolutions  
 436 in the A-Branch were compared, Model (1-iii) underperformed Model (1-v) by 1.37 points in the  
 437 corresponding metric. These findings suggest that the complementary integration of deterministically  
 438 obtained frequency components from the E-Branch and adaptively derived frequency features from  
 439 the A-Branch enhances the model’s representational capacity.

440 **Frequency-SSM and Channel-SSM ablation.** Table 3 shows the performance of different ar-  
 441 chitectures in the Frequency-SSM and Channel-  
 442 SSM. We compared models using the following  
 443 architectures for capturing temporal dependen-  
 444 cies: (2-i) Attention (Vaswani et al., 2017), (2-  
 445 ii) S4-LegS (Gu et al., 2022), (2-iii) Mega (Ma  
 446 et al., 2022), (2-iv) Mamba (Gu & Dao, 2024),  
 447 (2-v) Mamba-2 (Dao & Gu, 2024), and (2-vi)  
 448 S5 (Smith et al., 2023). Table 3 indicate that the  
 449 classification accuracy of models (2-i), (2-ii), (2-  
 450 iii), (2-iv), and (2-v) on OpenBMI underperformed Model (2-vi) by 2.88, 1.93, 1.76, 2.17, and 1.33  
 451 points, respectively. These results suggest that S5, a Deep SSM employing a time-invariant system  
 452 and MIMO configuration, is effective for capturing temporal dependencies in EEG and ECoG signals.  
 453

454 **Module-wise ablation.** Table 4  
 455 presents the performance of the three  
 456 main modules: Wavelet-Convolution,  
 457 Frequency-SSM, and Channel-SSM.  
 458 We compared four model config-  
 459 urations: (3-i) exclusion of Wavelet-  
 460 Convolution, (3-ii) exclusion of  
 461 Frequency-SSM, (3-iii) exclusion of Channel-SSM,  
 462 and (3-iv) the complete model incorporating  
 463 all three modules. Regarding classification accuracy on OpenBMI, Models (3-i), (3-ii), and (3-iii)  
 464 underperformed Model (iv) by 5.74, 2.48, and 0.98 points, respectively. These findings indicate that  
 465 each module contributes to improving overall model performance, with the Wavelet-Convolution  
 466 module exerting the most significant impact.  
 467

## 6 CONCLUSION AND LIMITATIONS

468 **Conclusion.** In this study, we focused on a classification task based on EEG and ECoG signals  
 469 recorded during MI tasks. We proposed Cortical-SSM, an extension of Deep SSMs designed to  
 470 capture integrated dependencies across temporal, spatial, and frequency domains. For frequency  
 471 feature extraction, we proposed the Wavelet-Convolution, which extracts non-black-box frequency-  
 472 analyzable features while maintaining a learnable representation. In comprehensive evaluations on  
 473 three MI EEG and ECoG benchmarks, our method consistently outperformed the comparison baseline  
 474 methods. Furthermore, we demonstrated that for both EEG and ECoG signals, neurophysiologically  
 475 significant regions were attended to in the visual explanations generated by our proposed method.

476 **Limitations and future work.** While Cortical-SSM captures integrated dependencies across  
 477 temporal, spatial, and frequency domains from EEG and ECoG signals, it has limitations that  
 478 suggest promising directions for future work. 1) Limited cross-domain integration: Cortical-SSM  
 479 processes each domain independently to enhance interpretability, but this may cause overreliance on  
 480 a single domain (e.g., temporal) when it suffices for the classification, underutilizing complementary  
 481 cues. Future work could explore progressive or joint learning strategies to promote balanced feature  
 482 utilization. See Appendix F.3 for detailed analysis. 2) Sensitivity to domain shifts: As with the existing  
 483 baselines, Cortical-SSM does not explicitly address subject- or session-level domain shifts (Cho et al.,  
 484 2017; Kaya et al., 2018). As shown in Section 5.1, the Shapiro–Wilk test rejects normality across  
 485 folds, suggesting substantial variance. Incorporating domain adaptation techniques, such as learning  
 invariant representations via mutual information maximization, offers a promising path forward.

Table 3: Ablation study on architectures for capturing temporal dependencies.

Model	Architecture	Accuracy [%] ↑	
		OpenBMI	ECoG-ALS
(2-i)	Attention	78.74±5.11	56.72± 9.37
(2-ii)	S4-LegS	79.69±4.98	69.38±11.22
(2-iii)	Mega	79.86±2.05	71.48±12.06
(2-iv)	Mamba	79.45±3.25	67.03± 8.56
(2-v)	Mamba-2	80.29±3.69	68.36± 8.52
(2-vi)	S5	<b>81.62±5.20</b>	<b>75.08± 9.69</b>

Table 4: Ablation study on the core modules.

Model	Wavelet	Frequency	Channel-SSM	Accuracy [%] ↑				
				Conv.	SSM	SSM	OpenBMI	ECoG-ALS
(3-i)			✓			✓	75.88±2.12	63.13±10.42
(3-ii)	✓				✓		79.14±2.75	65.00± 8.93
(3-iii)	✓	✓				✓	80.64±2.31	73.91± 9.42
(3-iv)	✓	✓	✓			✓	<b>81.62±5.20</b>	<b>75.08± 9.69</b>

756 **A ADDITIONAL RELATED WORK**

758 **Deep state space models.** Rooted in the theoretical foundations of classical state space models  
 759 from control theory (Kalman, 1960), Deep SSMs leverage the Linear State-Space Layer (Gu et al.,  
 760 2021) to model sequential data effectively. Moreover, a key innovation lies in the integration of  
 761 the HiPPO matrix (Gu et al., 2020), which fuses the concept of recurrent memory with optimal  
 762 polynomial approximation. Subsequent developments have substantially expanded this paradigm (Gu  
 763 et al., 2022; Smith et al., 2023; Gu & Dao, 2024). For instance, S4 (Gu et al., 2022) introduced  
 764 a learnable HiPPO parameterization, while S5 (Smith et al., 2023) extended the framework to a  
 765 Multi-Input Multi-Output (MIMO) setting. Notably, the recent Mamba architecture (Gu & Dao, 2024)  
 766 introduces an input-dependent selection mechanism that enables time-varying state transitions, and  
 767 its performance is reported to surpass that of Transformers in certain language modeling tasks. This  
 768 development has catalyzed cross-domain adoption, with success being demonstrated in fields such as  
 769 computer vision (Zhu et al., 2025; Wang et al., 2025a), speech synthesis (Jiang et al., 2025; Li et al.,  
 770 2024b), and medical applications (Ma et al., 2024; Guo et al., 2024). Together, these advancements  
 771 establish Deep SSMs as a viable alternative to attention-based models.

772 **Multivariate time-series forecasting models.** Multivariate time-series forecasting has found broad  
 773 applications across diverse domains, ranging from medical signal prediction (e.g., electromyography  
 774 and electrocardiography analysis (Zhang et al., 2023; Li et al., 2024a)) as well as other applications  
 775 (Kaneda et al., 2022; Bi et al., 2023; Huang et al., 2024). Notably, Transformer-based approaches  
 776 are widely studied due to their demonstrated capability for long range sequence modeling (e.g., (Zhou  
 777 et al., 2021; Wu et al., 2023; Nie et al., 2023; Zhang & Yan, 2023)). For example, Informer (Zhou  
 778 et al., 2021) proposed an efficient forecasting method based on a ProbSparse self-attention mechanism  
 779 and a generative decoder. Other notable examples include PatchTST (Nie et al., 2023), which divides  
 780 time-series signals into smaller patches for Transformer input, and Crossformer (Zhang & Yan,  
 781 2023), which introduces a two-stage attention mechanism to capture inter-variable and temporal  
 782 dependencies separately. In contrast, DLinear (Zeng et al., 2023) achieves performance comparable to  
 783 Transformer-based approaches by utilizing a simple yet effective MLP-based method that decomposes  
 784 time-series into seasonal and trend components. Drawing on this findings, iTransformer (Liu et al.,  
 785 2024) proposes a strategy in which the matrix operations in the Transformer are transposed, thereby  
 786 capturing inter-variable dependencies through the Attention mechanism while modeling temporal  
 787 dependencies with an MLP.

788 **Datasets and benchmarks.** MI EEG/ECoG classification has been extensively studied using  
 789 standardized benchmarks including BCI Competition III (Blankertz et al., 2006), BCI Competition  
 790 IV (Brunner et al., 2008), and the dataset by Schalk et al. (Schalk et al., 2004). In MI EEG/ECoG,  
 791 however, domain shifts across experimental sessions and subjects have been reported (Cho et al., 2017;  
 792 Kaya et al., 2018; Maswanganyi et al., 2022). These domain shifts arise from intrinsic variability  
 793 in neural signals, influenced by factors typified by participant’s alertness and wakefulness during  
 794 EEG/ECoG measurement. For instance, Maswanganyi et al. (Maswanganyi et al., 2022) observed  
 795 approximately 12% accuracy variation in a four-class MI EEG classification task under cross-session  
 796 evaluation. Similarly, Song et al. (Song et al., 2022) reported up to 41% performance discrepancies  
 797 in cross-subject scenarios for another four-class MI-EEG classification task. While aforementioned  
 798 benchmarks provide foundational insights, their limited number of experimental sessions and subjects  
 799 hinders a comprehensive assessment of the impact of such domain shifts. Therefore, in EEG settings,  
 800 several multi-subject, multi-session benchmarks have been proposed including OpenBMI (Lee et al.,  
 801 2019), as well as the datasets by Cho et al. (Cho et al., 2017), Kaya et al. (Kaya et al., 2018), and  
 802 Stieger et al. (Stieger et al., 2021). In contrast, for ECoG settings, the substantial measurement  
 803 barriers limit the feasibility of recording signals from multiple subjects, making the handling of  
 804 domain shifts across experimental sessions a critical concern. To the best of our knowledge, the only  
 805 standard benchmark comprising multiple sessions of ECoG signals is Task 1 of BCI Competition III,  
 806 but it provides only a limited number of experimental sessions ( $n = 2$ ). Therefore, in this work, we  
 807 employ a clinical dataset of ECoG signals recorded from a single subject across multiple sessions  
 808 ( $n = 8$ ) during MI tasks.

809 **B TERMINOLOGY**

The terminology used in this paper is defined as follows:

- Electroencephalogram (EEG): Biosignals recorded from electrodes placed on the scalp.
- Electrocorticogram (ECoG): Biosignals recorded from electrodes placed on the brain surface following a craniotomy.
- Electrode: In EEG, this refers to wet electrodes or dry electrodes depending on the dataset, whereas in ECoG, this refers to subdural electrodes.
- Motor imagery (MI): Mental representation of physical movements without an overt motor output.

## C DEEP STATE SPACE MODELS

Recent advancements in Deep SSMs (Gu et al., 2022; Smith et al., 2023; Dao & Gu, 2024) have demonstrated their remarkable advantages over predominant architectures (including Transformer (Vaswani et al., 2017)) across various sequence modeling tasks. Inspired by classical SSM (Kalman, 1960), Deep SSMs establish a principled framework in which input signals  $\mathbf{x}(t) \in \mathbb{R}^P$  are mapped to output signals  $\mathbf{y}(t) \in \mathbb{R}^P$  via latent states  $\mathbf{h}(t) \in \mathbb{R}^Q$ , as follows:

$$\frac{d\mathbf{h}(t)}{dt} = \mathbf{A}\mathbf{h}(t) + \mathbf{B}\mathbf{x}(t), \quad \mathbf{y}(t) = \mathbf{C}\mathbf{h}(t) + \mathbf{D}\mathbf{x}(t), \quad (8)$$

where  $P$  and  $Q$  denote the number of variables for the input/output signals and the latent states, respectively. Moreover,  $\mathbf{A} \in \mathbb{R}^{Q \times Q}$  represents the state matrix, while  $\mathbf{B} \in \mathbb{R}^{Q \times P}$ ,  $\mathbf{C} \in \mathbb{R}^{P \times Q}$ , and  $\mathbf{D} \in \mathbb{R}^{P \times P}$  denote the projection matrices. Notably, the Deep SSM variant S5 (Smith et al., 2023) has demonstrated remarkable effectiveness in capturing sequential relationships for continuous signals. Here, we detail the processing steps employed in S5.

In S5, the HiPPO-N matrix (Gu et al., 2022) is adopted as  $\mathbf{A}$  to effectively capture long-range dependencies in sequential signals. Since the HiPPO-N matrix is real symmetric, it can be diagonalized as  $\mathbf{A} = \mathbf{V}\Lambda\mathbf{V}^{-1}$ , thereby transforming Equation (8) into the following form:

$$\frac{d\tilde{\mathbf{h}}(t)}{dt} = \tilde{\mathbf{A}}\tilde{\mathbf{h}}(t) + \tilde{\mathbf{B}}\mathbf{x}(t), \quad \mathbf{y}(t) = \tilde{\mathbf{C}}\tilde{\mathbf{h}}(t) + \mathbf{D}\mathbf{x}(t), \quad (9)$$

where  $\tilde{\mathbf{h}}(t) = \mathbf{V}^{-1}\mathbf{h}(t)$ ,  $\tilde{\mathbf{B}} = \mathbf{V}^{-1}\mathbf{B}$ , and  $\tilde{\mathbf{C}} = \mathbf{C}\mathbf{V}$ . Moreover, by introducing a timescale parameter  $\Delta \in \mathbb{R}_+$ , Equation 9 is discretized using the zero-order hold (ZOH) method (Zhang & Chong, 2007) as follows:

$$\tilde{\mathbf{h}}_t = \bar{\Lambda}\tilde{\mathbf{h}}_{t-1} + \bar{\mathbf{B}}\mathbf{x}_t, \quad \mathbf{y}_t = \bar{\mathbf{C}}\tilde{\mathbf{h}}_t + \bar{\mathbf{D}}\mathbf{x}_t, \quad (10)$$

where  $\bar{\Lambda} = \exp(\Lambda\Delta)$ ,  $\bar{\mathbf{B}} = \Lambda^{-1}(\bar{\Lambda} - \mathbf{I})\tilde{\mathbf{B}}$ ,  $\bar{\mathbf{C}} = \tilde{\mathbf{C}}$ ,  $\bar{\mathbf{D}} = \mathbf{D}$ . In practice,  $\Delta \in \mathbb{R}^Q$  is used for the timescale parameter, and  $\mathbf{D}$  is restricted as a diagonal matrix. Under these conditions, the learnable parameters consist of  $\text{diag}(\Lambda)$ ,  $\tilde{\mathbf{B}}$ ,  $\tilde{\mathbf{C}}$ ,  $\text{diag}(\mathbf{D})$ , and  $\Delta$ . Furthermore, S5 achieves efficient modeling of Equation 10 through the introduction of parallel scanning.

## D VISUAL EXPLANATIONS

In our proposed method, we generate visual explanations in both the spatio-temporal and temporal-frequency domains through the following procedures. Our approach extends Grad-CAM (Selvaraju et al., 2017) to generate visual explanations tailored for time-series signals. Grad-CAM is formulated as follows, generating a feature map  $\mathbf{Z}^n \in \mathbb{R}^{I \times J}$  that represents the explanation for the  $n$ -th output class from the gradient of the loss with respect to  $\hat{y}_n$ :

$$\alpha_r = \frac{1}{IJ} \sum_{i \in I} \sum_{j \in J} \frac{\partial \hat{y}^{(n)}}{\partial o_{r,i,j}}, \quad \mathbf{Z}^{(n)} = \text{ReLU} \left( \sum_{r \in R} \alpha_r \mathbf{o}_r \right), \quad (11)$$

where  $\hat{y}_n$  denotes the  $n$ -th element of  $\hat{\mathbf{y}}$ .  $I$ ,  $J$ , and  $R$  denote the number of vertical and horizontal pixels, and the number of dimensions of the feature map, respectively. Furthermore,  $\mathbf{o}_r \in \mathbb{R}^{I \times J}$  and

$o_{r,i,j} \in \mathbb{R}$  denote the feature map of the  $r$ -th dimension and the feature indexed by position  $(i, j)$  within  $\mathbf{o}_r$ , respectively. In this context,  $\mathbf{o}_r$  is required to retain the spatial relationships of the input.

Next, we describe our method for generating visual explanations in the spatio-temporal domain. While Grad-CAM operates on 2D feature maps  $\mathbf{o}_r$  and performs weighting across  $\{\mathbf{o}_r\}_{r=1}^R$ , our method deals with time-series signals and therefore performs weighting across 1D time-series vectors. Here, we generate visual explanations using  $\mathbf{V}^{(L)}$ , the feature closest to the output layer, which preserves the spatio-temporal relationships of the input signal. As detailed in Subsection 3.4, the feature within  $\mathbf{V}^{(L)}$  are processed independently for each electrode. Therefore, we generate a separate visual explanation for each electrode by weighting across  $\{\mathbf{v}_{f,m}^{(L)}\}_{f=1}^F$ . This yields the feature map  $\mathbf{Z}_{\text{ch}}^n \in \mathbb{R}^{M \times T}$ , representing the spatio-temporal visual explanation for the  $n$ -th output class, obtained as follows:

$$\alpha_{f,m}^n = \frac{1}{T} \sum_{t \in T} \frac{\partial \hat{y}_n}{\partial v_{f,m,t}^{(L)}}, \quad (12)$$

$$\mathbf{Z}_{\text{ch}}^n = \left\{ \text{ReLU} \left( \sum_{f \in F} \alpha_{f,m}^n \mathbf{v}_{f,m}^{(L)} \right) \mid m = 1 \dots M \right\}. \quad (13)$$

Finally, we describe our method for generating visual explanations in the temporal-frequency domain. Here, we generate visual explanations using  $\mathbf{U}^{(L)}$ , the feature closest to the output layer, which preserves the temporal-frequency relationships of the input signal. As detailed in Subsection 3.3, in contrast to  $\mathbf{V}^{(L)}$ , the features within  $\mathbf{U}^{(L)}$  are processed independently for each frequency component. Therefore, we generate a separate visual explanation for each frequency component by weighting across  $\{\mathbf{u}_{f,m}^{(L)}\}_{m=1}^M$ . This yields the feature map  $\mathbf{Z}_{\text{freq}}^n \in \mathbb{R}^{F \times T}$ , representing the temporal-frequency visual explanation for the  $n$ -th output class, as in Equations 12 and 13.

## E DETAILED EXPERIMENTAL SETUP

### E.1 DATASETS

We constructed the training, validation, and test sets according to the procedures described below, using them for model training, hyperparameter tuning, and performance evaluation, respectively. During training, we computed classification accuracy on the validation set after each epoch. For the final evaluation on the test set, we employed the model parameters corresponding to the highest validation accuracy.

**OpenBMI.** It is a public dataset of EEG recorded from 54 healthy subjects while they performed an MI task (Lee et al., 2019). The task involves two types of MI: right-hand grasping and left-hand grasping. The experimental design was based on the protocol established by Pfurtscheller et al. (Pfurtscheller & Neuper, 2001). While recording the signals, a display was positioned in front of the subjects, and the type movement to be imagined was indicated through visual cues including left and right arrows.

Subjects engaged in two sessions, performing 400 MI trials per session. A total of 21,600 samples were collected from 54 subjects. Each sample was recorded at a sampling rate of 1000 Hz, following a 3-second presentation of fixation cross, a 4-second MI, and a 6-second ( $\pm 1.5$  seconds) rest period. Additionally, visual cues were continuously presented during the 4-second MI period. EEG signals were recorded using BrainAmp systems with Ag–AgCl electrodes, and a total of 62 electrodes were positioned according to the international 10–20 system (Klem, 1999). Notably, this study focused on the 4-second MI period.

We adopted  $k$ -fold cross-validation ( $k = 8$ ) in a subject-independent manner. EEG samples collected from 54 subjects were partitioned at the subject level and randomly shuffled across the subjects. For each fold, samples from 44, 5, and 5 subjects were allocated to the training, validation and test sets, respectively. Given that each subject contributed 400 samples, the training, validation, and test sets consist of 17600, 2000, and 2000 samples, respectively.

918 **Stieger2021.** It is a public dataset of EEG recorded from 62 healthy subjects during motor im-  
 919 agery (Stieger et al., 2021). This dataset consists of three types of tasks(LR, UD, and 2D; defined  
 920 below) using MI control a cursor on a display. The movements to be imagined included left-hand  
 921 grasping, right-hand grasping, bilateral hand grasping, and voluntarily rest, with each task involv-  
 922 ing different combinations of these movements. In the LR task, left-hand and right-hand grasping  
 923 correspond to cursor movements in the left and right directions, respectively. The UD task involved  
 924 bilateral hand grasping and voluntarily rest, which correspond to cursor movements in the upward  
 925 and downward directions, respectively. The 2D task integrated the LR and UD tasks, which involved  
 926 four types of movements, with cursor movement directions corresponding to those in the LR and UD  
 927 tasks. While recording the signals, a display was positioned in front of the subjects, and a yellow  
 928 bar indicating the direction corresponding to the movement was presented at the edge of the screen  
 929 as a visual cue. Subjects were required to move the cursor, located at the center of the screen, by  
 930 imagining the movement corresponding to the direction of the yellow bar. In this process, cursor  
 931 movement was controlled based on the alpha power from electrodes C4 and C3 in the international  
 932 10–10 system (Nuwer, 2018).

933 Subjects engaged in 7 to 11 sessions, performing MI tasks ranging from 1050 to 1650 trials per  
 934 task. A total of 269099 samples were collected from 64 subjects. Each sample was recorded at a  
 935 sampling rate of 1000 Hz, following a 2-second rest period, a 2-second presentation of visual cues,  
 936 and up to 6 seconds of MI. The MI recording was terminated when the cursor reached the screen  
 937 edge in any direction. EEG signals were recorded using SynAmps RT and Neuroscan caps, with 64  
 938 electrodes positioned according to the international 10–10 system. Notably, this study focused on  
 939 202950 samples obtained from 41 participants who completed all 11 sessions. For each sample, we  
 940 used a 4 second window, encompassing 2 seconds before and 2 seconds after the onset of MI.

941 Similar to OpenBMI, we employed  $k$ -fold cross validation ( $k = 8$ ) in a subject-independent manner.  
 942 EEG samples from 41 subjects were first partitioned at the individual level and randomly shuffled  
 943 among the subjects. Subsequently, samples from 33, 4, and 4 subjects were allocated to the training,  
 944 validation, and test sets, respectively. With each subject providing 1650 samples, the dataset was split  
 945 into training, validation, and test sets of 54450, 6600, and 6600 samples, respectively.

946 **ECoG-ALS.** It is an ECoG dataset  
 947 recorded from a single subject with  
 948 ALS during an MI task. This task in-  
 949 volved four types of MI: elbow ex-  
 950 tension and flexion, as well as hand  
 951 extension and grasping. While record-  
 952 ing the signals, a display was posi-  
 953 tioned in front of the subject, and the  
 954 type of movement to be imagined was  
 955 communicated via textual instructions.  
 956 To ensure precise timing of MI, syn-  
 957 chronized auditory and visual cues, in-  
 958 cluding voice prompts and on-screen  
 959 arrows, were presented to the subject.

960 A single subject performed the four  
 961 types of MI, each repeated 40 times  
 962 per experimental session, over the  
 963 course of eight sessions. Conse-  
 964 quently, a total of 1280 samples were  
 965 collected from the subject. Each sam-  
 966 ple was recorded at a sampling rate  
 967 of 1000 Hz following a 4-second rest  
 968 and 2-seconds of MI. In this study, we  
 969 used a 4-second window encompass-  
 970 ing 2 seconds before and 2 seconds af-  
 971 ter the onset of MI. The ECoG signals  
 972 were recorded from 94 subdural elec-  
 973 trodes positioned near the central sulcus of the left hemisphere.  
 974 Figure 5 illustrates the spatial distri-  
 975 bution of these electrodes. Among the electrodes positioned  
 976 in the precentral and postcentral gyrus, elec-  
 977 trodes 9–25 and 49–60 were located within the Hand

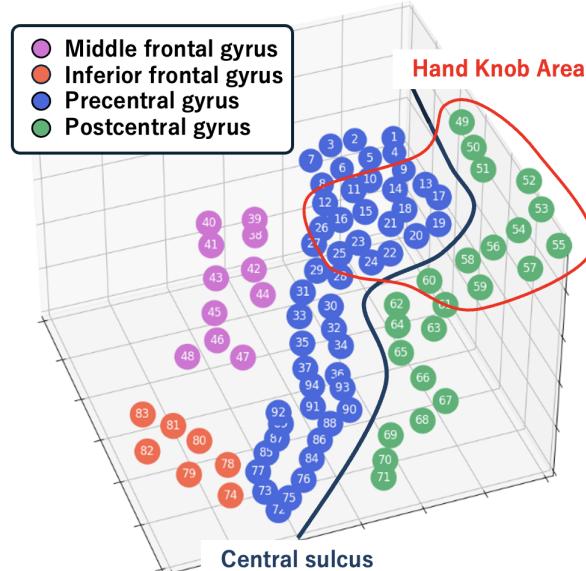

Figure 5: Electrode distribution in ECoG-ALS. Electrodes 9–25 and 49–60, positioned within the precentral and postcentral gyrus, respectively, are located in the Hand Knob Area (Yousry et al., 1997).

972 Table 5: Performance comparison for the LR and UD tasks in Stieger2021 (Stieger et al., 2021).  
 973 **Bold** and underlined text indicate the best and second-best methods for each evaluation metric.

Knob Area (Yousry et al., 1997). Previous studies have reported that this area exhibits a significant increase in high-frequency components during motor imagery (MI), supporting the relevance of these electrodes to the current task.

For the ECoG-ALS dataset, we employed  $k$ -fold cross-validation ( $k = 8$ ) in a session-independent manner. ECoG samples collected over eight experimental sessions on different days were segmented per session and randomly shuffled across the sessions. Subsequently, samples from six sessions were assigned to the training set, one session was assigned to the validation set, and the remaining session was assigned to the test set. Given that there are 160 samples per session, the training, validation, and test sets consisted of 960, 160, and 160 samples, respectively.

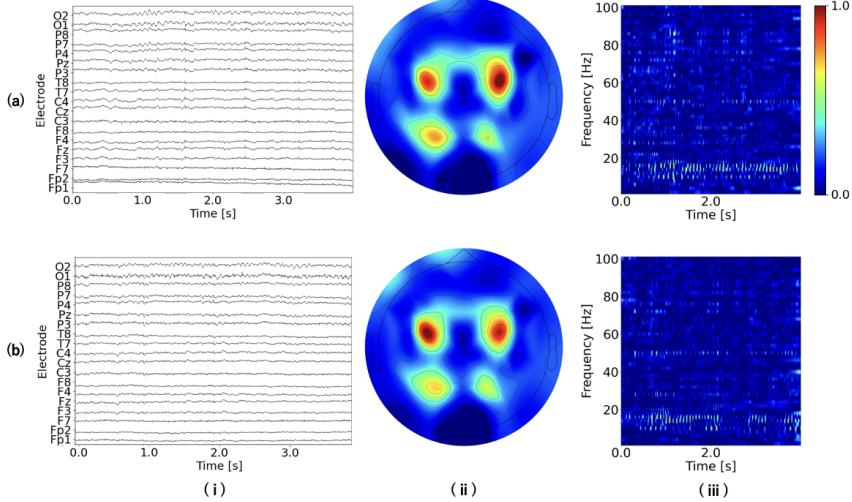

## E.2 IMPLEMENTATION DETAILS

We employed the AdamW optimizer ( $\beta_1 = 0.9, \beta_2 = 0.999$ ) with a learning rate of  $1.0 \times 10^{-4}$ . The batch size was set to 8 and the training ran for 100 epochs. For the Wavelet-Convolution, we set the frequency dimension  $F = 50$  and targeted the frequency range  $(f_{\min}, f_{\max}) = (1 \text{ Hz}, 100 \text{ Hz})$ . For both the Frequency-SSM and Channel-SSM, we set the stacked block number  $L = 2$ .

Overall, our model contained approximately 0.93 million trainable parameters and 2.34 billion multiply-add operations. Training was performed on a Nvidia GeForce RTX 4090 with 24GB of

1063 Figure 6: Successful cases of the proposed method on OpenBMI (Lee et al., 2019). Rows (a) and (b)  
 1064 display samples for which the ground-truth class is left-hand grasping. For each sample, Column  
 1065 (i) shows recorded EEG signals, Column (ii) presents the spatio-temporal visual explanations, and  
 1066 Column (iii) illustrates the temporal-frequency visual explanations.

1067 VRAM and an Intel Core i9-13900KF processor with 64GB of RAM. The training times per task for  
 1068 our proposed method on OpenBMI, Stieger2021, and ECoG-ALS were approximately 157 min, 50  
 1069 min, and 4 min, respectively. The inference time per sample in the corresponding benchmarks was  
 1070 approximately 2-3 ms.

## 1073 F ADDITIONAL RESULTS

### 1076 F.1 QUANTITATIVE RESULTS FOR STIEGER2021

1078 Tables 5 and 6 present the quantitative results of the proposed method and the baseline methods for  
 1079 the three tasks (LR, UD, and 2D) included in Stieger2021(Stieger et al., 2021). For details on the  
 selection of the baseline methods and evaluation metrics, please refer to Section 5.1. According to

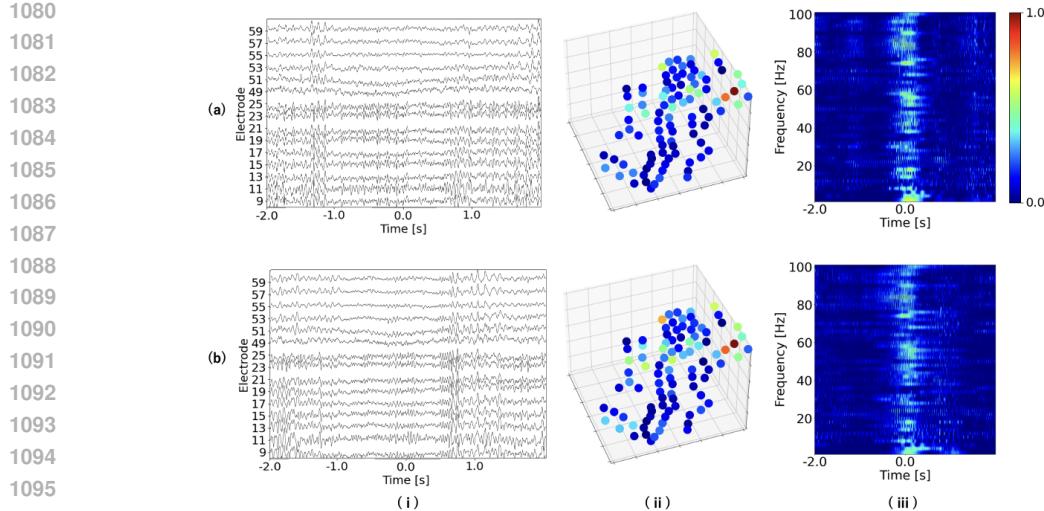

Figure 7: Successful cases of the proposed method on ECoG-ALS. In this figure, Rows (a) and (b) correspond to samples whose ground-truth class is hand extension. For each sample, Column (i) displays the recorded ECoG signals, Column (ii) presents the spatio-temporal visual explanations, and Column (iii) illustrates the temporal-frequency visual explanations.

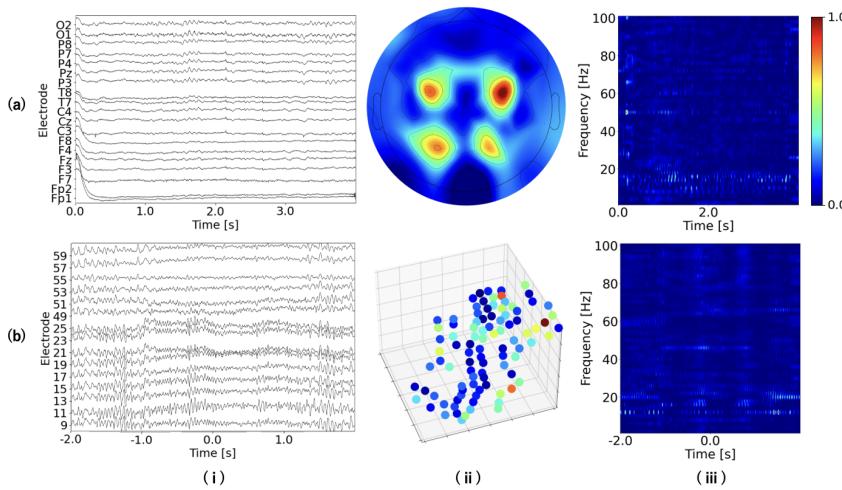

Figure 8: Failure cases of the proposed method. Rows (a) and (b) show samples from OpenBMI (Lee et al., 2019) and ECoG-ALS, respectively. Columns (i)–(iii) present, respectively, (i) the recorded EEG or ECoG signals, (ii) the visual explanations in the temporal-frequency domain, and (iii) the visual explanations in the spatio-temporal domain.

Table 6, the proposed method achieved the highest performance in the 2D task of Stieger2021, with accuracy, macro-F1, AUROC, AUPRC, and Cohen’s Kappa of 66.07%, 66.01%, 87.67%, 75.37%, and 0.55 points, respectively. Similarly, as shown in Tables 5 and 6, the proposed method also demonstrated the best performance in both the LR and UD tasks of Stieger2021.

## F.2 SAMPLE-SPECIFIC INTERPRETABILITY

Figure 6 shows successful cases by the proposed method on OpenBMI (Lee et al., 2019). In the figure, Rows (a) and (b) display samples where the ground truth class corresponds to left-hand grasping, while Columns (i)–(iii) respectively present: (i) recorded EEG signals, (ii) spatio-temporal visual explanations, and (iii) temporal-frequency visual explanations. Column (ii) reveals that the proposed method consistently attended to regions surrounding the C3 and C4 electrodes. Furthermore, in contrast to the sample-agnostic visual explanations in Figure 3, the proposed method in this sample also attended to regions near the P3 and P4 electrodes, located over the left and right parietal cortices.

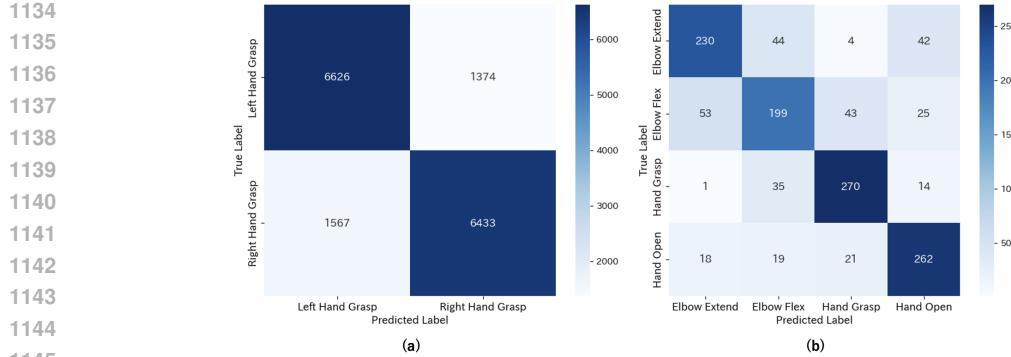

Figure 9: Confusion matrices for OpenBMI (Lee et al., 2019) and ECoG-ALS.

These areas are associated with somatosensory processing (Pause et al., 1989; Dijkerman & de Haan, 2007) and may hold functional relevance. Since the OpenBMI dataset includes motor imagery of both left- and right-hand movements, it is plausible that these regions capture proprioceptive representations of the imagined limb movements. Additionally, Column (iii) indicates consistent attention to regions surrounding the mu band. Taken together, these results suggest that the proposed method effectively focuses on neurophysiologically meaningful EEG regions.

Next, Figure 7 presents successful cases of the proposed method on ECoG-ALS. In the figure, Rows (a) and (b) display samples where the ground truth class is hand extension. Following the structure of Figure 6, Columns (i)-(iii) respectively present: (i) recorded ECoG signals, (ii) spatio-temporal visual explanations, and (iii) temporal-frequency visual explanations. As shown in Row (ii), electrodes located in the Hand Knob Area (Yousry et al., 1997) were significantly attended. Meanwhile, Row (iii) indicates that the period approximately 0.5 seconds around the MI onset was strongly attended to. Therefore, these results suggest that our proposed method effectively attends to neurophysiologically critical regions of ECoG.

Finally, Figure 8 illustrates cases where the proposed method failed. Row (a) shows a sample from OpenBMI where the ground-truth label was left-hand grasp, yet our method incorrectly predicted right-hand grasp. Similarly, Row (b) presents a sample from ECoG-ALS in which the ground-truth label was hand extension, but the method erroneously predicted elbow extension. Columns (i)–(iii) correspond, respectively, to the (i) recorded EEG or ECoG signals, (ii) the temporal-frequency visual explanations, and (iii) the spatio-temporal visual explanations. Notably, from Subfigures 8 (a-ii) and 8 (b-ii), regions surrounding the C3/C4 electrodes and the Hand Knob Area were significantly attended to. In contrast, Subfigures 8 (a-iii) and 8 (b-iii) indicate that the spatio-temporal domain was weakly attended to. These observations suggest that, for these samples, the proposed method predominantly focused on neurophysiologically critical regions in the spatial domain. We hypothesize that this misclassification can be attributed to domain shifts across experimental sessions and subjects in EEG, and across experimental sessions in ECoG, with the impact of domain shift in the spatial domain being relatively minor compared with that in the temporal-frequency domain.

### F.3 ERROR ANALYSIS

Figure 9 presents the confusion matrices for all test sets obtained through  $k$ -fold cross validation ( $k = 8$ ) for (a) OpenBMI (Lee et al., 2019) and (b) ECoG-ALS. For OpenBMI, the F1-scores for left and right hand grasp were 81.84% and 81.39%, respectively. In contrast, for ECoG-ALS, the elbow extension class achieved 230 True Positives (TP), 72 False Positives (FP), 888 True Negatives (TN), and 90 False Negatives (FN), resulting in an F1-score of 73.95%. Likewise, the F1-scores for the elbow flexion, hand extension, and hand grasp classes were 64.51%, 82.07%, and 79.03%, respectively. Therefore, the hand extension class exhibited the highest F1-score. On average, there were 367.63 failure modes per fold for OpenBMI and 39.88 per fold for ECoG-ALS.

To investigate the limitations of our proposed method, we conducted an error analysis on 100 failure modes from both OpenBMI and ECoG-ALS. The causes of failure can be broadly grouped into three categories:

1188

1189

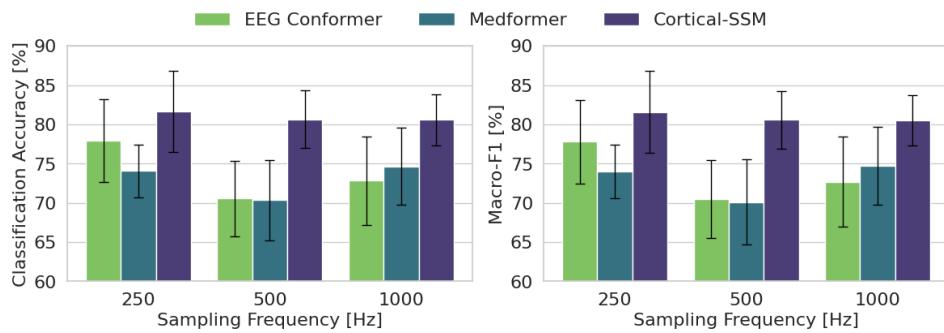

Figure 10: Sensitivity analysis of EEG sequence length on OpenBMI (Lee et al., 2019).

- **Irrelevant Attention Error (IAE):** This category refers to modes where regions that deviate from neurophysiologically significant areas were attended to, or where regions in the temporal, spatial, and frequency domains were insufficiently attended.
- **Prediction error (PE):** This category includes cases where neurophysiologically significant regions were attended to, yet the predictions were incorrect.
- **Noise/artifact Induced Error (NAIE):** This category refers to modes where the EEG or ECoG signal-to-noise ratio (SNR) was below -15 dB. For SNR calculation, we defined 1-100 Hz as the signal band, and 0-1 Hz and above 100 Hz as noise bands.

Furthermore, we defined neurophysiologically significant regions as follows:

- OpenBMI: The mu band around 10 Hz and regions surrounding the C3 and C4 electrodes in the 10–20 system (Klem, 1999).
- ECoG-ALS: Regions near 0 seconds representing the onset of MI and areas surrounding the Hand Knob Area (Yousry et al., 1997).

Table 7 indicates that the main bottleneck in both benchmarks was IAE. We hypothesize that this issue arises because our method tends to overemphasize certain regions within the temporal, spatial, and frequency domains during training. Our approach processes features from each domain independently to provide explicit visual explanations from all three domains. Consequently, when successful classification is achieved using features from only a subset of these domains, features from the remaining domains may not be effectively utilized. A possible solution could be training with features from the temporal, spatial, and frequency domains in a stepwise manner, which would be effective for achieving balanced attention across domains and reducing IAE. Furthermore, the number of NAIE modes was 26 for OpenBMI and 5 for ECoG-ALS, revealing a substantial difference between the benchmarks. This disparity can be attributed to the distinct recording methodologies of EEG and ECoG signals. The lower NAIE in ECoG signals likely results from their proximity to the signal source, leading to higher signal quality compared with EEG signals.

#### F.4 SENSITIVITY ANALYSIS ON SEQUENCE LENGTH

To investigate the effect of sequence length on decoding performance, we performed a sensitivity analysis on the OpenBMI dataset by resampling EEG signals originally recorded at 1000 Hz to three sampling rates (250 Hz, 500 Hz, and 1000 Hz), as illustrated in Figure 10. The 250 Hz condition

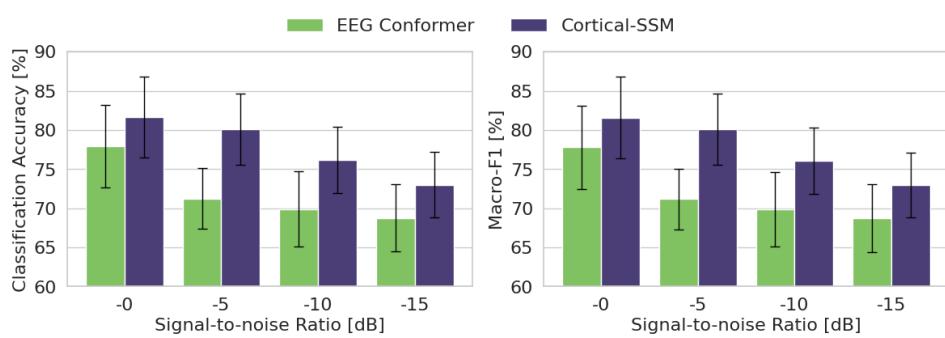

Figure 11: Sensitivity analysis of EEG signal-to-noise ratio on OpenBMI (Lee et al., 2019).

corresponds to the setting used in the original experimental setup, and all conditions employ 4-second EEG segments as input. We compared our method against two representative EEG/ECoG decoding baselines: EEG Conformer (Song et al., 2022) and Medformer (Wang et al., 2024d). While EEG Conformer and Medformer revealed accuracy drops of up to 7.34 and 3.73 points, respectively, our method shows only a marginal decrease of 1.06 points. These results suggest that the proposed method scales with sequence length.

### F.5 SENSITIVITY ANALYSIS ON SIGNAL-TO-NOISE RATIO

To evaluate the impact of noise and signal degradation, we conducted an additional experiment in which the signal-to-noise ratio (SNR) of EEG signals from the OpenBMI dataset was progressively degraded by 0dB, 5dB, 10dB, and 15dB as shown in Figure 11. Here, we compared the performance of our proposed method with the second-best baseline, EEG Conformer (Song et al., 2022). Following Appendix F.3, the signal bandwidth was set to 1-100Hz. As shown in the figure, our method consistently outperformed EEG Conformer across all SNR levels in terms of classification accuracy and macro-F1, demonstrating its effectiveness even in the presence of substantial noise and signal degradation common in clinical settings.

## G THE USE OF LARGE LANGUAGE MODELS

In this work, large language models (LLMs) were used solely for auxiliary purposes, such as polishing, editing, and formatting the manuscript. They were not employed in any part of the methodology, nor did they contribute to the implementation or evaluation of the proposed methods. Therefore, LLMs were not involved as essential, original, or non-standard components of the research.
