SELF-SUPERVISED LEARNING FOR CELL SEGMENTATION AND QUANTIFICATION IN DIGITAL PATHOLOGY IMAGES

Anonymous authors
Paper under double-blind review

ABSTRACT

Parkinson's Disease (PD) is the second most common neurodegenerative disease in humans. PD is characterized by the gradual loss of dopaminergic (DA) neurons in the Substantia Nigra (a part of the mid-brain). At present, counting the number of dopaminergic neurons in the Substantia Nigra is one of the most important indexes in evaluating drug efficacy in PD animal models. Currently, analyzing and quantifying dopaminergic neurons is conducted manually by expert biologists through careful analysis of digital pathology images. However, this approach is laborious, time-consuming, and highly subjective, which significantly delays the progress in PD research and drug development. As such, a reliable and unbiased automated system is highly demanded for the quantification of dopaminergic neurons in digital pathology images. To this end, in this paper, we propose an end-to-end deep learning framework for the segmentation and quantification of dopaminergic neurons in PD animal models. To the best of knowledge, this is one of the first machine learning model that detects the cell body of DA neurons, counts the number of DA neurons and provides the phenotypic characteristics of individual DA neurons in each section as a numerical output. Our framework relies on self-supervised learning advances to handle the limited amount of data for training deep models. Extensive experiments and correlation metrics demonstrate the effectiveness of the developed method in quantifying neurons with a very high precision. As a result, the proposed method can provide quicker turnaround for drug efficacy studies, better understanding of DA neuronal health status and unbiased results in PD pre-clinical research.

1 INTRODUCTION

Image segmentation is a fundamental tool to developing artificial intelligence medical imaging applications (Tajbakhsh et al., 2020), such as radiology and digital pathology. For instance, deep learning cell segmentation models can enable robust and fast approaches to quantify cells in histopathology images, enabling more sensitive analysis of biological experiments in animals and humans (Moshkov et al., 2020; Greenwald et al., 2022). However, deep learning models rely on large-scale high quality data, limiting their applications in biological use cases. In this paper we study the benefits of self-supervised learning techniques to develop robust neuronal cell segmentation and quantification models which are crucial for experimental disease models and gene-function studies. The developed model can be further optimized to separate adjacent neuronal cells for automatic quantification of neuronal cells.

In this study, we establish a deep learning-based framework for segmentation and quantification of Tyrosine Hydroxylase (TH) positive dopaminergic (DA) neurons in the Substantia Nigra (SN) of mouse brain tissues. SN is the area of the mid-brain that consists of DA neurons which are most susceptible to genetic and sporadic factors that cause their loss as observed in PD pathogenesis. TH is an enzyme that is specifically expressed in DA neurons. TH staining is the most reliable method used for detecting DA neurons. TH stains the soma (cell body), nucleus and the axons of DA neurons. Loss of dopaminergic neurons leads to motor neuron associated dysfunctions as observed in PD patients and animal models (Johnson et al., 2012). Preventing loss of dopaminergic neurons is the most important goal of PD targeting therapies. The TH staining intensity is also

an indicator of the health status of the DA neurons and is considered the most reliable method to identify loss of DA neurons (Ghosh et al., 2021). Pre-clinical research on Parkinson's disease is highly dependent on segmentation and quantification of DA neurons in the SN (Poewe et al., 2017; Guatteo et al., 2022). The unique morphology of DA neurons also makes it difficult to use generalized cell segmenting models to identify them and delve deeper into understanding the biology of DA neurons. Generalist cell segmentation model such as Cellpose have been developed to solve this problem but its efficiency in detecting specific type of neurons such as DA neurons is still limited (Robitaille et al., 2022). A generalist model does not provide additional information that is specific to DA neurons which holds high value in PD research. Hence, it has become crucial to develop a machine learning model that can analyze and quantify DA neurons precisely in the SN with a quick turnaround time and immune to user associated bias. This will in turn make a huge impact in the field of PD pre-clinical research by identifying the efficacy of potent drugs in a shorter time-frame and accelerating the possibility of taking a potential drug into the clinic.

Our model leverages a combination of data sampling techniques and cross-domain self supervised learning (Haghighi et al., 2022; Azizi et al., 2021) on both unlabeled natural images and domain specific pathology images to learn transferable and generalize representations for pathology images. Such representations can be further fine-tuned and deployed for the neuronal cell segmentation using limited labeled data from the biological experiments. We compare the performance of fine tuned model which is originally trained on different data, (1) natural images, (2) pathology images, or (3) natural images followed by digital pathology images. We next compare the predicted number of TH cells from our model to manual counts done by histopathology experts to investigate the accuracy of automated quantification. Furthermore, we analyze the effects of the combination of various augmentation methods on the segmentation performance of the model. Experimental results and extensive analysis indicate that our model can outperform existing models, especially in low data scenarios.

In summary, we make the following contributions:

- The first end-to-end framework for automatic segmentation and quantification of dopaminergic neurons in whole-slide digital pathology images of PD models.
- A cross-domain self-supervised pre-training approach that exploits the power of unlabeled natural and medical images for representation learning.
- A comprehensive set of experiments that demonstrate the effectiveness and efficiency of our model in detecting and quantifying DA neurons using a limited amount of annotated data.
- A numerical and visual data output to indicate the phenotypic characteristics of DA neurons segmented by the model

2 Related Works

CNN-based quantification of dopaminergic neurons. Deep learning methods have been successfully utilized in analyzing human digital pathology images for different tasks, including cell segmentation and cell counting (Falk et al., 2019; Greenwald et al., 2022; Moshkov et al., 2020; Hatipoglu & Bilgin, 2017). However, the number of studies that employ deep learning for the quantization of dopaminergic neurons in animal models of Parkinson's disease are relatively limited. Penttinen et al. (Penttinen et al., 2018) implemented a deep learning-based method for processing whole-slide digital imaging to count DA neurons in SN of rat and mouse models. This study leverages the TH positive nucleus to detect the TH cells which is susceptible to error because of the existence of other cells of the brain which also have a nucleus and overlap in the same area. Additionally, the architecture of DA neurons in SN makes it difficult to distinguish between overlapping cells when detected only relying on nucleus as annotations. Zhao et al. (Zhao et al., 2018) developed a framework for automatic localization of SN region and detection of neurons within this region. The SN localization is achieved by using a Faster-RCNN network, whereas neuron detection is done using a LSTM network. However, these studies are limited to counting neurons and/or detecting neuron locations and do not provide additional information about individual cells, such as cell attributes and morphology, which is essential for understanding the biology behind DA neuronal loss and its association with PD pathogenesis.

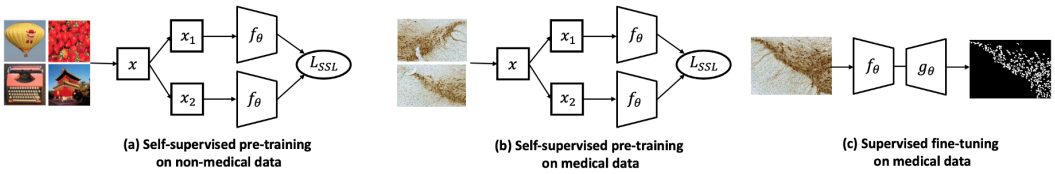

Figure 1: An overview of our approach. To address the annotated data scarcity challenge for training deep models, we perform (a) self-supervised pre-training on natural images, and then (b) self-supervised pre-training on digital pathology images. We finally (c) fine-tune the self-supervised pre-trained model with limited annotated data for target neuron segmentation task.

Self-supervised Learning. Self-supervised learning methods aim to learn generalizable representations from unlabeled data. This paradigm involves training a neural network on a manually created (pretext) task for which ground truth is obtained from the data. The learned representations can be transferred and fine-tuned for various target tasks with limited labeled data. Instance discrimination methods (Zbontar et al., 2021; He et al., 2020; Caron et al., 2021; Grill et al., 2020; Chen & He, 2021; Chen et al., 2020) have recently sparked a renaissance in the SSL paradigm. These methods consider each image as a separate class and seek to learn representations that are invariant to image distortions. Motivated by the success in computer vision, instance discrimination SSL methods have been adopted in medical applications. A recent transfer learning study for medical imaging (Hosseinzadeh Taher et al., 2021) demonstrated the efficacy of existing instance discrimination methods pre-trained on ImageNet for various medical tasks. A group of work focused on designing SSL frameworks by exploiting consistent anatomical structure within radiology scans (Haghighi et al., 2021; 2020). Another line of studies designed contrastive-based SSL for medical tasks (Taher et al., 2022; Azizi et al., 2021; Chaitanya et al., 2020; Kaku et al., 2021; Haghighi et al., 2022), including whole slide image classification (Li et al., 2021). In contrast to the previous works, our work is the first study that investigates the efficacy of SSL for digital pathology images of PD animal models to compensate the lack of large-scale annotated datasets for training deep learning models.

3 METHOD

3.1 ANIMAL STUDIES, ANNOTATIONS AND DATA-SET

The data-set used in this study was obtained by manually labeling 30,000 TH positive DA neurons in 2D histology digital images. This is an internal data-set. The digital images were obtained from multiple animal studies where mouse brains were sectioned at 35 micron thickness and stained with TH and either Haematoxylin or Nissl as a background tissue stain. The sections were then imaged using a whole slide scanner microscope, Nanozoomer system (Hamamatsu Corp, San Jose, CA) at 20x resolution (0.46 microns/pixel). Whole coronal brain section images containing the SN were exported from the digital scans at 20x resolution and were used to annotate the TH positive DA neurons and train the model. This procedure helped us to obtain a large data-set which consists of multiple internal data-sets and takes into account the variability that arises from different staining conditions. The ground truth (GT) for this study was labelled and quality controlled by biologists who specialize in mouse brain anatomy and PD research. The blind test data-set used for analyzing model's efficiency was a separate animal study in which the model has not been directly trained on the study group. The DA neurons were detected by the model (red) and visually represented to compare it with the manually counted neurons (blue) by the biologist.

3.2 SELF-SUPERVISED PRE-TRAINING

Our approach is established on continual self-supervised pre-training in which a model is first pre-trained on a massive general dataset, such as ImageNet, and then pre-trained on domain-specific datasets. For the first step (see Figure 1.a), we train the self-supervised model on the ImageNet dataset using state-of-the-art instance discrimination approaches, such as Barlow Twins (Zbontar et al., 2021). For the second step (see Figure 1.b), we continue the self-supervised pre-training on the

Pre-training	Initialization	Dice(%)
-	Random	86.43±0.96
Supervised	ImageNet	85.86±3.37

in-domain medical dataset. Finally, we fine-tune the pre-trained models for the neuron segmentation (target) task using labeled images (see Figure 1.c).

Barlow Twins (Zbontar et al., 2021). This SSL approach aims to reduce the amount of redundant information about each sample in the learnt representations while simultaneously making the representation invariance to image distortions. To do so, given an image sample X, two distorted views of the sample are generated by applying a data augmentation function $\mathcal{T}(.)$ on X. The two distorted views X_1 and X_2 are then processed by the backbone network f_θ to produce latent representations $Z_1 = f_\theta(\mathcal{T}(X_1))$ and $Z_2 = f_\theta(\mathcal{T}(X_2))$. The backbone network f_θ includes a standard ResNet-50 encoder and a three-layer MLP projection head. The model is trained by minimizing the following loss function:

$$\mathcal{L}_{SSL} = \sum_i (1 - \mathcal{C}_{ii})^2 + \lambda \sum_i \sum_{i \neq j} \mathcal{C}_{ij}^2 \tag{1}$$

where $\mathcal{C}$ is the cross-correlation matrix computed between Z_1 and Z_2 along the batch dimension. λ is a coefficient to identify the weight of each loss terms. The model is trained by making the cross-correlation matrix $\mathcal{C}$ close to the identity matrix. In particular, by equating the diagonal elements of the $\mathcal{C}$ to 1, the learned representation will be invariant to the image distortions. By equating the off-diagonal elements of the $\mathcal{C}$ to 0, the different elements of the representation will be decorrelated, so that the output units contain non-redundant information about the images.

4 Experiments and Results

4.1 Self-supervised models provide more generalizable representations

Experimental setup. In this experiment, we evaluate the transferability of three popular SSL methods using officially released models, including DeepCluster-v2 (Caron et al., 2021), Barlow Twins (Zbontar et al., 2021), and SwAV (Caron et al., 2021). All SSL models are pre-trained on the ImageNet dataset and employ a ResNet-50 backbone. As the baseline, we consider (1) training the target model from random initialization (without pre-training) and (2) transfer learning from the standard supervised pre-trained model on ImageNet, which is the *de facto* transfer learning pipeline in medical imaging (Azizi et al., 2021). Both baselines benefit from the same ResNet-50 backbone as the SSL models.

Results. Table 1a displays the results, from which we draw the following conclusions: (1) transfer learning from the supervised ImageNet model lags behind training from random initialization. We attribute this inferior performance to the remarkable domain shift between the pre-training and target tasks. In particular, supervised ImageNet models are encouraged to capture domain-specific semantic features, which may be inefficient when the pre-training and target data distributions are far apart. Our observation is in line with recent studies (Raghu et al., 2019) on different medical tasks suggests that transfer learning from supervised ImageNet models may offer limited performance gains when the target dataset scale is large enough to compensate for the lack of pre-training. (2) Transfer learning from self-supervised models provide superior performance compared with both training from random initialization and transfer learning from the supervised ImageNet model. In particular, the best self-supervised model (i.e. SwAV) yields 1.3% and 2.27% performance boosts compared with training from random initialization and the supervised ImageNet model, respectively. Intuitively, self-supervised pre-trained models, in contrast to supervised pre-trained models, encode features that are not biased to task-relevant semantics, providing improvement across domains. Our

observation in accordance with previous studies (Hosseinzadeh Taher et al., 2021) demonstrates the effectiveness of self-supervised ImageNet models for medical applications.

Pre-training Method	Pre-training Dataset	Dice(%)
Random	-	67.22±8.24
Barlow Twins	ImageNet	79.50±2.02
SwAV	ImageNet	80.83±1.17
Barlow Twins	In-domain	70.92±5.41
Barlow Twins	ImageNet→In-domain	**81.73±1.03**

Table 2: Comparison of pre-training dataset for self-supervised learning.

4.2 Self-supervised models provide superior performance in semi-supervised learning

Experimental setup. We conduct further experiments to evaluate the advantage that self-supervised pre-trained models can provide for small data regimes. To do so, we randomly select 25% of the training data and fine-tune the self-supervised pre-trained models on this subset of data. We then compare the performance of self-supervised models with training the target model from random initialization and fine-tuning the supervised ImageNet model.

Results. The results are shown in Table 1b. First, we observe that transfer learning from either supervised or self-supervised pre-trained models can offer significant performance improvements compared with training from random initialization. In particular, the supervised ImageNet model provides a 9.5% performance improvement compared to the random initialization of the target model. Moreover, self-supervised models– DeepCluster-v2, Barlow Twins, and SwAV, offer 11.5%, 12.3%, and 13.6% performance boosts, respectively, in comparison with random initialization. These observations imply the effectiveness of pre-training in providing more robust target models in low data regimes. Second, we observe that self-supervised models provide significantly better performance than the supervised ImageNet model. Specifically, DeepCluster-v2, Barlow Twins, and SwAV achieve 1.96%, 2.74%, and 4% performance boosts, respectively, compared to the supervised ImageNet baseline. These observations restate the efficacy of self-supervised models in delivering more generic representations that can be used for target tasks with limited data, resulting in reduced annotation costs.

4.3 Impact of pre-training data on self-supervised learning

Experimental setup. We investigate the impact of pre-training datasets on self-supervised learning. To do so, we train Barlow Twins on three data schemas, including (1) SSL on the ImageNet dataset, (2) SSL on the medical dataset (referred to as the in-domain), and (3) SSL on both ImageNet and in-domain datasets (referred to as ImageNet→In-domain). For ImageNet→In-domain pre-training, we initialize the model with SvAW pre-trained on ImageNet, followed by SSL on our in-domain dataset. We fine-tune all pre-trained models for the neuron segmentation task using 25% of training data.

Results. Table 2 shows the segmentation accuracy measured by the Dice score (%) for different pretraining scenarios. First, we observe that pre-training on only in-domain dataset yields lower performance than pre-training on only the ImageNet dataset. We attribute this inferior performance to the limited number of in-domain pre-training data compared with the ImageNet dataset (1500 vs. 1.3M). Moreover, we observe that the best performance is achieved when both ImageNet and in-domain datasets are utilized for pre-training. In particular, ImageNet→In-domain pre-training surpasses both in-domain and ImageNet pre-trained models. These results imply that pre-training on ImageNet is complementary to pre-training on in-domain medical datasets, resulting in more powerful representations for medical applications.

4.4 Dopaminergic Neuron Detection and counting

Experimental setup. The DA neurons segmented by the model were compared to the DA neurons detected by a biologist in the same tissue section from the blind data-set. The biologist detected

Table 4: Ablation Experiments.

the DA neurons and counted them manually on an image analysis platform ImageJ. The output from the model was overlaid with the manually detected cells and based on the color coding of the DA neurons by the model, the true positive (TP), false positive (FP) and false negative (FN) were calculated by the biologist. We calculated precision, recall and F1-score metrics for the detected neurons in the test images. In these measures, TP is the number of neurons successfully detected by the model; FP is the number of neurons detected by the model but are not actually neurons; and FN is the number of neurons not detected by the model. We further compare the performance of our method in neuron counting to human counting. To do so, we calculate the percentage error between the total number of neurons counted by our method and human counting. We also conduct an ablation study to illustrate the superiority of our cell counting method over the naive approach of counting cells by the number of connected components in the images.

Results. The performance metrics for neuron detection are shown in Table 3a. As seen, our method can effectively detect dopaminerginc neurons in whole-slide digital pathology images; in particular, our approach achieves a precision, recall, and F1-score of 95.25%, 95.49%, and 95.31%, respectively. Moreover, Table 3b presents the neuron counting results against human counting. As seen, automatic counting of the cells through computing the connected components within segmentation masks yields an error rate of 21.66%, while incorporating the connected components' sizes in counting significantly decreases the error rate to 9%. This results demonstrate the effectiveness of our approach in handling the overlapping neurons and providing a reliable automatic system for neuron counting.

4.5 Ablation Experiments

Experimental setup. We conduct extensive ablation experiments on different data augmentation techniques and network architectures. We examine seven different combinations of transformation that are commonly used in the literature, including (1) no augmentation (mode 1), (2) Flip, Rotation, RandomBrightnessContrast, and RandomGamma (mode 2), (3) Flip, Rotation, RGBShift, Blur, GaussianNoise (mode 3), (4) Flip, Rotation, RGBShift, Blur, GaussianNoise, RandomResizedCrop (mode 4), (5) Flip, Rotation, RGBShift, Blur, GaussianNoise, RandomResizedCrop, Elastic Transformation (mode 5), (6) Flip, Rotation, RandomBrightnessContrast, RandomGamma, RGBShift, Blur, GaussianNoise, RandomResizedCrop (mode 6), and (7) Flip, Rotation, RandomBrightnessContrast, RandomGamma, RGBShift, Blur, GaussianNoise, RandomResizedCrop, Elastic Transformation (mode 7). For network architectures, we examine U-Net and DeepLabV3+. In ablation experiments, all models are initialized with SvAW pre-trained model and fine-tuned with 25% of data.

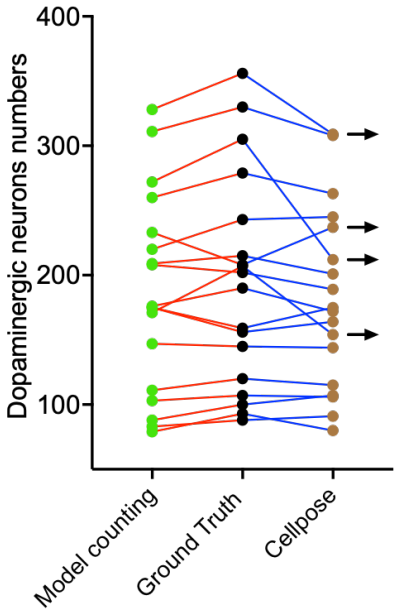
Figure 4: Correlation plot depicting the number of DA neurons counted by a biologist vs the number of DA neurons counted by the model. Blind data set was used to count the neurons from 18 brain sections stained with TH staining to identify the DA neurons and Nissl stain to stain the brain tissue. The sections for this study were chosen from multiple animal studies.

Results. Table 4a shows the results of different data augmentation techniques. According to these results, the lowest performance comes from mode 1 (no augmentation), highlighting that combining pre-training with data augmentation techniques yields more accurate segmentation results for downstream tasks with limited amounts of data. Additionally, the combination of Flip, Rotation, RGBShift, Blur, GaussianNoise, RandomResizedCrop (mode 4) provides the best performance among all data augmentation approaches. This implies that color transformations such as RGBShift, Blur, and GaussianNoise can help the deep model in gleaning more generalizable representations. Furthermore, a comparison of the results obtained by modes 3 and 4, the latter of which includes an additional RandomResizedCrop, reveals that random cropping significantly contributes to performance improvements. Moreover, a comparison of the results obtained by modes 4 and 5, the latter of which includes an additional elastic transformation, demonstrates that elastic transformation has a negative impact on performance; the same observation can be drawn from the comparison of modes 6 and 7.

Table 4b presents the results of different network architectures for downstream neuron segmentation task. As seen, U-Net, which was originally designed for medical segmentation tasks, provides superior performance over DeepLabV3+.

4.6 Qualitative results

Experimental setup. We visualize the segmentation results of our best model from Table 1on the test data. To do so, we first employ zero padding to make the size of the test images equal to a



ANOVA summary	
F	0.1309
P value	0.8776
P value summary	ns
Significant diff. among means (P < 0.05)?	No
R squared	0.005108

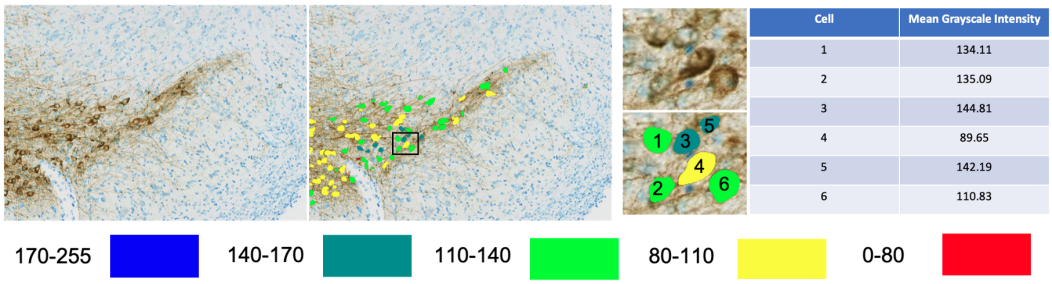
Model counting vs. Ground Truth	-8.556	-67.54 to 50.43	No	ns	>0.9999
Model counting vs. Cellpose	4.278	-54.71 to 63.26	No	ns	>0.9999

Figure 5: Data showing the comparison between Cellpose model and the model developed in this study to count DA neurons in individual sections. The green, black and brown dots depict the cells counted by the model, ground truth (GT) and Cellpose respectively. The red lines indicate the comparison between GT and the Model. The blue lines indicate the comparison between GT and Cellpose. Sections were selected from the blind dataset.

power of 512. Then, we divide the test images into non-overlapping 512×512 patches and then feed patches to the network. We then assemble the model's predictions for images patches to generate the prediction for the whole image. To examine the model's efficiency in counting DA neurons, a biologist counted the cells manually (Ground Truth) in the same section (blind dataset). We then ran a correlation statistics to measure the R^2 between the model and the GT. We additionally compared the GT to the latest generalist cell segmentation model- Cellpose and ran a correlation statistics to compare. Finally, the counts for DA neurons from our model, GT and Cellpose were plotted head to head to examine the efficiency of our model.We measured the TH intensity after converting the image into grayscale (8-bit, 0-255 range). The lower the number or closer to 0, the darker the stain is. The higher the number or closer to 255, the lighter the stain. The TH intensity was measured on ImageJ, a platform used to analyze digital data.

Results. Figures 2 and 3 presents the visualization of the segmentation results from our best model. As seen, our method can effectively detect and segment the dopaminergic neurons of varying size and shape. Our quantitative results in Table 1, together with the qualitative results in Figures 2 and 3 demonstrate the capability of our framework in providing an effective solution for segmentation of dopaminergic neurons. Figure 4 shows the correlation plot between GT and model counted DA neurons. R^2 of 0.95 with a $pvalue < 0.0001$ was achieved by our model in correlation statistical analysis. Under same parameters and dataset, Cellpose achieved a R^2 of 0.89 with a $pvalue <$



Cell	Mean Grayscale Intensity

The bottom panel shows the intensity color legend, a magnified view of several cells outlined in the black box above and a table of mean grayscale intensity value for each cell.

0.0001 in the correlation statistical analysis Supplemental Figure 1. In Figure 5, the statistics shows there is not significant changes between the DA neurons counted by the model or Cellpose when compared to GT (One way ANOVA followed by post-hoc analysis). Deeper analysis into the data shows that Cellpose had a significant difference from GT in three sections but our model was able to detect the DA neurons with higher accuracy.Figure 6 shows the TH intensity (brown color) of individual DA neuronal cell body in 5 different gradients. The gradient was obtained by measuring the TH intensity for an entire data-set and splitting it into 5 different groups and a visual and numerical data was obtained for each neuron.

5 Conclusion

The goal of this study was to develop a robust machine learning model that can detect and count the DA neurons reliably in independent animal studies. This is an immediate requirement in the field of PD research to accelerate the in-vivo screening of potential drugs so that more drugs can be taken into the clinic for human trials. The existing manual counting or stereology based method is unable to keep up with the number of studies currently conducted in different labs focusing on this area. Additionally, it also suffers from human bias which makes the data interpretation extremely cumbersome. The study framework is established on a self-supervised learning paradigm to combat the lack of large-scale annotated data for training deep models. We also realized that using segmentation based methods facilitated us to go beyond counting the number of DA neurons which the existing machine learning models are implementing (2 references) In addition to counting the DA neurons, we were able to obtain phenotypic characteristics of the DA neurons which is very valuable to the scientific community. For such task, there are always challenges to consider such as limited datasets, staining profile of tissues, overlapping cells but our model has demonstrated very high efficiency taking into consideration all these factors. With the advancement in machine learning and biology, these models will improve and provide solutions to the ever increasing demand for data-analysis in research biology. Our data suggests that we could extrapolate this method to other species that are used as animal models in PD. With the addition of more dataset, we could go deeper in understanding the biology of DA neuronal loss by capturing the changes which are visible or sometimes not visible to the human eye. To summarize, this method will be very useful to shorten the time needed to analyze loss of DA neurons in animal studies and accelerate the drug discovery of PD.
