BUILDING HIERARCHICAL INTERPRETATIONS IN NATURAL LANGUAGE VIA FEATURE INTERACTION DETECTION

Anonymous authors
Paper under double-blind review

ABSTRACT

The interpretability of neural networks has become crucial for their applications in real-world with respect to reliability and trustworthiness. Existing explanation generation methods usually provide important features by scoring their individual contributions to the model prediction and ignore the interactions between features, which eventually provide a bag-of-words representation as an explanation. In natural language processing, this type of explanations is challenging for human users to understand the meaning of an explanation and draw the connection between explanation and model prediction, especially for long texts. In this work, we focus on detecting the interactions between features and propose a novel approach to build a hierarchy of explanations based on feature interactions. The proposed method is evaluated with three neural classifiers, LSTM, CNN, and BERT, on two benchmark text classification datasets. The generated explanations are assessed by both automatic evaluation measurements and human evaluators. Experiments show the effectiveness of the proposed method in providing explanations that are both faithful to models, and understandable to humans.

1 INTRODUCTION

Deep neural networks have become a significant component in natural language processing (NLP), achieving state-of-the-art performance in various NLP tasks, such as text classification (Kim, 2014), question answering (Rajpurkar et al., 2016), and machine translation (Bahdanau et al., 2014). However, the lack of understanding on their decision making leads them to be characterized as black-box models and increases the risk of applying them in real-world applications (Lipton, 2016). Producing interpretable decisions has been a critical factor on whether people will trust and use the neural network models (Ribeiro et al., 2016).

Most of existing work on local explanation generation for NLP focuses on producing word-level explanations (Ribeiro et al., 2016; Lei et al., 2016; Plumb et al., 2018), where a local explanation consists of a set of words extracted from the original text. Figure 1 presents an example sentence with its sentiment prediction and corresponding word-level explanation generated by LIME (Ribeiro et al., 2016). Although the LIME explanation captures a negative sentiment word waste, it presents the explanation in a bag-of-words format. Without resorting to the original text, it is difficult for us to understand the contribution of word a and of, as both of them have no sentiment polarity. The situation will become even more serious when this type of explanations are extracted from longer texts.

In this work, we present a novel method to construct hierarchical explanations of a model prediction by capturing the interaction between features. Ultimately, our method is able to produce a hierarchical structure as illustrated in Figure 1. Produced by the proposed method, this example provides a comprehensive picture of how different granularity of features interacting with each other for model prediction. With the hierarchical structure, this example tells us how the words and phrases are combined and what are the contributions of words and phrases to the final prediction. For example, the contribution of the phrase of good is dominated by the word waste, which eventually leads to the right prediction.
Under review as a conference paper at ICLR 2020

Figure 1: A hierarchical interpretation for the NEGATIVE movie review a waste of good performance. The color of each block represents the importance of the corresponding word/phrase with respect to the model prediction.

To capture feature interactions, we adopt the interacted Shapley value (Lundberg et al., 2018), an extension of Shapley value (Shapley, 1953) from cooperative game theory, to measure the interactions between features. Based on the interaction scores, we propose a top-down method, called INTERSHAPLEY, to segment a text recursively into phrases and then words eventually. The proposed method is evaluated on text classification tasks with three typical neural network models: long short term memory networks (Hochreiter & Schmidhuber, 1997, LSTM) and convolutional neural networks (Kim, 2014, CNN), and a state-of-the-art model BERT (Devlin et al., 2018) on some benchmark datasets. The comparison of our method is against several competitive baselines from prior work on explanation generation, including Leave-one-out (Li et al., 2016), Contextual Decomposition (Murdoch et al., 2018; Singh et al., 2018), L- and C-Shapley (Chen et al., 2018), and LIME (Ribeiro et al., 2016).

Our contribution of this work is three-fold: (1) we propose an effective method to calculate feature importance and extend the Shapley value to measure feature interactions; (2) we design a top-down segmentation algorithm to build hierarchical interpretations based on feature interactions; (3) we compare the proposed method with several competitive baselines via both automatic and human evaluations, and show the INTERSHAPLEY method outperforms the existing methods on both word- and phrase-level explanations.

2 RELATED WORK

Over the past years, many different research directions have been explored to build interpretable models or improve the interpretability of neural networks: (1) tracking the inner-workings of neural networks to understand their decision-making, such as contextual decomposition (CD) (Murdoch et al., 2018) for long short-term memories (LSTMs) (Murdoch et al., 2018) and convolutional neural networks (CNNs) (Godin et al., 2018); (2) decoding interpretable knowledge (e.g., contextual information, latent representations) from networks to explain model predictions, such as gradient-based interpretation methods (Hechtlinger, 2016; Sundararajan et al., 2017) and attention-based methods (Ghaeini et al., 2018; Xie et al., 2017); (3) modifying neural network architectures to make their output more explainable, such as retreating to simpler models (Alvarez-Melis & Jaakkola, 2018) or incorporating strong regularizers (Yuan et al., 2019); and (4) developing explainable model-agnostic methods to learn the behaviors of neural network models and explain them, such as LIME (Ribeiro et al., 2016) and KernelSHAP (Lundberg & Lee, 2017). The first three directions have limited capacity in real-world applications, as they require deep understanding of neural network architectures (Murdoch et al., 2018) or only work with specific models (Alvarez-Melis & Jaakkola, 2018). On the other hand, model-agnostic methods (Ribeiro et al., 2016; Lundberg & Lee, 2017) generate expla-
Model-agnostic interpretations. Model-agnostic methods are applicable for any black-box models, generating explanations solely based on model predictions. Li et al. (2016) proposed a method, called Leave-one-out, to probe the black-box model by erasing a given word and observing the change in the probability on the predicted class. Another work, LIME (Ribeiro et al., 2016), estimated individual word contributions locally by linear approximation based on perturbed examples. A line of most related works are Shapley-based methods, such as SHAP (Lundberg & Lee, 2017), L-Shapley and C-Shapley (Chen et al., 2018), where the variants of Shapley value (Shapley, 1953) are used to evaluate feature importance. They mainly focus on the challenge of reducing computational complexity of Shapley value by approximations (Kononenko et al., 2010; Datta et al., 2016).

Hierarchical interpretations. Previous work on interpreting neural networks mainly focuses on word-level interpretations, where the top-ranked words are selected based on their contributions to the prediction. There are a few works on building hierarchical interpretations. For example, agglomerative contextual decomposition (ACD) (Singh et al., 2018) use the word-level CD scores as the joining metric determining which features are clustered together. Unlike our method, this work is model-dependent, and proposes a bottom-up clustering method to aggregate features with respect to their interactions. Besides, Lundberg et al. (2018) extednted SHAP values to SHAP interaction values to calculate the interactions between features along a given tree structure. Similarly, Chen & Jordan (2019) suggests to utilize a linguistic tree structure to capture the contributions beyond individual features for text classification. The difference with our work is that both method from (Lundberg et al., 2018; Chen & Jordan, 2019) require hierarchical structures given, while our method constructs the structures without resorting external resources.

3 Method

In this section, we first introduce a new definition of feature importance score in subsection 3.1, which forms the basis of the feature interaction detection method discussed in subsection 3.2. Then, subsection 3.3 presents a novel method of building a hierarchy of explanations by recursively optimizing the feature interaction score on a given text.

3.1 Feature Importance Score

In general, a feature importance score is defined on a set of features with respect to a subset of it. The feature importance score characterizes the importance of a feature in each model prediction, and it is fundamental in computing the interaction score and building the hierarchy. Given a set of features $x = \{x_1, \ldots , x_n\}$, and the interested feature set $x_S = \{x_i | i \in S\}$ with $S$ being the feature index set, the feature importance score can be defined as follows,

$$f(x_S) = g_y(x_S) - \max_{y' \neq y, y' \in \mathcal{Y}} g_{y'}(x_S),$$

where $g_y(x)$ is the model output with respect to label $y$, $\mathcal{Y}$ is the possible label set, and $\hat{y}$ is the predicted label obtained by the model, i.e., $\hat{y} = \arg \max_{y \in \mathcal{Y}} g_y(x)$. In this work, $x$ is a sequence of words (sentence or text) and $x_S$ is a subset of $x$.

The feature importance score defined in Equation 1 measures the difference between the probability on the predicted class and the probability of the second most probable class. It measures how far the prediction is to the prediction boundary, hence the confidence of classifying $x_S$ into the predicted label $\hat{y}$. Particularly in text classification, it can be interpreted as the contribution to a specific class $\hat{y}$. For a given text $x$, $x_S$ in this case is usually considered as a consecutive subsequence of words from $x$ for interpretable explanations. It is also a common practice that words outside of $S$ are replaced with the special token ($\text{pad}$) (Chen et al., 2018; Shrikumar et al., 2017; Lundberg & Lee, 2017) in order to keep the same length between $x$ and $x_S$.

There are several existing importance measures, as mentioned in section 2. The effectiveness of Equation 1 as a feature importance score is shown in subsection 4.1.
3.2 Feature Interaction Score

By considering the prediction process as a coalition game (Lundberg et al., 2018), where each player (feature) contribute fairly, the feature interactions can be measured consistently, meaning the computed scores are in line with human intuition and are robust to model changes (Lundberg et al., 2018). Such scores often have the form of Shapley values. Motivated by the Shapley interaction score (Fujimoto et al., 2006; Lundberg et al., 2018), and combined with our model-agnostic feature importance score in Equation 1, the feature interaction score in the hierarchy is computed as follows,

$$\psi(p, q, z^\ell) = \sum_{S \subseteq N^\ell \setminus \{p, q\}} \frac{|S|!(n_x - |S| - 1)!}{2(n_x - 1)!} \gamma_{p, q}(z^\ell, S),$$

(2)

where $z^\ell$ is a set of features at the $\ell$-th level of the hierarchy; $N^\ell$ is the index set of features from $z^\ell$; $|S|$ is the size of the set $S$. Note that at level $\ell (\ell > 0)$, features in $z^\ell$ maybe the original features from $x$, or subsets of $x$. Additionally, $\gamma_{p, q}(z^\ell, S)$ is the interaction between features $z^\ell_p$ and $z^\ell_q$ considering the contributions of other features from $z^\ell$ indexed by $S$, which is defined as

$$\gamma_{p, q}(z^\ell, S) = f(z^\ell_{S \cup \{p, q\}}) - f(z^\ell_{S \cup \{p\}}) - f(z^\ell_{S \cup \{q\}}) + f(z^\ell_S).$$

(3)

The total interaction between $z^\ell_p$ and $z^\ell_q$ is the sum of $\psi(p, q, z^\ell)$ and $\psi(q, p, z^\ell)$ (Lundberg et al., 2018). Since $\psi(p, q, z^\ell)$ is symmetric with respect to $p$ and $q$, the total interaction between $p$ and $q$ at level $\ell$ is $\phi(p, q, z^\ell) = 2\psi(p, q, z^\ell)$.

3.3 Building Hierarchical Interpretation

To build the hierarchical interpretation, we adopt a top-down approach to first split a feature set into two subsets by minimizing their interaction. Formally, given the feature set $z^\ell = (z^\ell_1, \ldots, z^\ell_{n_x})$ at level $\ell$, we can obtain various candidate sets $\hat{z}^{\ell+1}_{i}$ of the next level by splitting one element $z^\ell_i, \forall i \in \{1, \ldots, n_x\}$ at a time. For example, one $\hat{z}^{\ell+1}_i$ could be $\hat{z}^{\ell+1}_i = (z^\ell_1, \ldots, \hat{z}^{\ell}_{i_1}, \hat{z}^{\ell}_{i_2}, \ldots, z^\ell_{n_x})$, where the union of $\hat{z}^{\ell}_{i_1}$ and $\hat{z}^{\ell}_{i_2}$ should be $z^\ell_i$. Of course, such partition is not unique and the number of potential partitions depends on the size of $z^\ell_i$. The best feature set at level $\ell + 1$ when choosing to split $z^\ell_i$ should satisfy the following

$$z^{\ell+1} = \arg\min_{\hat{z}^{\ell+1}_i} \phi(i_1, i_2, \hat{z}^{\ell+1}_i),$$

(4)

s.t. $\hat{z}^{\ell}_{i_1} \cup \hat{z}^{\ell}_{i_2} = z^\ell_i$.

(5)

Equation 4 finds the best partition by minimizing the interaction between two candidate subsets. The selection of $i$ at each level is random since the relations of features at different level will not be affected. The feature segmentation and hierarchical structure construction process can be briefly described as follows. At level-zero, we have $z^0 = x$. By applying Equation 4, we obtain $z^1 = [z^1_1, z^1_2]$, where $z^1_1$ and $z^1_2$ are two subsets of $x$. In the hierarchy, they are the children of $x$. The same process is applied to each elements in $z^\ell$, until no segmentation can be done. In the following sections, we call our method as INTERSHAPLEY.

Note that in generally, the solution defined from Equation 4 to Equation 5 has exponential computational complexity, which originates both from Equation 5 and Equation 2. However, in practical settings, where certain structure exists, the complexity can be greatly reduced. In NLP, features (i.e. words) are usually arranged in order, and $i_1$ and $i_2$ in Equation 5 are adjacent. With the aid of Shapley value approximation(Chen et al., 2018), where only $k$ neighbors are involved computation, the computational complexity measured in number of model evaluations will be $O(4^kn \log n)$. So the method scales well with $n$.

4 Experiments

The proposed method is evaluated on text classification tasks with three typical neural network models, LSTM, CNN, and BERT, on SST and IMDB datasets. The detailed experimental setup is in Appendix C. We employ both automatic and human evaluations on word-level and phrase-level explanations, to show the ability of INTERSHAPLEY in interpreting neural network models.
Table 1 shows the models used in our experiments achieve the state-of-the-art performance on both datasets.

4.1 Word-level Evaluation

We adopt two evaluation metrics from prior work on evaluating word-level explanations: the area over the perturbation curve (AOPC) (Nguyen, 2018; Samek et al., 2016) and log-odds scores (Chen et al., 2018). These two metrics measure local fidelity by deleting or masking words in the decreasing order of their importance scores and comparing the probability change on the predicted label.

**AOPC.** Word-level explanations provide a sequence of words according to their importance scores. AOPC is calculated as the average change in prediction probability on the predicted class over all of the test data by deleting top \(k\%\) words. Higher AOPCs are better, which means that the deleted words are important for model prediction.

\[
AOPC(k) = \frac{1}{N} \sum_{i=1}^{N} \{ p(\hat{y} | x_i) - p(\hat{y} | \tilde{x}_i^{(k)}) \},
\]

where \(\hat{y}\) is the predicted label, \(N\) is the number of samples, \(p(\hat{y} | \cdot)\) is the probability on the predicted class, and \(\tilde{x}_i^{(k)}\) is constructed by dropping the top \(k\%\) word features from \(x_i\).

**Log-odds.** The log-odds score is calculated by averaging the difference of negative logarithmic probabilities on the predicted class over all of the test data before and after masking the top \(r\%\) features with zero paddings. Under this metric, lower log-odds scores are better.

\[
\text{Log-odds}(r) = \frac{1}{N} \sum_{i=1}^{N} \log \frac{p(\hat{y} | \tilde{x}_i^{(r)})}{p(\hat{y} | x_i)},
\]

The notations are the same as in Equation 6 with the only difference that \(\tilde{x}_i^{(r)}\) is constructed by replacing the top \(r\%\) word features with the special token \(\langle \text{pad} \rangle\) in \(x_i\).

**Results** Figure 2 shows the results of AOPCs and log-odds scores of LSTM model on SST dataset. INTERSHAPLEY achieves the best performance on both evaluation metrics. Together with the other results in Appendix D, this evaluation demonstrate the effectiveness of our method in extracting keywords via feature importance scores, which lays a solid foundation for feature interaction detection.

The L- and C-Shapley perform worse on IMDB dataset than on SST data, because a small window size (2 as recommended) may cause relatively large error in approximating Shapley values for long sentences. The performance of LIME drops significantly on BERT comparing to the other two models, as Figure 10 shows, which suggests that this locally linear approximation may not be capable of deep neural network models. We also observed an interesting phenomenon that the simplest baseline Leave-one-out can achieve relatively good performance, even better than L- and C-Shapley, and CD. And we suspect that is because the criteria of Leave-one-out for picking keywords matches the evaluation metrics.

4.2 Phrase-level Evaluation

This section presents some evaluation on phrase-level explanations extracted with the proposed methods. Take the hierarchy in Figure 1 as an example, the set of phrases extracted from this hierarchical structure include \{waste of good performance, waste of good, of good\}. On phrase level, we can use the same way as in Equation 1 to compute importance scores. The quantitative evaluation in subsubsection 4.2.1 shows our method successfully captures the strongest interactions using a contrastive comparison, the qualitative analysis in subsubsection 4.2.2 illustrates how different levels of features interact with each other while contributing to final predictions.
4.2.1 Quantitative Evaluation

We evaluate the interaction effect of an important phrase by extracting the words within this phrase and then randomly insert them back to the original sentence. For example, in a sentence with \( n \) words \( \mathbf{x} = (x_1, \ldots, x_i, \ldots, x_j, \ldots, x_n) \), if \((x_i, \ldots, x_j)\) is the most important phrase, then for every word in \((x_i, \ldots, x_j)\), we randomly pick a position in \((x_1, \ldots, x_{i-1}, x_{j+1}, \ldots, x_n)\) and insert that word back. Let \( \bar{\mathbf{x}} \) be the newly constructed word sequence in this way. The quantitative evaluation is to compare the difference between \( p(\hat{y} | \mathbf{x}) \) and \( p(\hat{y} | \bar{\mathbf{x}}) \). Intuitively, by breaking the strong interaction within \((x_i, \ldots, x_j)\), it will lead to a significant drop on the probability of predicted label \( \hat{y} \). To obtain a robust evaluation, for each sentence \( \mathbf{x}_i \), we construct \( K \) different word sequences \( \{\bar{\mathbf{x}}_i^{(k)}\} \) \( K \) and compute the average as

\[
\text{Cohesion-loss} = \frac{1}{N} \sum_{i=1}^{N} \frac{1}{K} \sum_{k=1}^{K} (p(\hat{y} | \mathbf{x}_i) - p(\hat{y} | \bar{\mathbf{x}}_i^{(k)})), \tag{8}
\]

where \( \bar{\mathbf{x}}_i^{(k)} \) is the \( k \)th disturbed sample of \( \mathbf{x}_i \), and \( K = 100 \) is number of perturbations for each sentence. Note that when we pick the most important phrase, we consider the one whose length is no more than 5 as the explanation because a very long clause is uninterpretable. Then we calculate the average length of the most important phrases over all test data as the Average Explanation Length (Ave. Exp. length).

Table 2 shows the results of cohesion-loss of INTERSHAPLEY and ACD with different models on SST and IMDB datasets. On the IMDB dataset, we only tested on a subset with 2000 randomly selected samples due to computation costs. INTERSHAPLEY outperforms ACD with higher cohesion-loss and smaller average length of generated explanations on both datasets with LSTMs, which indicates that INTERSHAPLEY can capture more important and concise phrases. Comparing the results of INTERSHAPLEY among different models, the cohesion-loss drops on the LSTM model with IMDB dataset, indicating the model’s consistent ability to capture meaningful phrases. However, BERT performs the opposite. We reason that it is the length constraint on selected phrases that limits BERT’s performance, since BERT often utilizes a large range of context for predictions.

4.2.2 Qualitative Analysis

Figure 3 visualizes the hierarchical interpretations of INTERSHAPLEY and ACD for LSTM on a negative movie review from SST dataset, where red and green colors represent the negative and positive sentiments respectively. In this case, LSTM makes a wrong prediction as positive. INTERSHAPLEY gives correct positive and negative sentiments for bravura and emptiness respectively, and captures the interaction between them that bravura exercise flips the polarity of emptiness to positive, which explains why the model makes the wrong prediction. However, ACD incorrectly marks the two keywords with opposite polarities, and misses the feature interaction.
Table 2: Cohesion-loss and Average Explanation Length (Ave. Exp. length) of INTERSHAPLEY and ACD with different models on SST and IMDB dataset. As ACD is model-dependent, we only show its results on LSTM model by applying the code from the original work.

Figure 3: INTERSHAPLEY and ACD for LSTM on a negative movie review, where the importance scores of INTERSHAPLEY and CD scores are normalized for comparing. LSTM makes wrong prediction (positive). Red and green colors represent the negative and positive sentiments respectively.

Figure 4 visualizes INTERSHAPLEY for LSTM and BERT on a positive movie review, on which BERT makes a correct prediction, while LSTM makes a wrong prediction. The comparison between Figure 4(a) and Figure 4(b) shows the difference of feature interactions within the two models and explains why a model makes the correct/wrong prediction. For example, Figure 4(b) illustrates that BERT captures the key phrase not a bad in level 1, and thus makes the positive prediction, while LSTM (as shown in 4(b)) misses the interaction between not and bad, and the phrases not a and bad journey both push the model making the negative prediction. Due to the page limitation, more examples are presented in Appendix E.

4.3 HUMAN EVALUATION

We employ For a given text, we pick the most important feature, which can be a word or a phrase, with the highest importance score from the hierarchy as the explanation, and limit the length of the explanation no more than five words for the convenience of human evaluation. We evaluated the explanation by asking human annotators to guess the output of a model based on the explanation and the input text Nguyen (2018). For each example, human annotators was asked to pick a label from {NEGATIVE, POSITIVE, N/A} based on their understanding of the explanation. N/A means that the explanation may be some irrelevant words/phrase, and annotators cannot decide the model prediction. An example interface in shown in Appendix F. We measured the number of human annotations that are coherent with the actual model predictions, and defined the coherence score as the ratio between the coherent annotations and the total number examples. Ten human annotators were participated in this evaluation via Amazon Mechanical Turk (AMT).

We randomly pick 60 movie reviews from the IMDB dataset, half of which are used in one of the following experiments. First, we compare the explanations obtained from INTERSHAPLEY and ACD with LSTM model. For the same model, higher coherence score means that the explanations are more human understandable. Second, we apply INTERSHAPLEY to the three neural models, and compare the corresponding explanations. With the same explanation generation method, a more interpretable mode usually can achieve higher coherence score.

Results. Table 3 shows the coherence scores of the two interpretation methods. INTERSHAPLEY outperforms ACD with much higher coherence score, which means that the important features captured by INTERSHAPLEY are highly consistent with human comprehension in explaining model predictions. Table 4 shows the accuracy and coherence scores of different models. INTERSHAPLEY achieves relatively high coherence scores on all of the three neural networks, which validates its ability in interpreting black-box models. Although BERT can achieve higher prediction accuracy than other two models, its coherence score is lower, which illustrates that the interpretability of more complex model is even worse.

5 CONCLUSION

In this paper, we propose an effective method, INTERSHAPLEY, building model-agnostic hierarchical interpretations via detecting feature interactions. In this work, we mainly focus on sentiment classification task. We test INTERSHAPLEY with three different neural network models on two benchmark datasets, and compare it with several competitive baseline methods. The superiority of INTERSHAPLEY is approved by both automatic and human evaluations.

B  COMPARISON BETWEEN TOP-DOWN AND BOTTOM-UP APPROACHES

Given the sentence a waste of good performance for example. Figure 5 shows the hierarchical interpretations for the LSTM model using the bottom-up and top-down approaches respectively. Figure 5(a) shows that the interaction between waste and good can not be captured until the last (top) layer, while the important phrase waste of good can be extracted in the intermediate layer by top-down algorithm. We can see that waste flips the polarity of good to negative, causing the model predicting negative as well.

![Figure 5: Hierarchical interpretations for the LSTM model using the bottom-up and top-down approaches respectively. Red and green colors represent the negative and positive sentiments respectively.](image-url)
C EXPERIMENTAL SETUP

Models. In this work, we use a recurrent neural network (RNN) with uni-directional one-layer LSTM Hochreiter & Schmidhuber (1997), a CNN model with single convolutional layer Kim (2014), and BERT Devlin et al. (2018) which has achieved remarkable performance on a variety of NLP tasks including text classification. The CNN model includes a single convolutional layer with filters of the window sizes ranging from 3 to 5. The LSTM is also single layer with 300 hidden states. Both models are initialized with 300-dimensional pretrained word embeddings Mikolov et al. (2013). We use the pre-trained BERT model\(^1\) with 12 transformer layers, 12 self-attention heads, and the hidden size of 768, and fine-tune it in different downstream tasks to achieve the best performance.

Datasets. We use two benchmark datasets on text classification: the SST-2 corpus (Socher et al., 2013) and the IMDB corpus (Maas et al., 2011). SST-2 is the binary-class version of the Stanford sentiment treebank and IMDB is a balanced dataset with 25000 training examples and 25000 test examples. We split 90% of the training examples for training, and the rest as the development set.

Competitive Baselines. We compare our method with some competitive baselines, including Leave-one-out (Li et al., 2016), CD (Murdoch et al., 2018), L- and C-Shapley (Chen et al., 2018), and LIME (Ribeiro et al., 2016) for word-level explanation generation, and ACD (Singh et al., 2018) for phrase-level explanation generation.

D OTHER RESULTS OF AOPCS AND LOG-ODDS

(a) AOPCs of LSTM on IMDB dataset.  
(b) Log-odds of LSTM on IMDB dataset.

Figure 6: The AOPC and log-odds scores of LSTM on IMDB dataset.
