

ACCELERATING DIFFUSION TRANSFORMERS WITH TOKEN-WISE FEATURE CACHING

Anonymous authors

Paper under double-blind review

ABSTRACT

Diffusion transformers have shown significant effectiveness in both image and video synthesis at the expense of huge computation costs. To address this problem, feature caching methods have been introduced to accelerate diffusion transformers by caching the features in previous timesteps and reusing them in the following timesteps. However, previous caching methods ignore that different tokens exhibit different sensitivities to feature caching, and feature caching on some tokens may lead to $10\times$ more destruction to the overall generation quality compared with other tokens. In this paper, we introduce token-wise feature caching, allowing us to adaptively select the most suitable tokens for caching, and further enable us to apply different caching ratios to neural layers in different types and depths. Extensive experiments on PixArt- α , OpenSora, and DiT demonstrate our effectiveness in both image and video generation with no requirements for training. For instance, $2.36\times$ and $1.93\times$ acceleration are achieved on OpenSora and PixArt- α with almost no drop in generation quality.

1 INTRODUCTION

Diffusion models (DMs) have demonstrated impressive performance across a wide range of generative tasks such as image generation (Rombach et al., 2022) and video generation (Blattmann et al., 2023). Recently, the popularity of diffusion transformers further extends the boundary of visual generation by scaling up the parameters and computations (Peebles & Xie, 2023). However, a significant challenge for diffusion transformers lies in their high computational costs, leading to slow inference speeds, which hinder their practical application in real-time scenarios. To address this, a series of acceleration methods have been proposed, focusing on reducing the sampling steps (Song et al., 2021) and accelerating the denoising networks (Bolya & Hoffman, 2023; Fang et al., 2023).

Among these, cache-based methods (Ma et al., 2024b; Wimbauer et al., 2024), which accelerate the sampling process by reusing similar features across adjacent timesteps (*e.g.* reusing the features cached at timestep t in timestep $t - 1$), have obtained abundant attention in the industrial community thanks to their plug-and-play property. As the pioneering works in this line, DeepCache (Ma et al., 2024b) and Block Caching (Wimbauer et al., 2024) were proposed to reuse the cached features in certain layers of U-Net-like diffusion models by leveraging the skip connections in the U-Net. However, the dependency on the U-Net architectures also makes them unsuitable for diffusion transformers, which have gradually become the most powerful models in visual generation. Most recently, FORA (Selvaraju et al., 2024) and Δ -DiT (Chen et al., 2024b) have been proposed as a direct application of previous cache methods to diffusion transformers, though still not fully analyzed and exploited the property of the transformer-architecture. To tackle this challenge, this paper begins by studying how feature caching influences diffusion transformers at the token level.

Difference in Temporal Redundancy: Figure 1 shows the distribution of the feature distance between the adjacent timesteps for different tokens, where a higher value indicates that this token exhibits a lower similarity in the adjacent timesteps. It is observed that there exist some tokens that show relatively lower distance (in light blue) while some tokens show extremely higher distance (in dark blue), almost $2.5\times$ larger than the mean distance, indicating caching such tokens can lead to an overlarge negative influence. This observation indicates that *different tokens have different redundancy across the dimension of timesteps*, (*i.e.* different temporal redundancy).

Figure 1: **Temporal Redundancy:** Distribution of the distance between the feature of tokens in the previous and the current timestep.

Figure 2: **Error Propagation:** Distribution of the error in the final layer output when the same noise is applied to each token in the first layer.

Difference in Error Propagation: Figure 2 introduces the other interesting perspective of *error propagation* in diffusion transformers. Specifically, self-attention and cross-attention layers are widely utilized in diffusion transformers to formulate the dependency between different tokens. As a result, the error in one of the tokens may propagate to some other tokens by self-attention and finally result in the error in all of the tokens. To understand the error propagation in tokens of diffusion transformers, we apply Gaussian noise with the same intensity to each token and compute the resulting error in all the tokens in the output of the final layer. Surprisingly, Figure 2 shows that the same noise in different tokens leads to significantly different propagation errors, with the largest propagation error being more than $10\times$ the smallest one. In the context of feature caching, this indicates that *the same error introduced by feature cache can result in vastly different errors in the final generation result due to error propagation*.

Moreover, we have also investigated the difference of the tokens in layers of different depths and types, which demonstrates significant differences, as introduced in the following sections. In summary, different tokens exhibit *significant differences* in their sensitivities to feature caching, indicating that they deserve different priorities during the caching process. This motivates us to study the token-wise feature caching strategy, which aims to select the maximal number of tokens to maximize the acceleration ratio while minimizing the resulting error introduced by the feature caching by selecting the tokens that make the least caching error.

To tackle this challenge, this paper introduces Token-wise Caching ToCa for training-free acceleration of diffusion transformers, which provides a fine-grained caching strategy for different tokens in the same layer and the tokens in different layers. The core challenge of ToCa is to accurately select the tokens that are suitable for feature caching with the computation-cheapest operations. Consistent with the two previous analyses, we mainly study this problem from the perspective of *temporal redundancy* and *error propagation* by defining four scores for token selection. Specifically, for *temporal redundancy*, we try to select the tokens with the highest similarity (*i.e.* lowest difference) with their value in the previous timesteps by considering their frequency of being cached, as well as their distribution in the spatial dimension of the images. For *error propagation*, we attempt to cache the tokens which makes the least influence on other tokens based on their attendance in self-attention and cross-attention layers. Besides, all of these scores can be obtained without any additional computation costs.

Extensive experiments on text-to-image, text-to-video and class-to-image generation demonstrate the effectiveness of ToCa on PixArt- α , OpenSora, and DiT over previous feature caching methods. For instance, $2.36\times$ acceleration can be achieved on OpenSora without requirements for training, outperforming halving the number of timesteps directly by 1.56 on VBench. On PariPrompt, ToCa even leads to 1.13 improvements on CLIP Score, indicating higher consistency to the text conditions.

In summary, the contributions of this paper are as follows:

1. We propose Token-wise Caching (ToCa) as a fine-grained feature caching strategy tailored to acceleration for diffusion transformers. To the best of our knowledge, ToCa first introduces the perspective of error propagation in feature caching methods.
2. We introduce four scores to select the most suitable tokens for feature caching in each layer with no additional computation costs. Besides, ToCa enables us to apply different caching ratios in layers of different depths and types, and also bring a bag of techniques for feature caching.
3. Abundant experiments on PixArt- α , OpenSora, and DiT have been conducted, which demonstrates that ToCa achieves a high acceleration ratio while maintaining nearly lossless generation quality. Our codes have been released for further exploration in this domain.

2 RELATED WORK

Transformers in Diffusion Models Diffusion models (DMs) (Ho et al., 2020; Sohl-Dickstein et al., 2015), which iteratively denoise an initial noise input through a series of diffusion steps, have achieved remarkable success across various generation applications (Rombach et al., 2022; Balaji et al., 2022). Early DMs (Ho et al., 2020; Rombach et al., 2022) are based on the U-Net architecture (Ronneberger et al., 2015), consistently achieving satisfactory generation results. Recently, Diffusion Transformer (DiT) (Peebles & Xie, 2023) has emerged as a major advancement by replacing the U-Net backbone with a Transformer architecture. This transition enhances the scalability and efficiency of DMs across various generative tasks (Chen et al., 2024a; Brooks et al., 2024). For example, PixArt- α (Chen et al., 2024a) utilizes DiT as a scalable foundational model, adapting it for text-to-image generation, while Sora (Brooks et al., 2024) demonstrates DiT’s potential in high-fidelity video generation, inspiring a series of related open-source projects (Zheng et al., 2024; Lab & etc., 2024). Despite their success, the iterative denoising process of these DMs is significantly time-consuming, making them less feasible for practical applications.

Acceleration of Diffusion Models To improve the generation efficiency of DMs, numerous diffusion acceleration methods have been proposed, falling broadly into two categories: (1) *reducing the number of sampling timesteps*, and (2) *accelerating the denoising networks*.

The first category aims to achieve high-quality generation results with fewer sampling steps. DDIM (Song et al., 2021) introduces a deterministic sampling process that reduces the number of denoising steps while preserving generation quality. DPM-Solver (Lu et al., 2022a) and DPM-Solver++ (Lu et al., 2022b) propose adaptive high-order solvers for a faster generation without compromising on generation results. Rectified flow (Liu et al., 2023) optimizes distribution transport in ODE models to facilitate efficient and high-quality generation, enabling sampling with fewer timesteps. Step-distillation (Salimans & Ho, 2022; Meng et al., 2023) minimizes the number of timesteps with knowledge distillation from multiple timesteps to fewer ones. Consistency models (Song et al., 2023) accelerate generative modeling by mapping noise directly to data and enforcing self-consistency across steps. In the second category, various efforts have been paid to token reduction (Bolya & Hoffman, 2023), knowledge distillation (Li et al., 2024), and weight quantization (Li et al., 2023b; Shang et al., 2023) and pruning (Fang et al., 2023) on the denoising networks. Additionally, recent cache-based methods reduce redundant computations to accelerate inference for DMs. These cache-based methods have obtained abundant attention since they have no requirements for additional training. DeepCache (Ma et al., 2024b) eliminates redundant computations in Stable Diffusion (Rombach et al., 2022) by reusing intermediate features of low-resolution layers in the U-Net. Faster Diffusion (Li et al., 2023a) accelerates the sampling process of DMs by caching U-Net encoder features across timesteps, skipping encoder computations at certain steps. Unfortunately, DeepCache and Faster Diffusion are designed specifically for U-Net-based denoisers and can not be applied to DiT (Chen et al., 2024b). Recently, FORA (Selvaraju et al., 2024) and Δ -DiT (Chen et al., 2024b) have been proposed to cache the features and the residual of features for DiT. Learning-to-Cache (Ma et al., 2024a) learns an optimal cache strategy, which achieves a slightly higher acceleration ratio but introduces the requirements of training. However, these methods apply the identical cache solution to all the tokens and even all the layers, which leads to a significant performance degradation in generation quality.

3 METHODOLOGY

3.1 PRELIMINARY

Diffusion Models Diffusion models are formulated to contain two processes, including a forward process which adds Gaussian noise to a clean image, and a reverse process which gradually denoises a standard Gaussian noise to a real image. By denoting t as the timestep and β_t as the noise variance schedule, then the conditional probability in the reverse (denoise) process can be modeled as

$$p_{\theta}(x_{t-1} | x_t) = \mathcal{N}\left(x_{t-1}; \frac{1}{\sqrt{\alpha_t}} \left(x_t - \frac{1 - \alpha_t}{\sqrt{1 - \bar{\alpha}_t}} \epsilon_{\theta}(x_t, t)\right), \beta_t \mathbf{I}\right), \quad (1)$$

where $\alpha_t = 1 - \beta_t$, $\bar{\alpha}_t = \prod_{i=1}^T \alpha_i$, and T denotes the number of timesteps. Importantly, ϵ_{θ} denotes a denoising network with its parameters θ that takes x_t and t as the input and then predicts the

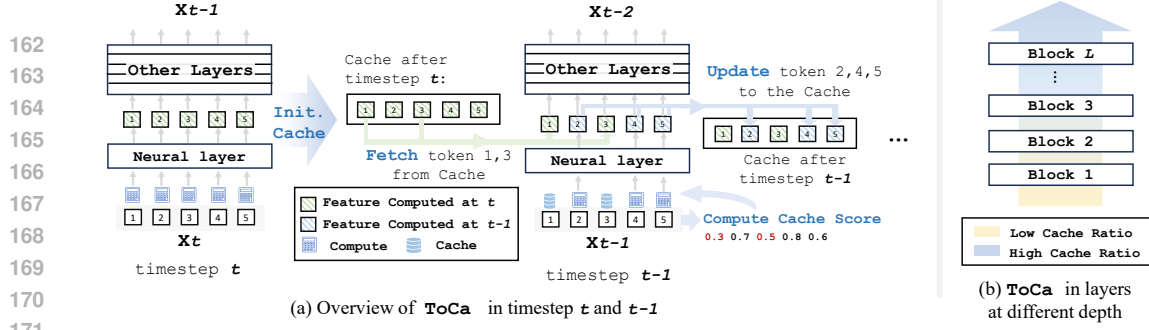

Figure 3: The overview of ToCa on the example of the first layer with caching ratio $R = 40\%$. (a) In the first timestep of the cache period, ToCa computes all the tokens and stores them in the cache for initialization. Then, in the next timestep, ToCa first computes the caching score of each token and selects the tokens for cache based on them. Then, ToCa fetches the features of cached tokens from the cache while performing real computations in the other tokens. Then, the features of tokens that have been computed are utilized to update their value in the cache. (b) ToCa applies a higher cache ratio in the deep layer and a relatively lower cache ratio in the shallow layers.

corresponding noise for denoising. For image generation with \mathcal{T} timesteps, ϵ_θ is required to infer for \mathcal{T} times, which takes most of the computation costs in the diffusion models. Recently, fruitful works demonstrate that formulating ϵ_θ as a transformer usually leads to better generation quality.

Diffusion Transformer Diffusion transformer models are usually composed of stacking groups of self-attention layers f_{SA} , multilayer perceptron f_{MLP} , and cross-attention layers f_{CA} (for conditional generation). It can be roughly formulated as $g_1 \circ g_2 \circ \dots \circ g_L$ where $g^i = \{f_{SA}^i, f_{CA}^i, f_{MLP}^i\}$. The upper script denotes the index of layer groups and L denotes its maximal number. We omit the other components such as layer norm and residual connections here for simplicity. For diffusion transformers, the input data \mathbf{x}_t is a sequence of tokens corresponding to different patches in the generated images, which can be formulated as $\mathbf{x}_t = \{x_i\}_{i=1}^{H \times W}$, where H and W denote the height and width of the images or the latent code of images, respectively.

3.2 NAIVE FEATURE CACHING FOR DIFFUSION TRANSFORMERS

We follow the naive scheme for feature caching adopted by most previous caching methods (Ma et al., 2024b) for diffusion denoisers. Given a set of \mathcal{N} adjacent timesteps $\{t, t+1, \dots, t+\mathcal{N}-1\}$, naive feature caching performs the complete computation at the first timestep t and stores the intermediate features in all the layers, which can be formulated as $\mathcal{C}(\mathbf{x}_t) := f(\mathbf{x}_t^l)$, for $\forall l \in [0, L]$, where “ $:=$ ” indicates the operation of assigning the value. Then, in the next $\mathcal{N}-1$ timesteps, feature caching avoids the computation of self-attention, cross-attention, and MLP layers by reusing the feature cached at timestep t . By denoting the cache as \mathcal{C} and the expected feature of the input \mathbf{x}_t in the l_{th} layer as $\mathcal{F}(\mathbf{x}_t^l)$, then for $\forall l \in [1, L]$, the naive feature caching can be formulated as

$$\mathcal{F}(\mathbf{x}_{t+1}^{l-1}) = \mathcal{F}(\mathbf{x}_{t+2}^{l-1}) = \dots = \mathcal{F}(\mathbf{x}_{t+\mathcal{N}}^{l-1}) := \mathcal{C}(\mathbf{x}_t^l). \quad (2)$$

In these \mathcal{N} timesteps, naive feature caching avoids almost all the computation in $\mathcal{N}-1$ timesteps, leading to around $\mathcal{N}-1$ times acceleration. After the \mathcal{N} timesteps, the feature cache then starts a new period from initializing the cache as aforementioned, again. The effectiveness of feature caching can be explained by the extremely low difference between the tokens in the adjacent timesteps. However, as \mathcal{N} increases, the difference between the feature value in the cache and their correct value can be exponentially increased, leading to degeneration in generation quality, which motivates us to study more fine-grained methods for feature caching.

3.3 TOKEN-WISE FEATURE CACHING

The naive feature caching scheme caches all the tokens of the diffusion transformers with the same strategy. However, as demonstrated in Figure 1, 2 and 5, feature cache introduces significantly different influence to different tokens, motivating us to design a more fine-grained caching method in the token-level. In this section, we begin with the overall framework of ToCa, then introduce our strategy for token selection and caching ratios.

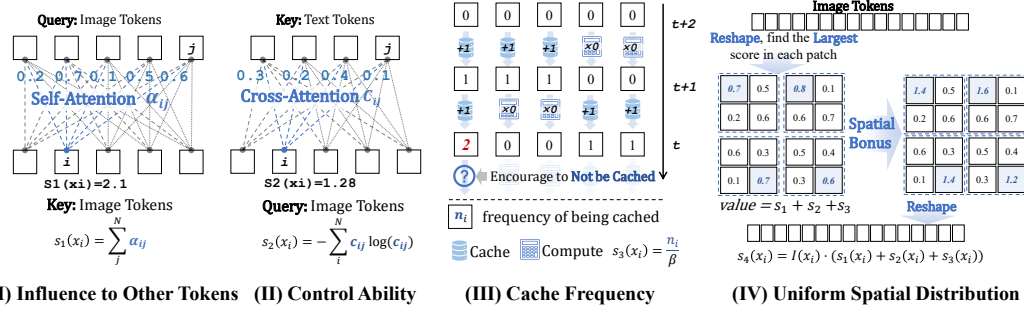

Figure 4: The computation of caching scores in ToCa, where a token with a **lower cache score** is encouraged to be **cached**: (I) Self-attention weights are utilized to measure the influence of each token on the other tokens, where a token with higher influence is considered not suitable for caching. (II) Cross-attention weights are utilized to measure the influence of each image token on the text (condition) tokens, where an image token with higher entropy is considered not suitable for caching. (III) Tokens that have been cached multiple times are encouraged to not be cached in the following layers. (IV) We increase the cache score for the token with the largest cache score in its neighboring pixels to make the cached tokens distributed uniformly in the spatial dimension.

3.4 OVERALL FRAMEWORK

Cache Initialization Similar to previous caching methods, given a set of adjacent timesteps $\{t, t+1, \dots, t+\mathcal{N}-1\}$, our method begins with computing all the tokens at the first timestep t , and storing the computation result (intermediate features) of each self-attention, cross-attention, and MLP layer in a cache, denoted by \mathcal{C} , as shown in the left part in Figure 3. This can be considered as the initialization of \mathcal{C} , which has no difference compared with previous caching methods.

Computing with the Cache In the following timesteps, we can skip the computation of some unimportant tokens by re-using their value in the cache \mathcal{C} . We firstly pre-define the *cache ratio* R of tokens in each layer, which indicates that the computation of $R\%$ of the tokens in this layer should be skipped by using their value in the cache, and the other $(1-R\%)$ tokens should still be computed. To achieve this, a caching score function \mathcal{S} is introduced to decide whether a token should be cached, which will be detailed in the next section. Then, with \mathcal{S} , we can select a set of cached tokens as $\mathcal{I}_{\text{Cache}}$ and the other set of tokens for real computation as $\mathcal{I}_{\text{Compute}} = \{x_i\}_{i=1}^N - \mathcal{I}_{\text{Cache}}$. Then, the computation of the layer f for i_{th} token x_i can be formulated as $\mathcal{F}(x_i) = \gamma_i f(x_i) + (1-\gamma_i)\mathcal{C}(x_i)$, where $\gamma_i = 0$ for $i \in \mathcal{I}_{\text{Cache}}$ and $\gamma_i = 1$ for $i \in \mathcal{I}_{\text{Compute}}$. $\mathcal{C}(x_i)$ denotes fetching the cached value of x_i from \mathcal{C} , which has no computation costs and hence leads to overall acceleration in f .

Cache Updating As a significant difference between traditional cache methods and ToCa, traditional cache methods only update the feature in the cache at the first timestep for each caching period while ToCa can update the feature in the cache at all the timesteps, which helps to reduce the error introduced by feature reusing. For the tokens $x_i \in \mathcal{I}_{\text{Compute}}$ which are computed, we update their corresponding value in the cache \mathcal{C} , which can be formulated as $\mathcal{C}(x_i) := \mathcal{F}(x_i)$ for $i \in \mathcal{I}_{\text{Compute}}$.

3.5 TOKEN SELECTION

Given a sequence of tokens $\mathbf{x}_t = \{x_i\}_{i=1}^N$, token selection aims to select the tokens that are suitable for caching. To this end, we define a caching score function $\mathcal{S}(x_i)$ to decide whether the i_{th} token x_i should be cached, where a token with a higher score has a lower priority for caching and a higher priority to be actually computed. The $\mathcal{S}(x_i)$ is composed of four sub-scores $\{s_1, s_2, s_3, s_4\}$, corresponding to the following four principals.

(I) Influence to Other Tokens: If a token has a significant contribution to the value of other tokens, then the error caused by token caching on this token can easily propagate to the other tokens, ultimately leading to discrepancies between all tokens and their correct values. Consequently, we consider the contribution of each token to other tokens as one of the criteria for defining whether it should be cached, estimated with an attention score in self-attention. Recall that the self-attention can be formulated as $\mathbf{O} = \mathbf{A}\mathbf{V}$, where $\mathbf{A} = \text{Softmax}(\frac{\mathbf{Q}\mathbf{K}^T}{\sqrt{d}}) \in \mathbb{R}^{N \times N}$ denotes the normalized attention map. \mathbf{Q} , \mathbf{K} , \mathbf{V} and $\mathbf{O} \in \mathbb{R}^{N \times d}$ are query, key, value and output tokens respectively; d is the hidden size of each token and N is the total number of tokens. More specifically, the i_{th} output

Figure 5: (a) The distance between features at the last timestep and the current timestep for features in different layer depths. (b) The distribution of errors in the output of the final layer when the same Gaussian noise is applied to tokens in different layer depths. (c) The distribution of errors in the output of the final layer when the same Gaussian noise is applied to tokens in different layer types.

token is obtained through $o_i = \sum_{j=1}^N \alpha_{ij} v_j$, where α_{ij} is the (i, j) element of the attention map \mathbf{A} , denoting the contribution of value token v_j to the output token o_j . With these notations, we define s_1 to measure the contribution of x_i to other tokens as $s_1(x_i) = \lambda_1 \sum_{i=1}^N \alpha_{ij}$, as shown in Figure 4(a).

(II) Influence to Control Ability: The control ability of diffusion models in the text-to-image generation is usually achieved with a cross-attention layer which injects the control signal (*e.g.* text) into the image tokens. Hence, the cross-attention map reflects how each image token is influenced by the control signal. In this paper, we define the image tokens that are influenced by more tokens in the control signal as the tokens that are not suitable for caching, since the caching error on these tokens leads to more harm in the control ability. Specifically, by denoting c_{ij} as the (i, j) element in the cross attention score $\mathbf{C} = \text{Softmax}(\frac{\mathbf{QK}_{\text{text}}^T}{\sqrt{d}})$, where \mathbf{K}_{text} denotes the keys of text tokens (control tokens). Then, as shown in Figure 4(b), we employ the entropy $H(x_i)$ of the cross-attention weight for each image token x_i as its influence on the control-ability of diffusion models, which can be formulated as $s_2(x_i) = H(x_i) = -\sum_{j=1}^N c_{ij} \log(c_{ij})$.

(III) Cache Frequency: We observe that when a token is cached across multiple adjacent layers, the error introduced by feature caching in this token can be quickly accumulated, and the difference between it and its correct value can be exponentially amplified, which significantly degrades the overall quality of images. Hence, we define recently cached tokens as unsuitable for cache in the next layers and time steps. Conversely, the tokens that have not been cached for multiple layers and timesteps are encouraged to be cached. As shown in Figure 4(c), this selection rule is achieved by recording the times of being cached for each token after their last real computation, which can be formulated as $s_3(x_i) = \frac{n_i}{N}$, where n_i represents the number of times that x_i has been cached after its last computation. N is the number of timesteps in each feature caching cycle.

(IV) Uniform Spatial Distribution: The pixels in the neighboring patch of the images usually contain similar information. As discussed in previous works, overwhelmingly pruning the information in a local spatial region may result in significant performance degradation in the whole images (Bolya & Hoffman, 2023). Hence, to guarantee that the errors introduced by caching are not densely distributed in the same spatial region, we define the following scoring function: $s_4(x_i) = \mathcal{I}(x_i) \cdot (\lambda_1 \cdot s_1(x_i) + \lambda_2 \cdot s_2(x_i) + \lambda_3 \cdot s_3(x_i))$, where $\mathcal{I}(x_i)$ is an indicator function which equals to 1 if x_i has the highest score of $\lambda_1 \cdot s_1(x_i) + \lambda_2 \cdot s_2(x_i) + \lambda_3 \cdot s_3(x_i)$ in its neighboring $k \times k$ pixels and 0 in the other settings, and λ_j are hyper-parameters to balance each score.

In summary, the overall caching score of x_i can be formulated as

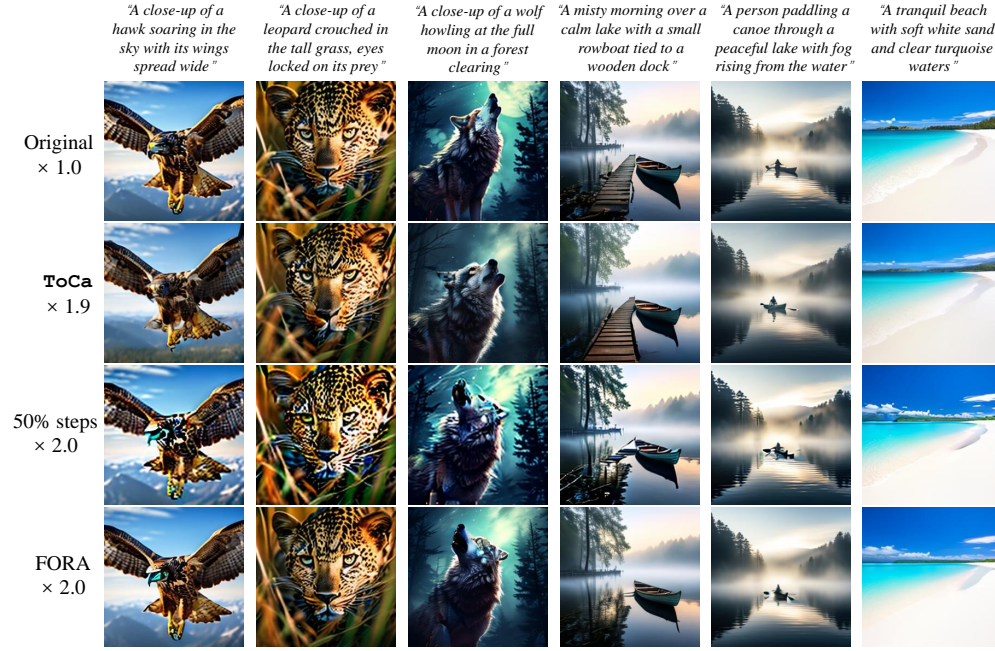

$$\mathcal{S}(x_i) = \lambda_1 \sum_{i=1}^N \alpha_{ij} - \lambda_2 \sum_{j=1}^N c_{ij} \log(c_{ij}) + \lambda_3 \frac{n_i}{N} + \lambda_4 \mathcal{I}(x_i) \cdot \left(\lambda_1 \sum_{i=1}^N \alpha_{ij} - \lambda_2 \sum_{j=1}^N c_{ij} \log(c_{ij}) + \lambda_3 \frac{n_i}{N} \right), \quad (3)$$

where λ_j are hyper-parameters to balance each score. Then, with the cache ratio R , the index set for the cached tokens is obtained in the following form:

$$\mathcal{I}_{\text{Cache}} = \arg \min_{\{i_1, i_2, \dots, i_{R\% \times N}\} \subseteq \{1, 2, \dots, n\}} \{\mathcal{S}(x_{i_1}), \mathcal{S}(x_{i_2}), \dots, \mathcal{S}(x_{i_n})\}. \quad (4)$$

3.6 DIFFERENT CACHE RATIOS IN DIFFERENT LAYERS

Figure 5 shows the difference in feature caching of different layers, where (a) shows that the output features of different layers have different distances compared with their value in the last step (*i.e.* different temporal redundancy). (b) and (c) show that when errors in the same density are applied to

Figure 6: Visualization examples for different acceleration methods on PixArt- α .

layers in different depths and types, the resulting error in the final layer exhibits extremely different magnitudes. Specifically, in the three studies, the disparity between the maximum and minimum error can be several orders of magnitude. Fortunately, ToCa enables us to apply different caching ratios for layers in various depths and types. By denoting the overall caching ratio for all the layers and timesteps as \mathcal{R}_0 , then two factors r_{depth} and r_{type} are introduced to adjust the caching ratios. Then the final caching ratio of the layer in l depth and type can be written as $R_{\text{type}}^l = R \times r_l \times r_{\text{type}}$.

r_l : As introduced in Figure 5(a) and (b), although the features of the shallow layers tend to exhibit lower differences than the deeper layers, the error introduced by the cached tokens in the shallow layers can be propagated to the other tokens and amplified during the computation in all the following layers, resulting in a much larger caching error. Based on this observation, we set larger and smaller cache ratios for deeper and shallower layers, respectively, by setting $r_l = 0.5 + \lambda_l(l/L - 0.5)$, where 0.5 is utilized for 1-center and L denotes the maximal depth and λ_l controls the slope.

r_{type} : As shown in Figure 5(c), layers of different types have different sensitivities to feature caching. Especially, the error on the token in self-attention layers can quickly propagate to other tokens, due to the property that each token in self-attention layers can attend to all the tokens. A naive solution is to set lower cache ratios for self-attention layers. However, we observe that even if only a smaller ratio of tokens is cached, the error introduced by these tokens still quickly propagates to all other tokens, and has almost the same negative influence as caching all the tokens. Based on this fact, we propose to cache all tokens in self-attention layers. For MLP and cross-attention layers, r_{type} is set to the ratio of their computation costs over the overall computation costs. This strategy encourages layers with more computation costs to have a higher cache ratio.

4 EXPERIMENT

4.1 EXPERIMENT SETTINGS

Model Configurations We conduct experiments on three commonly-used DiT-based models across different generation tasks, including PixArt- α (Chen et al., 2024a) for text-to-image generation, OpenSora (Zheng et al., 2024) for text-to-video generation, and DiT-XL/2 (Peebles & Xie, 2023) for class-conditional image generation with NVIDIA A800 80GB GPUs. Each model utilizes its default sampling method: DPM-Solver++ (Lu et al., 2022b) with 20 steps for PixArt- α , rflow (Liu et al., 2023) with 30 steps for OpenSora and DDPM (Ho et al., 2020) with 250 steps for DiT-XL/2. For each model, we configure different average forced activation cycles \mathcal{N} and average caching ratios R for ToCa as follows: PixArt- α : $\mathcal{N} = 3$ and $R = 70\%$, OpenSora: $\mathcal{N} = 3$ for temporal

Evaluation and Metrics For text-to-image generation, we utilize 30,000 captions randomly selected from COCO-2017 (Lin et al., 2014) to generate an equivalent number of images. FID-30k is computed to assess image quality, while the CLIP Score (Hessel et al., 2021) is used to evaluate the alignment between image content and captions. In the case of text-to-video generation, we leverage the VBench framework (Huang et al., 2024), generating 5 videos for each of the 950 benchmark prompts under different random seeds, resulting in a total of 4,750 videos. The generated videos are comprehensively evaluated across 16 aspects proposed in VBench. For class-conditional image generation, we uniformly sample from 1,000 classes in ImageNet (Deng et al., 2009) to produce 50,000 images at a resolution of 256×256 , evaluating performance using FID-50k (Heusel et al., 2017). Additionally, we employ sFID, Precision, and Recall as supplementary metrics.

4.2 RESULTS ON TEXT-TO-IMAGE GENERATION

In Table 1, we compare ToCa configured with parameters to achieve an acceleration ratio close to 2.0, against two other training-free acceleration approaches: FORA (Selvaraju et al., 2024), a recent cache-based high-acceleration method, and the 10-step DPM-Solver++ sampling (Lu et al., 2022b). In terms of *generation quality*, the quantitative results demonstrate that ToCa achieves the lowest FID among the compared acceleration methods while maintaining a high acceleration ratio. Figure 6 also illustrates that our generated results most closely resemble those of the original PixArt- α . Regarding *generation consistency*, Table 1 demonstrates that ToCa achieves the highest CLIP score on both MS-COCO2017 (Lin et al., 2014) and the PartiPrompts (Yu et al., 2022). Figure 6 shows that ToCa generates images that align more closely with the text descriptions compared to other methods. This is particularly evident in the fourth case, where only ToCa successfully generates an image matching "a small rowboat tied to a wooden dock", while other methods fail to generate the content of "a wooden dock". This may be caused by cross-attention score s_2 in ToCa that ensures the frequent refreshing of tokens that are semantically relevant to the text descriptions, resulting in generated images with enhanced semantic consistency to the text prompts.

Figure 7: Visualization examples for different acceleration methods on OpenSora. Please kindly refer to the supplementary material or the anonymous [web page](#) for viewing these videos.

Notably, Table 1 shows that under similar acceleration ratios, ToCa exhibits a very marginal decrease in generation quality. In contrast, directly halving the number of timesteps leads to 9.37 increments in FID, indicating a significant performance drop. This observation indicates that when the number of sampling steps is already relatively low (*e.g.*, 20 steps), further reduction in the number of sampling steps may severely compromise the generation quality. In contrast, ToCa remains effective, demonstrating the distinct advantage of ToCa in the situation of low sampling steps.

4.3 RESULTS ON TEXT-TO-VIDEO GENERATION

We compare ToCa with adjusted rflow sampling steps from 20 to 10, alongside other acceleration methods including FORA, PAB (Zhao et al., 2024), Δ -DiT (Chen et al., 2024b), and T-GATE (Zhang et al., 2024) using OpenSora (Zheng et al., 2024) for text-to-video generation. As presented in Table 2, the experimental results show that ToCa achieves an impressive VBench score offering the lowest computational cost and highest inference speed among all methods tested. The VBench score of the 2.36 \times accelerated ToCa scheme drops by only 0.79 compared to the non-accelerated scheme, while FORA’s score decreases by 2.22, resulting in a 64.4% reduction in quality loss. Additionally, more VBench metrics results are presented in Figure 8, which illustrate that ToCa significantly speeds up the original OpenSora with only slight performance degradation on a few metrics. Notably, ToCa stands out as the sole acceleration method achieving nearly overall consistency performance with the original OpenSora, clearly outperforming another cache-based acceleration method FORA. This again highlights the effectiveness of our proposed cross-attention-based token selection strategy, ensuring that the generated videos are highly aligned with the text descriptions. We further present some video generation results in Figure 7, where we observe that the visual fidelity, and overall consistency of ToCa are closest to the original OpenSora. Please kindly refer to our video demos in the supplementary material or the anonymous [web page](#) for viewing the video demo.

Figure 8: VBench metrics and acceleration ratio of proposed ToCa and other methods

4.4 RESULTS ON CLASS-CONDITIONAL IMAGE GENERATION

Quantitative comparison between ToCa with other training-free DiT acceleration methods is shown in Table 3, which demonstrates that ToCa outperforms other methods in terms of both FID and sFID by a clear margin under the similar acceleration ratio. For instance, ToCa leads to 0.39 and 0.22 lower values in sFID and FID compared with FORA with a similar acceleration ratio, respectively.

Table 3: Quantitative comparison on class-to-image generation on ImageNet with DiT-XL/2.

Method	Latency(s) ↓	FLOPs(T) ↓	Speed ↑	sFID ↓	FID ↓	Precision ↑	Recall ↑
DiT-XL/2-G (cfg = 1.50)	2.012	59.36	1.00×	4.98	2.31	0.82	0.58
33% steps	0.681	19.71	3.01×	6.31	2.76	0.81	0.57
37% steps	0.748	22.08	2.69×	6.04	2.64	0.81	0.58
FORA($\mathcal{N} = 3$)	0.807	20.02	2.97×	6.21	2.80	0.80	0.59
FORA($\mathcal{N} = 2.8$)	0.815	21.68	2.74×	6.13	2.80	0.80	0.59
ToCa ($\mathcal{N} = 4, R = 93\%$)	0.820	21.61	2.75×	5.74	2.58	0.81	0.59

Table 4: Ablation studies with DiT-XL/2-G (cfg=1.50). s_1 is used in all experiments. s_2 is not used since DiT does not have cross-attention layers.

R	Schedule	Uniform Spatial	Cache	ImageNet
r_l	r_{type}	Distribution s_4	Frequency s_3	FID-5k ↓
✓	✓	✓	✓	9.32
✗	✓	✓	✓	9.60
✓	✗	✓	✓	9.67
✓	✓	✗	✓	9.35
✓	✓	✓	✗	9.65

Table 5: Ablation studies of token selection based on different attention scores (s_1 and s_2) with PixArt- α . "Random" indicates replacing attention scores with random values. s_3, s_4, r_l, r_{type} are used in all three settings.

Token Selection Methods	MS-COCO2017 FID-30k ↓	PartiPrompts CLIP ↑
Cross-Attention s_2	28.33	17.75
Self-Attention s_1	28.21	17.13
Random	28.46	17.08

Ablation Study Table 4 presents the effect of the two factors on adjusting the caching ratio in different layers, where applying different caching ratios to layers in different types (r_{type}) and different depths (r_l) leads to 0.28 and 0.35 FID reduction, respectively. Besides, using the score of uniform spatial distribution (s_3) and cache frequency (s_4) reduces FID by 0.02 and 0.33, respectively. Table 5 compares the influence of selecting tokens with the self-attention weights (s_1) and the cross-attention weights (s_2). The other ToCa modules including s_3, s_4, r_l, r_{type} are utilized in these experiments. It is observed that s_1 tends to achieve a lower FID while s_2 tends to reach a higher CLIP score, which is reasonable since self-attention is mainly utilized for the generation of the overall images while cross-attention is utilized to inject the conditional signals. In summary, these results demonstrate that all the cache scores in ToCa have their benefits in different dimensions.

Figure 9: Visualization of cached tokens selected with and without s_3 (cache frequency). The pixel with a darker color indicates the corresponding tokens are more frequently cached. (c) The distribution of the number of being cached for each token w/ and w/o s_3 .

Visualization on the Cached Tokens Figure 9 (a-b) show the number of times that each token is cached during generation, where darker colors indicate more frequent caching. It is observed that both the two schemes perform more cache in the unimportant background tokens while performing more real computations in the tokens of the Arctic fox. However, the image without s_3 has a bad quality in the background since the background tokens have been cached too many times. In contrast, applying the score of cache frequency s_3 , which aims to stop caching the tokens that have been cached in the previous layers, can reduce the gap between the important and unimportant tokens, and prevent the background tokens from overlarge caching frequency. This observation has also been verified in Figure 9(c) that s_3 reduces the number of tokens cached by more than 4.5k times.

5 CONCLUSION

Motivated by the observation that different tokens exhibit different temporal redundancy and different error propagation, this paper introduces ToCa, a token-wise feature caching method, which adaptively skips the computation of some tokens by resuing their features in previous timesteps. By leveraging the difference in different tokens, ToCa achieves better acceleration performance compared with previous caching methods by a clear margin in both image and video generation, providing insights for token-wise optimization in diffusion transformers.

A APPENDIX

A.1 ENGINEERING DETAILS

This section introduces some engineering techniques in our work.

A.1.1 STEP-WISE CACHING SCHEDULING

In section 3.6, we propose a method for dynamically adjusting the caching ratio R based on the time redundancy and noise diffusion speed across different depths and types of layers, which constitutes a key part of our contributions. In the following section, we further explore the dynamic adjustment of R along the timestep dimension, as well as strategies for dynamically adjusting the forced activation cycle \mathcal{N} .

At the initial stages of image generation, the model primarily focuses on generating contours, while in the later stages, it pays more attention to details. In the early contour generation phase, it is not necessary for too many tokens to be fully computed with high precision. By multiplying by a term r_t , we achieve dynamic adjustment of R along the timestep dimension, where $r_t = 0.5 + \lambda_t(0.5 - t/T)$, λ_t is a positive parameter controlling the slope, t is the number of timesteps already processed, and T is the total number of timesteps. By adjusting R in this way, we shift some of the computational load from earlier timesteps to later ones, improving the quality of the generated images. Finally, the caching ratio is determined as $R_{\text{type}}^{l,t} = R \times r_l \times r_{\text{type}} \times r_t$.

Similarly, we set a larger forced activation cycle \mathcal{N} during the earlier stages, while a smaller \mathcal{N} is used during the later detail generation phase to enhance the quality of the details. To ensure that the adjustment of \mathcal{N} has minimal impact on the theoretical speedup, we define it as follows: $\mathcal{N}_t = \mathcal{N}_0 / (0.5 + w_t(t/T - 0.5))$, where \mathcal{N}_0 corresponds to the expected theoretical speedup induced by \mathcal{N} , and w_t is a hyperparameter controlling the slope.

A.1.2 PARTIALLY COMPUTATION ON SELF-ATTENTION

In the previous section, we mentioned that partial computation in the Self-Attention module can lead to rapid propagation and accumulation of errors. Therefore, we considered avoiding partial computation in the Self-Attention module, meaning that during the non-forced activation phase, the Self-Attention module has $r_{\text{type}} = 0$. In the subsequent Sensitivity Study, we explored a trade-off scheme between Self-Attention and MLP modules, with the corresponding formulas for allocation being $r_{\text{type}} = 1 - 0.4\lambda_{\text{type}}$ for the Self-Attention module, and $r_{\text{type}} = 1 + 0.6\lambda_{\text{type}}$ for the MLP module. The factors 0.6 and 0.4 are derived from the approximate computational ratio between these two modules in the DiT model.

A.1.3 TOKEN SELECTION FOR CFG AND NON-CFG

In the series of DiT-based models, the tensors of cfg (class-free guidance) and non-cfg are concatenated along the batch dimension. A pertinent question in token selection is whether the same token selection strategy should be applied to both the cfg and non-cfg parts for the same image (i.e., if a token is cached in the cfg part, it should also be cached in the corresponding non-cfg part). We have observed significant sensitivity differences among models with different types of conditioning regarding whether the same selection strategy is used. For instance, in the text-to-image and text-to-video models, such as PixArt- α and OpenSora, if independent selection schemes are applied for the cfg and non-cfg parts, the model performance degrades substantially. Thus, it is necessary to enforce a consistent token selection scheme between the cfg and non-cfg parts.

However, in the class-to-image DiT model, this sensitivity issue is considerably reduced. Using independent or identical schemes for the cfg and non-cfg parts results in only minor differences. This can be attributed to the fact that, in text-conditional models, the cross-attention module injects the conditioning information into the cfg and non-cfg parts unevenly, leading to a significant disparity in attention distribution between the two. Conversely, in class-conditional models, the influence on both parts is relatively uniform, causing no noticeable changes in token attention distribution.

A.2 MORE IMPLEMENTATION DETAILS ON EXPERIMENTAL SETTINGS

For the DiT-XL/2 model, we uniformly sampled from 1,000 classes in ImageNet (Deng et al., 2009) and generated 50,000 images with a resolution of 256×256 . We explored the optimal solution for DiT-XL/2 using FID-5k (Heusel et al., 2017) and evaluated its performance with FID-50k. Additionally, sFID, Inception Score, and Precision and Recall were used as secondary metrics. For the PixArt- α model, we used 30,000 captions randomly selected from COCO-2017 (Lin et al., 2014) to generate 30,000 images. We computed FID-30k to assess image quality and used the CLIP Score between the images and prompts to evaluate the alignment between image content and the prompts. For the OpenSora model, we used the VBench framework (Huang et al., 2024), generating 5 videos for each of the 950 VBench benchmark prompts under different random seeds, resulting in a total of 4,750 videos. These videos have a resolution of 480p, an aspect ratio of 16:9, a duration of 2 seconds, and consist of 51 frames saved at a frame rate of 24 frames per second. The model was comprehensively evaluated across 16 aspects: subject consistency, imaging quality, background consistency, motion smoothness, overall consistency, human action, multiple objects, spatial relationships, object class, color, aesthetic quality, appearance style, temporal flickering, scene, temporal style, and dynamic degree.

PixArt- α : We set the average forced activation cycle of ToCa to $\mathcal{N} = 2$, supplemented with a dynamic adjustment parameter $w_t = 0.1$. The parameter $\lambda_t = 0.4$ adjusts R at different time steps, and the average caching ratio is $R = 70\%$. The parameter $r_l = 0.3$ adjusts R at different depth layers. The module preference weight $r_{type} = 1.0$ shifts part of the computation from cross-attention layers to MLP layers.

OpenSora: For OpenSora, we fixed the forced activation cycle for temporal attention, spatial attention, and MLP at 3, and set the forced activation cycle for cross-attention to 6. The ToCa strategy ensures that a portion of token computations is conducted solely in the MLP, with R_{mlp} fixed at 85%.

DiT: We set the average forced activation cycle of ToCa to $\mathcal{N} = 3$, supplemented with a dynamic adjustment parameter $w_t = 0.03$ to gradually increase the density of forced activations as the sampling steps progress. The parameter $\lambda_t = 0.03$ adjusts R at different time steps. Additionally, during the sampling steps in the interval $t \in [50, 100]$, the forced activation cycle is fixed at $\mathcal{N} = 2$ to promote more thorough computation in sensitive regions. The average caching ratio is $R = 93\%$, and the parameter $\lambda_l = 0.06$ adjusts R at different depth layers. The module preference weight $r_{type} = 0.8$ means that during steps outside the forced activation ones, no extra computations are performed in attention layers, but additional computations are performed in the MLP layers.

All of our experiments were conducted on 6 A800 GPUs, each with 80GB of memory, running CUDA version 12.1. The DiT model was executed in Python 3.12 with PyTorch version 2.4.0, while PixArt- α and OpenSora were run in Python 3.9. The PyTorch version for PixArt- α was 2.4.0, and

Figure 10: Visualization examples for different acceleration methods on DiT.

for OpenSora it was 2.2.2. The CPUs used across all experiments were 84 vCPUs from an Intel(R) Xeon(R) Gold 6348 CPU @ 2.60GHz.

A.3 SENSITIVITY STUDY

We explored the optimal parameter configuration for the ToCa acceleration scheme on DiT and analyzed the sensitivity of each parameter. The experiments used FID-5k and sFID-5k as evaluation metrics. From Figure 11 (a) to (f), we respectively investigated the effects of the caching ratio weights λ_l , λ_{type} , λ_t , the weight of Cache Frequency score λ_3 , Uniform Spatial Distribution λ_4 , and the dynamic adjustment weight for forced activation w_t . It is observed that: (a) The optimal parameter is $\lambda_l = 0.06$, where the corresponding cache ratio shows approximately 6% variation at both the last and first layers. (b) The optimal parameter is $\lambda_{type} = 2.5$, at which point the Self-Attention layer does not perform any partial computation, with the entire computational load shifted to the MLP layer. It is also noted that as the computation load decreases in the Self-Attention layer and increases in the MLP layer, the generation quality shows a steady improvement. (c) The optimal parameter in the figure is $\lambda_t = 0.03$, and at this point, there is little difference between the best and worst methods, suggesting that the model is not particularly sensitive to the adjustment of cache ratio along the timesteps. (d) The optimal weight for the Cache Frequency score is $\lambda_3 = 0.25$. We observe that as λ_3 increases, the model’s generation quality initially shows a noticeable improvement, but beyond a weight value of 0.25, the fluctuation is minimal. This indicates that the Cache Frequency has reached a relatively uniform state, achieving a dynamic balance in caching among different tokens. (e) We conducted a search for the Uniform Spatial Distribution score with grid sizes of 2 and 4, and the experimental results show that the generation quality with a grid size of 2 is generally better than that with a grid size of 4. This suggests that a finer-grained spatial uniformity indeed contributes to an improvement in generation quality. (f) We explored the impact of dynamically adjusting the forced activation cycle on the model’s generation quality and analyzed the effect of fixing the Force activation cycle β at 2 for the relatively more sensitive 50–100 timesteps. The experimental results show that enforcing this fixed cycle in the 50–100 timesteps significantly improves generation quality, with the optimal parameter configuration being $w_t = 0.4$.

In summary, these observations indicate that our method is not sensitive to the choice of hyper-parameters. Actually, our experiment results demonstrate that stable performance can be observed when directly transferring hyper-parameters from one model to another model in the same model family such as DiT in different sizes.

A.4 COMPUTATION COMPLEXITY ANALYSIS

A.4.1 MAIN COMPUTATIONS

Complexity of Attention Layer. In the Attention layer, tokens are first processed through a linear layer to generate queries, keys, and values. Next, the queries and keys are multiplied using a dot

Figure 11: **Sensitivity study on different weights.** From (a) to (f), the caching ratio weights λ_l , λ_{type} , λ_t , the Cache Frequency score weight λ_3 , the Uniform Spatial Distribution weight λ_4 , and the dynamic schedule weight for forced activation w_t are presented.

product, passed through a softmax function, and then multiplied with the values. Finally, the result is passed through another linear layer to produce the output. The computational cost of the Self-Attention layer can be expressed as:

$$\begin{aligned} \text{FLOPs}_{SA} &\approx N \times D \times 3 \times D \times 2 + N^2 \times D \times 2 + N^2 \times H \times 5 + N^2 \times D \times 2 + N \times D \times D \times 2 \\ &= 8 \times N \times D^2 + 4 \times N^2 \times D + 5 \times N^2 \times H \approx O(ND^2) + O(N^2D), \end{aligned} \quad (5)$$

where N is the number of tokens, D is the hidden state of each token and H is the number of heads, ($H \ll D$). The computational cost of a Cross-Attention layer can be expressed as:

$$\begin{aligned} \text{FLOPs}_{CA} &\approx N_1 \times D \times D \times 2 + N_2 \times D \times 2 \times D \times 2 + N_1 \times N_2 \times D \times 2 \\ &\quad + N_1 \times N_2 \times H \times 5 + N_1 \times N_2 \times D \times 2 + N_1 \times D \times D \times 2 \\ &= 4 \times (N_1 + N_2) \times D^2 + 4 \times N_1 \times N_2 \times D + 5 \times N_1 \times N_2 \times H \\ &\approx O((N_1 + N_2)D^2) + O(N_1N_2D) = O((N + N_2)D^2) + O(NN_2D), \end{aligned} \quad (6)$$

where $N_1 = N$, N_2 are the number of image and text tokens, D is the hidden state of each token and H is the number of heads, ($H \ll D$). In the previous computations, the softmax operation is approximated as involving 5 floating-point calculations per element.

Complexity of MLP Layer. The computational cost of MLP layer can be written as:

$$\begin{aligned} \text{FLOPs}_{MLP} &\approx N \times D_1 \times D_2 \times 2 + N \times D_2 \times 6 + N \times D_1 \times D_2 \times 2 \\ &= 4 \times N \times D_1 \times D_2 + 6 \times D_2 \times N \\ &= 16 \times N \times D^2 + 24 \times N \times D \approx O(ND^2), \end{aligned} \quad (7)$$

where N is the number of tokens, $D_1 = D$ and $D_2 = 4D_1$ are the hidden and middle-hidden state in MLP, respectively. The activation function for MLP is approximated to involve 6 floating-point operations per element.

A.4.2 COMPUTATION COSTS FROM TOKEN SELECTION

Self-Attention score s_1 . As mentioned in section 3.5, the Self-Attention score s_1 is computed as $s_1(x_i) = \sum_{j=1}^N \alpha_{ij}$, where x_i is the i_{th} token, and α_{ij} is the element in the self-attention map. Therefore, the computational complexity of the self-attention score is only $N \approx O(N)$. In a practical case achieving about 2.3 \times acceleration, the computation cost of the Self-Attention score accounts for approximately 0.28% of the main components.

Cross-Attention score s_2 . As mentioned in section 3.5, the Cross-Attention score s_2 is computed as $s_2(x_i) = -\sum_{j=1}^N c_{ij} \log(c_{ij})$, where the c_{ij} is the element in the cross-attention map. Therefore, the computational complexity of the cross-attention score is only $2N \approx O(N)$. In a practical case achieving about 2.3 \times acceleration, the computation cost of the Cross-Attention score accounts for approximately 0.35% of the main components.

Table 6: **Quantitative comparison on class-to-image generation** on ImageNet with **50 steps DDIM sampler** as baseline on DiT-XL/2.

Method	Latency(s) ↓	FLOPs(T) ↓	Speed ↑	sFID ↓	FID ↓	Precision ↑	Recall ↑
DiT-XL/2-G (cfg = 1.50)	0.455	23.74	1.00×	4.40	2.43	0.80	0.59
50% steps	0.238	11.86	2.00×	4.74	3.18	0.79	0.58
40% steps	0.197	9.50	2.50×	5.15	3.81	0.78	0.57
34% steps	0.173	8.08	2.94×	5.76	4.58	0.77	0.56
FORA ($\mathcal{N} = 2.5$)	0.219	10.48	2.27×	6.59	3.83	0.79	0.55
FORA ($\mathcal{N} = 3$)	0.211	8.58	2.77×	6.43	3.88	0.79	0.54
ToCa ($\mathcal{N} = 3, R = 93\%$)	0.227	10.23	2.32×	4.74	3.04	0.80	0.57
ToCa ($\mathcal{N} = 4, R = 93\%$)	0.209	8.73	2.72×	5.11	3.60	0.79	0.56

Table 7: **Quantitative comparison in text-to-image generation** for FLUX on Image Reward.

Method	Latency(s) ↓	FLOPs(T) ↓	Speed ↑	Image Reward ↑
FLUX.1-schnell (Labs, 2024)	2.882	277.88	1.00×	1.133
75% steps	2.162	208.41	1.33×	1.139
FORA ¹ (Selvaraju et al., 2024)	2.365	225.60	1.23×	1.129
FORA ² (Selvaraju et al., 2024)	2.365	225.60	1.23×	1.124
FORA ³ (Selvaraju et al., 2024)	2.365	225.60	1.23×	1.123
ToCa ($\mathcal{N} = 2, R = 90\%$)	1.890	181.30	1.53×	1.134

Cache Frequency score s_3 and Uniform Spatial Distribution score s_4 . The Cache Frequency score s_3 is updated at each step, so its update cost per timestep is N . When the Cache Frequency score is called for summation in practical applications, the computation cost is $2N$. Thus, the total cost for one layer is $3N \approx O(N)$. The Uniform Spatial Distribution score s_4 is computed by sorting within each grid of size $G \times G$ and weighting the top-scoring tokens. The computation cost is given by $\frac{N}{G^2} \times G^2 \log(G^2) + 2 \times \frac{N}{G^2}$, where G is the grid size, which is usually small. Therefore the computational complexity of s_4 is $O(N)$. In a practical case achieving about $2.3\times$ acceleration, the computation cost of the Cache Frequency score s_3 accounts for approximately 0.044% and the Uniform Spatial Distribution score s_4 accounts for 0.15% of the main computation components. In addition, the computational cost for sorting N tokens is $O(N \log N)$, which accounts for approximately 0.18% of the main computational cost.

In summary, although ToCa introduces additional computations, its computational complexity of $O(N)$ is negligible compared to the main computational modules with complexities of $O(N^2D)$ or $O(ND^2)$. In practical tests, the time taken for token selection is minimal, typically less than 1% of the main computational cost. At cache steps, taking a caching ratio of $\mathcal{R} = 90\%$ as an example, the computational cost of terms with a complexity of $O(ND^2)$ is reduced to 10% of the original, while the computational cost of terms with a complexity of $O(N^2D)$ is reduced to 1%. (However, as mentioned earlier, in practice, it is more efficient to shift all computations at cache steps to the MLP. Therefore, all terms with a complexity of $O(N^2D)$ at cache steps are ignored.)

A.5 IMPLEMENTED RESULTS ON CLASS-CONDITIONAL IMAGE GENERATION

In addition to the series of experiments conducted using the DDPM(Ho et al., 2020) sampling method on DiT, which have already been included in the main part, we also performed validation with the more practically relevant DDIM(Song et al., 2021) sampling method to further demonstrate the effectiveness of ToCa as shown in Table 6.

For instance, ToCa leads to 1.32 and 0.28 lower values in sFID and FID compared with FORA with a similar acceleration ratio of approximately $2.7\times$, respectively, and achieves 0.21 lower values in FID compared to the method of directly reducing the sampling steps with an acceleration ratio of approximately $2.5\times$. As a trade-off between acceleration and performance, we selected the scheme $\mathcal{N} = 3, R = 93\%$ as the final recommended approach for DDIM sampler.

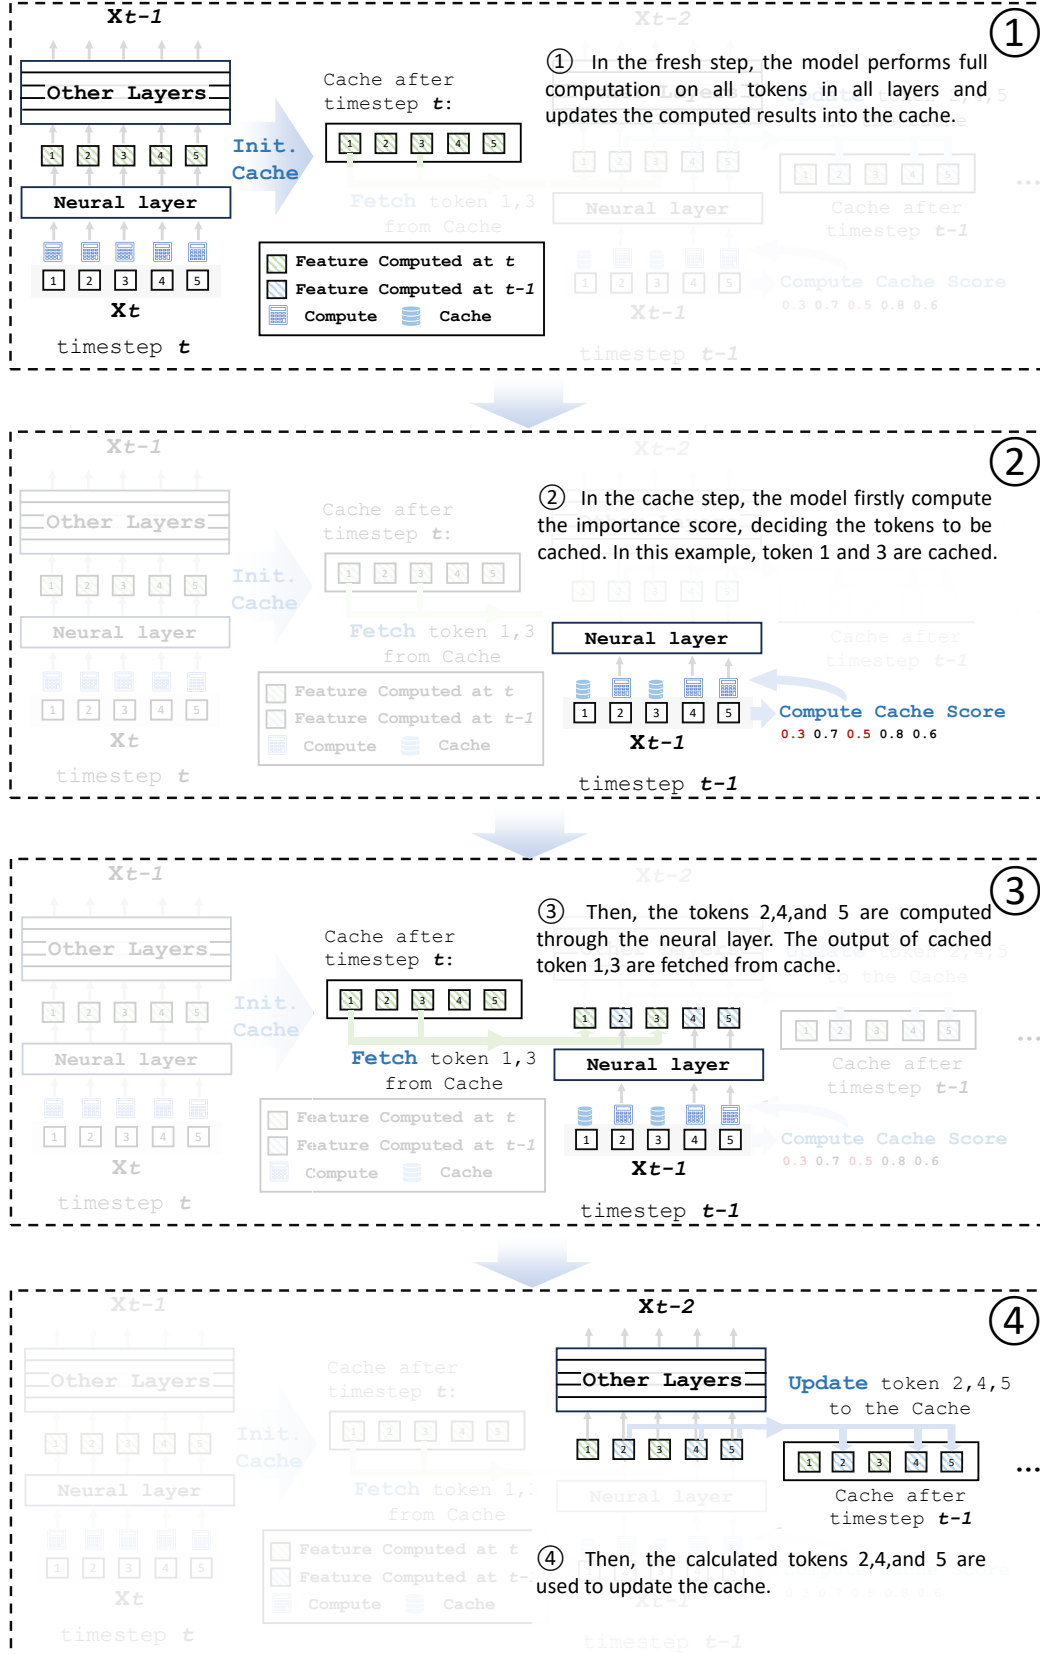

Figure 12: A more detailed workflow for the proposed ToCa. The cache-and-reuse procedure is conducted on the model at all layers and timesteps.

A.6 RESULTS ON HIGHER-RESOLUTION AND MORE ADVANCED TEXT-TO-IMAGE MODEL

As shown in Table 7, we compared the performance of FORA and $T\circ Ca$ on generating high-resolution images (1024×1024) using the more advanced text-conditional image generation model FLUX.1-schnell(Labs, 2024). The evaluation of generation quality was conducted using Image Reward, a metric better suited to measuring human preference. The generated images were based on 1,632 prompts from the PartiPrompts(Yu et al., 2022) dataset to comprehensively evaluate the generation quality of the acceleration methods on FLUX.1-schnell.

In this comparison, $FORA^1$, $FORA^2$, and $FORA^3$ correspond to skipping the 2nd, 3rd, and 4th steps, respectively, during the 4-step generation process. $T\circ Ca$ demonstrated nearly lossless performance under a $1.5\times$ acceleration, with Image Reward scores almost identical to the non-accelerated scenario. In contrast, all configurations of FORA showed quality degradation under a $1.2\times$ acceleration setting. The corresponding visual results are presented in Figure 13, demonstrating the lossless acceleration capability of $T\circ Ca$.

A.7 DETAILS FOR DISTRIBUTION FIGURES

In this section, we provide detailed explanations of the various distribution plots mentioned in the main text as supplementary information.

Figure 1 illustrates the distribution of the Frobenius norm of the differences between the feature maps x_t^L and x_{t+1}^L , which are the outputs of the last DiT Block at each timestep t and the previous timestep $t + 1$, respectively. The figure also presents the corresponding statistical frequency density of these Frobenius norm values for each token, based on 500 randomly generated samples produced by DiT. This analysis reveals the conclusion that different tokens exhibit varying levels of temporal redundancy.

Figure 2 illustrates the varying rates of error accumulation and propagation across different tokens. Specifically, Gaussian noise with an intensity of 0.5 was independently added to the i_{th} token of the first layer at each step. The Frobenius norm was then computed between the output features of all tokens at the last layer of the same step and the corresponding features from the noise-free output. This process was repeated for all steps and all layers. Given that each noise propagation required re-running the inference process, a random subset of 100 samples from the DiT model was selected for this case study, and the noise propagation results were recorded for each iteration. This analysis led to the conclusion that different tokens exhibit varying rates of error accumulation and propagation.

Figure 5(a) illustrates the varying temporal redundancy across layers of different depths. For each timestep, the Frobenius norm of the differences between the features of the current timestep and the corresponding features of the previous timestep at a specific layer depth was computed for each token. The resulting Frobenius norm values were then used to plot the distribution alongside their corresponding statistical frequency densities. To clearly demonstrate the trends, we selected layers 1, 15, and 28 for visualization. The samples used were randomly chosen from 200 DiT samples.

Figure 5(b) shows the variation in the offset distribution of the output values from the last layer of a timestep when Gaussian noise is added to a single token at different layer depths within the same timestep. This is measured by adding Gaussian noise with an intensity of 0.5 to a single token in a specific layer at one timestep and comparing the deviation in the output features of the last layer at that timestep with the noise-free scenario. For clarity, this operation was performed on layers 1, 15, and 25 across all timesteps, using 200 randomly selected samples from the DiT model to generate the examples. It is worth noting that Figure 5(b) may appear at first glance to violate the normalization condition for frequency density distributions. This is due to the large variations in Frobenius norm values, which necessitated the use of a logarithmic scale on the horizontal axis. Figure 5(a) and (b) demonstrate two key conclusions: deeper layers exhibit poorer temporal redundancy, but errors introduced in deeper layers have a smaller impact on the output at the same timestep.

Figure 5(c) illustrates the results on the PixArt- α model by adding Gaussian noise with an intensity of $0.5 \times \|x_k\|_F$ to a single token x_k in the 10th layer (approximately the middle layer) at each timestep. This process was performed for three different types of layers (self-attention, cross-attention, and MLP). The Frobenius norm of the error induced by the noise was measured on the output of the last layer and normalized by the average Frobenius norm $\|x_k\|_F$ of tokens of the

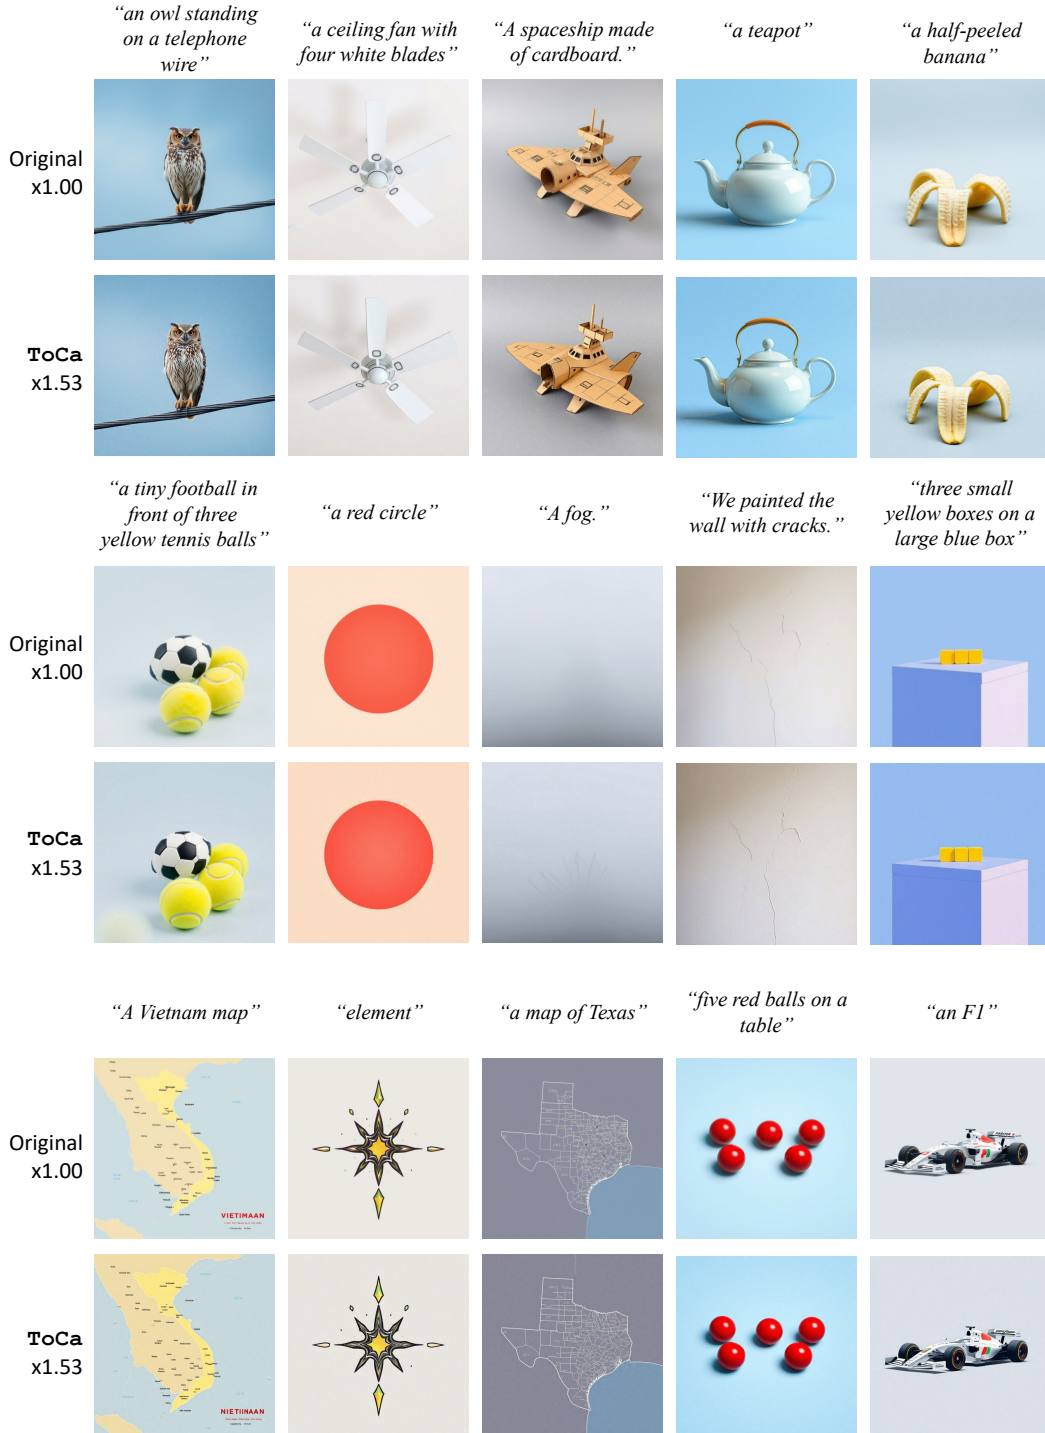

Figure 13: Visualization examples for original FLUX.schnell(Labs, 2024) and proposed ToCa with almost lossless acceleration.

Figure 14: Computation ratio for different types of computation layers on different timesteps and layers on DiT. The dark blue lines correspond to fully computed fresh steps. (a) The computation ratio distribution of the Self-Attention layers. As mentioned earlier, performing partial computation on attention layers is less cost-effective compared to MLP layers. Therefore, we do not implement partial computation on attention layers; apart from fresh steps, all other steps directly reuse the corresponding cached features. (b) The computation ratio distribution of the MLP layers. As shown, the computation ratio increases with deeper layers and as the number of inferred timesteps during the inference phase grows.

same type. The resulting distribution was plotted using 200 prompts randomly selected from the MS-COCO2017 dataset. It is important to note that the additional normalization step, based on the norm values of the tokens, was necessary because the norm values of tokens in self-attention, cross-attention, and MLP layers typically vary significantly. Normalization ensures a fair comparison across these layer types. Additionally, the distribution for the MLP layer in Figure 5(c) appears more dispersed. This is due to the generally larger variations in MLP output values across different prompts and timesteps. In practice, increasing the number of samples can make the distribution visually denser. However, given that each token requires a separate inference for the error propagation experiments, using 200 prompts already incurs a significant computational cost while remaining sufficient to reveal the trends.

Algorithm 1 ToCa

Input: current timestep t , current layer id l .

```

1: if current timestep  $t$  is a fresh step then
2:   Fully compute  $\mathcal{F}^l(x)$ .
3:    $\mathcal{C}^l(x) := \mathcal{F}^l(x)$ ; # Update the cache.
4: else
5:    $\mathcal{S}(x_i) = \sum_{j=1}^4 \lambda_j \cdot s_j$ ; # Compute the cache score for each token.
6:    $\mathcal{I}_{\text{Compute}} := \text{TopK}(\mathcal{S}(x_i), R\%)$ ; # Fetch the index of computed tokens.
7:   for all tokens  $x_i$  do
8:     if  $i \in \mathcal{I}_{\text{Compute}}$  then
9:       Compute  $\mathcal{F}^l(x_i)$  through the neural layer.
10:       $\mathcal{C}^l(x_i) := \mathcal{F}^l(x_i)$ ; # Update the cache.
11:     end if
12:   end for
13: end if
14: return  $\mathcal{F}^l(x)$ . # return features for both cached and computed tokens for the next layer.

```
