## HICD: Hallucination-Inducing via Attention Dispersion for Contrastive Decoding to Mitigate Hallucinations in Large Language Models

**Anonymous ACL submission** 

#### Abstract

Large Language Models (LLMs) often generate hallucinations, producing outputs that are contextually inaccurate or factually incorrect. We introduce **HICD**, a novel method designed to induce hallucinations for contrastive decod-006 ing to mitigate hallucinations. Unlike existing contrastive decoding methods, HICD selects attention heads crucial to the model's prediction as inducing heads, then induces hallucinations by dispersing attention of these inducing heads and compares the hallucinated outputs with the original outputs to obtain the final result. Our approach significantly improves performance on tasks requiring contextual faithfulness, such as context completion, reading com-016 prehension, and question answering. It also improves factuality in tasks requiring accurate 017 knowledge recall. We demonstrate that our inducing heads selection and attention dispersion method leads to more "contrast-effective" hallucinations for contrastive decoding, outperforming other hallucination-inducing methods. Our 022 findings provide a promising strategy for reducing hallucinations by inducing hallucinations in a controlled manner, enhancing the performance of LLMs in a wide range of tasks.<sup>1</sup>

#### 1 Introduction

027

037

039

Large language models(LLMs) have demonstrated exceptional performance across a wide range of NLP tasks (Brown et al., 2020; Wang et al., 2024). However, they are prone to hallucinations, where they generate content that deviates from facts or relevant contexts, hindering their practical applications in real-world scenarios. To address this challenge, efforts have been devoted to mitigate knowledge hallucinations in LLMs (Kojima et al., 2022; Dhuliawala et al., 2023). In this work, we focus on mitigating hallucinations during inference generation (Li et al., 2024). To address this, some studies have focused on developing effective inference-time decoding strategies. Among these, contrastive decoding based approaches have demonstrated strong performance (Shi et al., 2024). However, current contrastive decoding methods typically compare the model's inherent outputs, such as those from earlier layers or smaller models, with the original outputs(Chuang et al., 2024; Li et al., 2023b). Limited research has explored to construct hallucinated outputs that can effectively contrast with the original outputs(Sahoo et al., 2024). 040

Previous work suggested that weak models have the potential to harness the capabilities of stronger models(Burns et al., 2024). Therefore, investigating how to induce hallucinations to construct a weak model capable of improving contrastive decoding performance is a topic worth exploring. Building on this, (Zhang et al., 2023b) proposed inducing hallucinations in LLMs via slight finetuning or zero-shot prompting, and mitigating them through contrastive decoding with the original outputs. And there's a method that prunes retrieval heads to generate hallucinated outputs for comparison with the original outputs (Gema et al., 2024). However, these hallucination-inducing methods require additional fine-tuning or rely on model's internal parameters, limiting their adaptability in different datasets. Moreover, the plausibility of the hallucinations and their effectiveness for contrastive decoding have not been validated.

Other works have addressed the issue of hallucinations by focusing on model interpretability. Some studies examined attention heads that play a key role in output quality (Bansal et al., 2023). Another study revealed that key points causing hallucinations in LLMs are the inconsistencies in the information flow integration between memory heads and context heads, and effectively mitigated hallucinations by pruning conflicting attention heads (Jin et al., 2024). This suggests that targeting the

Figure 1: Illustration of Hallucination-Inducing Contrastive Decoding Method(HICD). The method include calculation of the importance scores and identification of the inducing heads (yellow), dispersing attention of inducing heads to induce hallucinations (pink) and applying contrastive decoding for hallucination mitigation (blue).

attention heads critical to hallucinated outputs can effectively control hallucination generation.

Inspired by these studies, we propose **HICD**, *a* method that induces hallucinations through attention dispersion on inducing heads for contrastive decoding to mitigate hallucinations. To address the limitation that existing hallucination-inducing methods rely on model's internal parameters, restricting adaptability to different datasets, we construct correct and incorrect (adversarial) samples by pairing questions with corresponding right and wrong answers. We then compute task-relevant importance scores for attention heads that are critical to generating correct outputs (right heads) and incorrect outputs (wrong heads). Finally, we select heads that contribute to correct outputs while suppressing those leading to incorrect outputs, resulting in a set of *inducing heads*.

To improve the effectiveness of contrastive decoding methods, the attention maps of the inducing heads are averaged, ensuring attention values are equalized across all tokens within each head. This redistribution disperses attention, effectively inducing hallucinated outputs optimized for contrastive decoding, as demonstrated by experiments. Finally, these hallucinated outputs are compared with the original model's outputs to mitigate hallucinations.

Our findings show that compared to existing contrastive decoding methods, HICD significantly improves faithfulness in tasks requiring contextual understanding, such as HellaSwag(Zellers et al., 2019), RACE(Lai et al., 2017), OpenBookQA (Mihaylov et al., 2018) on Llama-7b(Touvron et al., 2023a) and HaluEval-Sum(Li et al., 2023a) on Llama2-7b(Touvron et al., 2023b). Furthermore, HICD also enhances the model's accuracy in factual recall tasks like TruthfulQA(Lin et al., 2022) and Factor(Muhlgay et al., 2024). Our contributions are as follows: 110

133

135

- **Task-Driven Inducing Head Selection:** Inducing heads selected based on task, yield more effective hallucination induction than task-irrelevant selecting methods.
- Attention Dispersion: Averaging the attention maps of inducing heads increases the effectiveness of hallucinated outputs by allowing context with lower relevance to the prediction to influence the results.
- **Contrast Effective:** HICD leads to more effective hallucination outputs and better mitigation during contrastive decoding.

#### 2 Background

#### 2.1 Multi-head Attention

Multi-head attention is crucial in transformer-based models, enabling them to capture complex depen-

 $I_{h}(\mathcal{D}) = E_{(x,y)\sim\mathcal{D}} \left| \frac{\partial \mathcal{L}(y|x)}{\partial A^{h}([x;y])} \right|$ 

the desired dimensionality.

2.2

puted as:

where  $\mathcal{L}(y|x)$  is the loss function,  $A^h([x;y])$  is the output of attention head h, and (x, y) are inputoutput pairs from  $\mathcal{D}$ . The model's loss is computed using the negative log-likelihood:

dencies by attending to different parts of the input

Formally, given the input sequence  $x^{\ell-1} =$ 

 $[x_1^{\ell-1},\ldots,x_N^{\ell-1}]$  at layer  $\ell$ , an MHA block in the

transformer computes a set of attention heads. Each

attention head h at layer  $\ell$  is computed as follows:

 $s^{\ell,h} = \sigma\left(\frac{(X^{\ell-1}W_Q^{\ell,h})(X^{\ell-1}W_K^{\ell,h})^T}{\sqrt{d/M}}\right)$ 

where  $X^{\ell-1} \in \mathbb{R}^{N \times d}$  represents the input hid-

den states, d is the dimensionality, and M is the number of heads.  $W_Q^{\ell,h}$ ,  $W_K^{\ell,h}$ , and  $W_V^{\ell,h}$  are the

queries, keys, and values for the h-th head, respec-

tively. The attention score is the dot product of

queries and keys, scaled by  $\sqrt{d/M}$ , and passed

through the softmax function  $\sigma$  to get the attention

The final attention output for the *h*-th head,  $H^{\ell,h}$ ,

 $H^{\ell,h} = s^{\ell,h} X^{\ell-1} W_V^{\ell,h}$ 

 $A^{\ell} = [H^{\ell,1}; H^{\ell,2}; \dots; H^{\ell,M}] W_{O}^{\ell}$ 

projects the concatenated attention heads back to

The gradient-based importance score quantifies the

contribution of an attention head h to the model's predictions by calculating the sensitivity of the out-

put to changes in h (Michel et al., 2019; Bansal

et al., 2023). Given a dataset  $\mathcal{D}$ , the score is com-

Gradient-based Importance Score

where  $W_{Q}^{\ell}$  is a learnable output matrix that

nated to form the output of the MHA block:

The attention output of all heads is then concate-

distribution  $s^{\ell,h}$ .

is computed by:

sequence simultaneously (Halawi et al., 2023).

$$\mathcal{L}(y|x) = -\frac{1}{T_y} \sum_{j=1}^{T_y} \log p(y_j|x, y_{1:j-1}) \quad (5)$$

The importance scores for all heads are efficiently computed by performing a single forward and backward pass over the model with  $\mathcal{D}$ .

## 3 Method

(1)

(2)

(3)

(4)

The overall algorithm of HICD is shown in 1. First, we identify the inducing heads that are closely associated with generating hallucinations(3.1). Next, we apply attention dispersion to these inducing heads to induce task-relevant hallucinations (3.2). Finally, these hallucinated outputs are compared with the original model outputs through contrastive decoding to alleviate hallucinations (3.3).

## 3.1 Identification of Inducing Heads

To discover the attention heads that are crucial for correct and incorrect outputs on different datasets, we define a process for identifying the final set of inducing heads. We begin by constructing an adversarial dataset  $D'_m$  based on the original dataset  $(x, c) \in T_m$ , where m refers to the specific task, x represents the context, c denotes a set of answer choices. Given a dataset  $(x, c, y_i) \in D_m$ , where  $y_i$  is the right anwser that belongs to one of the choices c, and we generate the new sample  $(x, c, y_j) \in D'_m$ , where  $y_j \in c \setminus \{y_i\}$ . This results in adversarial samples that pair questions with incorrect answers, derived from the original dataset  $T_m$ .

Utilizing both the correct and adversarially constructed incorrect samples, we compute the gradient-based importance score for each attention heads, as defined in Equation 4. Based on these importance scores  $I_{l,h}(D_m)$  and  $I_{l,h}(D'_m)$ , we define a discrepancy correction factor  $F_{l,h}^m$  as:

$$F_{l,h}^{m} = I_{l,h}(D_{m}) - \frac{1}{|c \setminus \{y_{i}\}|} \sum_{y_{j}} I_{l,h}(D'_{m}) \quad (6)$$

where  $I_{l,h}(D_m)$  and  $I_{l,h}(D'_m)$  represent the importance scores in  $D_m$  and  $D'_m$ , respectively, with l referring to the layer and h representing the attention head. The term  $|c \setminus \{y_i\}|$  represents the size of the set c excluding the correct answer  $y_i$ . The final inducing heads score in dataset  $T_m$  is defined as:

$$S_{l,h}^{m}(D_m, D'_m) = I_{l,h}(D_m) - s \cdot F_{l,h}^{m}$$
(7)

where s is a hyperparameter scaling factor that controls the influence of the discrepancy between right and wrong heads on the inducing heads score. We select the top  $k_m$  attention heads based on the inducing heads score from dataset  $T_m$ . The optimal number  $k_m$  of inducing heads for each dataset is determined experimentally, as described in 4.2. For further implementation details, refer to Appendix A.4.

3.2

Induction

 $M^{\ell,h}$  such that:

**Attention Dispersion for Hallucination** 

We perform attention map averaging on the induc-

ing heads obtained in Section 3.1. Specifically,

given the query  $Q^{\ell,h}$  and key  $K^{\ell,h}$  of an inducing

head h at layer  $\ell$ , we apply a lower triangular mask

 $M_{ij}^{\ell,h} = \begin{cases} 0 & \text{if } i \ge j, \\ 1 & \text{if } i < j \end{cases}$ 

This mask is multiplied element-wise with the prod-

uct of  $Q^{\ell,h}$  and  $K^{\ell,h}$  to generate a modified query-

 $\alpha_{\text{new}}^{\ell,h} = M^{\ell,h} \odot \frac{(Q^{\ell,h} (K^{\ell,h})^T)}{\sqrt{d/M}}$ 

where  $\odot$  represents the element-wise multiplication

operation. This operation forces the lower triangu-

lar part of  $\alpha_{new}^{\ell,h}$  to become zero. Then, in Equation

10, applying the softmax operation  $\sigma$ , the attention

values for each position are equalized, with all en-

tries in the lower triangular part of the attention

map being set to  $\frac{1}{n}$ , where *n* refers to the index of

 $s_{\rm inducing}^{\ell,h} = \sigma(\alpha_{\rm new}^{\ell,h})$ 

 $H_{\rm inducing}^{\ell,h} = s_{\rm inducing}^{\ell,h} X^{\ell-1} W_V^{\ell,h}$ 

Then,  $s_{\text{inducing}}^{\ell,h}$  is substituted into Equation 2 to get Equation 11. After obtaining  $H_{\text{inducing}}^{\ell,h}$ , the model's

attention towards each token position in the induc-

ing head is equalized, thus achieving attention dis-

persion, with the processed model called *induced* 

model. Experiments in 4.3 demonstrate dispersing

attention in inducing heads induces more effective

**Contrastive Decoding for Hallucination** 

Given the induced model from Section 3.2, the goal

of this approach is to mitigate hallucination in the

generated output. We propose a contrastive decod-

ing approach that contrasts the token distributions

from the base model and the induced model, which

is defined as a re-weighting of the next-token distri-

butions of the base model and the induced model.

 $n(x_t|x_{<t}) \propto \exp\left[(1+\alpha)\log n_{\text{eviction}}(x_t|x_{<t})\right]$ 

hallucination outputs for contrastive decoding.

$$-\alpha \log p_{\text{inducing}}(x_t | x_{< t})]$$
(12)

In Equation 12, the new next-token distribution  $p(x_t|x < t)$  is derived by contrasting the next-token distributions of the original model  $p_{\text{original}}(x_t | x < t)$  and the induced model  $p_{\text{inducing}}(x_t | x < t).$

The scaling factor  $\alpha \in R$  controls the relative influence between the original and induced models. When  $\alpha > 0$ , the likelihood of the original model is emphasized, leading to a preference for token predictions consistent with the output of the original model. And the likelihood of the induced model is penalized by the term  $\alpha \log p_{\text{inducing}}(x_t | x < t)$ , which discourages the selection of tokens that are likely under the induced model.

(11)

#### 4.1 **Experimental Setup**

Datasets and Metrics. 1) Faithfulness evaluation: For context completion, we evaluate on HellaSwag(Zellers et al., 2019), where the goal is to predict the next sentence based on context. For reading comprehension (RACE-H and RACE-M(Lai et al., 2017)), representing high school and middle school levels. For question answering, we use the additional subset of Open-BookQA(Mihaylov et al., 2018) with a "fact1" field as reference context. 2) Knowledge hallucination: Evaluated with HaluEval-Sum(Li et al., 2023a), using accuracy for both hallucinated and correct summaries (Acc-A and Acc-H). 3) Factuality evaluation: Done with TruthfulQA(Lin et al., 2022) and Factor(Muhlgay et al., 2024), measuring the model's ability to provide truthful answers (TruthfulQA) and generate factual completions (Factor).

Models and baselines. Our experiments are basically conducted with the Llama family(Touvron et al., 2023a,b). We compare HICD with the following decoding methods: 1) greedy decoding, which greedily selects the next token with the highest probability; 2) DoLa(Chuang et al., 2024), which attempts to reduce hallucinations by contrasting output distributions from different layers of the model; 3) Contrastive decoding (CD)(Li et al., 2023b), which contrasts output distributions from models of different scales of parameters; 4) Context-Aware Decoding (CAD)(Shi et al., 2024), a variant of CD where the amateur model is the same as the expert model but is not presented with the additional context. Details of experimental setups and datasets are provided in Appendix A.

Table 1: Performance of different models and methods on faithfulness evaluation tasks. The best performance is indicated in **bold**, and the second-best is <u>underlined</u>. "\*" means we report results of previous research. Alpaca means using an instruction-following dataset to fine-tune. The hyperparameter settings are provided in Table 8.

#### 4.2 Main Results

HICD Mitigates Faithfulness Hallucinations. Table 1 presents the performance of different contrastive decoding methods in faithfulness-related tasks. HICD outperforms other methods in all tasks, showing significantly better contextual faithfulness. It achieves the highest or second-highest scores across tasks. Detailed parameter settings are provided in Appendix B.

For example, HICD achieves 84.23% accuracy on the HellaSwag context completion task with Llama-7B, a 6.6% improvement over greedy decoding and a significant improvement compared to other methods. It also performs well on reading comprehension and question answering tasks, surpassing other methods on the RACE benchmark and achieving competitive results on Open-BookQA. In the HaluEval-Sum knowledge hallucination task, HICD achieves significant improvements with Llama2-7B, scoring 37.46 (Acc-H) and 52.65 (Acc-A), outperforming the next best results by 9.7% and 2.3%, respectively. Additionally, with Llama2-7B, HICD outperforms CAD on RACE-Middle, and scores comparably to CAD on RACE-High and OpenBookQA, securing the second-best performance.

HICD Mitigates Factuality Hallucinations. Although HICD's primary goal is to improve contextual faithfulness by mitigating hallucinations, its effectiveness in factual consistency tasks remains an
open question. Therefore, we also evaluate HICD
on TruthfulQA and Factor tasks, where the model
is required to generate factually accurate outputs.
Besides comparing with the previously mentioned
baselines, we also compare with the model finetuned on the Alpaca dataset(Taori et al., 2023).

Table 2: Performance of different decoding methods on factuality evaluation tasks. The best performance is indicated in **bold**, the second-best is <u>underlined</u>. "\*" means we report results of previous research.

In Table 2, we can see that HICD improves the accuracy of the model in factual consistency tasks. Specifically, on the multiple choice task in TruthfulQA, with Llama-7B, HICD achieves competitive results across all metrics compared to the baselines, surpassing DoLa and Alpaca on the MC2 metric. In the Factor task, for all models, although HICD achieves slightly lower scores compared to 13B-CD and DoLa in Wiki dataset, it achieves the highest score in the News Factor dataset. More detailed results analyses are shown in Appendix C.

#### 4.3 More Analysis

Effect of inducing heads number on task performance of HICD. We further analyze the relationship between the number of inducing heads and downstream task performance with the LLaMA-7B model. The results, represented by all red lines in Figure 2, provide insight into this relationship.

For contextual faithfulness tasks, we adjust the number of *Topk* heads to identify the optimal number of inducing heads. For the *OpenBookQA* and *RACE-High* tasks, a strong correlation between

Figure 2: Effect of inducing head number on task performance. The red lines represent our HICD method, using average attention over inducing heads to induce hallucinations. The blue lines show the head-pruning method from prior research, where inducing heads are pruned (implementation details in Appendix C.1). The green dashed line represents the baseline model without hallucination induction. Spearman correlation coefficient r measures the correlation between inducing heads and task performance. The parameter  $\alpha$  and s tuning are shown in Appendix B.

the number of inducing heads and accuracy. We 374 attribute this to the strong dependence on the additional context provided in the datasets for making predictions. As a result, the inducing heads, which are crucial for capturing context relevant to the correctness of the model's predictions, play an indispensable role. Increasing the number of inducing heads enables the model to generate more context-aware hallucinations, improving the effective of contrastive decoding and task performance. However, for HellaSwag and RACE-Middle, performance peaks at 30 inducing heads and decreases with further increases. We hypothesize that beyond a threshold, adding more inducing heads harms output, making contrastive decoding less effective and hindering performance. This is consistent with (Bansal et al., 2023), which observed that removing a significant percentage of attention heads greatly reduces model performance.

400

401

402

403

404

405

For factuality tasks, such as *TruthfulQA*, a moderate correlation is observed between the number of inducing heads and various metrics, with Spearman correlations for MC1, MC2 at 0.48, 0.65, respectively. However, the impact on performance is limited. For example, MC1 accuracy improves by just 1.8 points on *TruthfulQA*, while accuracy for Wiki Factor and News Factor increases by 1.3% and 3.5%. We believe that hallucinations induced in factuality tasks are are less "contrast-effective" than in contextual tasks. As shown in Figure 2, hallucinations induced with fewer heads can even adversely affect contrastive decoding. Consequently, the hallucination mitigation effect of HICD is less

prominent in factuality tasks, as the number of inducing heads changes. Nevertheless, in all experiments, HICD produces more accurate results than the baseline. Detailes analyses see Appendix B.3.

**Comparison with Other Hallucination-Inducing** 

Methods. HICD demonstrates an ability to induce more "contrast-effective" hallucinations compared to other methods. We compare HICD with the following methods, as detailed in Appendix E:

- Prompt-based: A prompt is used to force LLMs to generate fabricated information to induce hallucinations.
- SH2-based: Low-information tokens are prepended to the context to shift the model's attention to unrelated content to induce hallucinations(Kai et al., 2024).
- PASTA-based: Attention steering is applied by increasing the attention weights of low-importance tokens to induce hallucination(Zhang et al., 2023a).
- Cut-based: Inducing heads are directly masked to trigger hallucinations.

As shown in Figure 2, in most tasks, the Cutbased method (blue lines) exhibits a weaker ability to mitigate hallucinations at the optimal number of inducing head compared to the Ave-based approach HICD (red lines). From the results in Table 3, HICD consistently outperforms both the Prompt-based and PASTA-based method in most datasets. This is especially evident in contextual faithfulness tasks, where HICD achieves the best overall performance.

Table 3: Comparison of different hallucination-inducing methods across various evaluation tasks: Prompt-based, which uses a prompt to compel LLMs to provide fabricated information for contrast; PASTA-based, which employs attention steering to enhance the weights of low-importance tokens for inducing hallucinations; SH2-based, which prepends low-information tokens to redirect the model's attention toward unrelated context to induce hallucinations; Cut-based, which directly masks inducing heads to trigger hallucinations.

Figure 3: Spearman correlation coefficients for inducing heads score ranking across different tasks. Higher correlation coefficients indicate that the inducing heads selected more similarly.

Although SH2-based method for inducing hallucination outperforms HICD on specific factuality tasks, such as the *TruthfulQA* in MC1 metric and the *FACTOR* datasets, the overall results indicate that HICD has a greater potential for inducing "contrast-effective" hallucinations. This advantage makes HICD particularly effective in mitigating hallucinations while maintaining superior performance in a wide range of evaluation tasks.

In-domain and Out-of-domain Inducing Head
Evaluation. We evaluate the performance of indomain and out-of-domain inducing head selection

477

The highest performance is consistently obtained from in-domain inducing heads. This demonstrates that task-relevant, in-domain head selection outperforms out-of-domain selection methods across all datasets, significantly improving model performance. Moreover, the results for out-of-domain inducing heads are generally better than baseline methods, indicating that the HICD approach exhibits a certain degree of generalizability across different datasets and tasks.

The performance of out-of-domain inducing heads is related to the correlation between indomain and out-of-domain heads rankings. As the correlation between out-of-domain and indomain inducing heads increases, their performance becomes more similar, with results presented in Figure 3. For example, the inducing heads from Race Middle, TruthfulQA, and HaluEval-Sum exhibit relatively high ranking similarity with OpenBookQA. Therefore, the out-of-domain heads from these tasks show performance that is notably closer to the in-domain OpenBookQA heads com-

Figure 4: Visualization of the relationship between token confidence and the norm f(x), where a subset of high-confidence tokens corresponds to higher f(x).

pared to other out-of-domain heads, as seen in Table 4. Similarly, the Factor (News and Wiki) tasks exhibit relatively lower Spearman correlation with other tasks, leading to similar performance among the Factor's out-of-domain heads, which shows a significant gap in performance compared to indomain heads. See details in Appendix F.

Analysis of Attention Map Averaging vs. Head Cutting in Inducing Effective Hallucinations. The attention mechanism transforms each input vector x into a norm f(x), calculates the attention weights  $\alpha$ , then computes the output  $\alpha f(x)$ . Compared to  $\alpha$ , the f(x) plays the dominant role in controlling the attention of the high-frequency and low-information tokens (Kobayashi et al., 2020). Besides, a higher token confidence corresponds to a lower information content (Kai et al., 2024).

Building on these intuitions, we analyze the relationship between token confidence and the norm f(x), as illustrated in Figure 4. Most tokens exhibit low f(x) values, but a subset of high-confidence, low-information tokens corresponds to higher f(x)values. We hypothesize this strengthens the final attention values at the positions of low-information tokens. Figure 5 compares the cosine similarity of the ||f(x)|| and  $||\alpha f(x)||$  (attention output) at different token positions across three methods. As shown, Ave Head results in higher similarity between ||f(x)|| and  $||\alpha f(x)||$  than the others, increasing the dominance of ||f(x)|| in determining the final attention values. Thus, HICD applies attention map averaging makes  $\alpha$  uniform across all positions, with the final attention determined by f(x). Higher values of f(x), dominated by lowinformation tokens, exert a greater influence.

To further illustrate the impact of attention averaging on model's outputs. Based on (Wang et al.,

Figure 5: Cosine similarity of the output norms ||f(x)||and  $||\alpha f(x)||$ (attention output) at different token positions under the methods: None, Cut Head, and Ave Head. Ave Head shows a higher similarity, allowing ||f(x)|| to dominate the final attention values.

Figure 6: Visualization of the information flow, Ave head increases the importance of information flow from more tokens, leading to spread-out attention distribution and more plausible hallucinations.

2023), we visualize the information flow in Figure 6. Compared to other methods, Ave Head increases the importance of information flow from more tokens to the token being predicted, making the model consider the impact of other irrelevant low-information tokens. This makes the hallucinated outputs seem more plausible and meaningful.

#### 5 Conclusion

In this paper, HICD are introduced to induce hallucinations on inducing heads for contrastive decoding to mitigate hallucinations. Experiments on several tasks show that HICD outperforms existing methods in contextual tasks and achieves competitive results in factual consistency tasks. We also find that selecting task-relevant inducing heads improves performance compared to out-of-domain selections. And attention averaging induces more contrast-effective hallucinations compared to other methods. Our work opens new directions for hallucination induction and mitigation, providing a promising strategy to reduce hallucinations and enhance LLM robustness across tasks.

### 6 Limitations

The HICD method shows strong improvements in 538 539 hallucination mitigation, but it has several limitations. First, its effectiveness depends on task-540 relevant induced head selection, which may not 541 generalize well to all tasks, especially those underrepresented in training data. Second, attention map averaging for hallucination induction can be computationally expensive, particularly for larger models and datasets, making scalability a concern for 546 real-time or resource-limited applications. Lastly, 547 the method's performance relies on the quality of 548 adversarial data, and future work should explore how different adversarial data construction methods impact performance across various tasks and 551 552 domains.

#### 1) Faithfulness Evaluation

For faithfulness evaluation, we use the following tasks:

• Context Completion (HellaSwag): HellaSwag (Zellers et al., 2019) is a dataset designed to evaluate the ability of a model to predict the next sentence based on context. It contains multiple-choice questions that require the model to select the most plausible continuation of a given context. The task tests how well the model maintains context coherence and handles commonsense reasoning. We use the validation split of HellaSwag, which contains 10,042 examples. The dataset can be accessed at: https://huggingface. co/datasets/Rowan/hellaswag.

• Reading Comprehension (RACE): RACE (Lai et al., 2017) is a reading comprehension dataset that contains two subsets: RACE-H (high school) and RACE-M (middle school). The dataset consists of questions based on passages, requiring the model to select the correct answer. RACE tests the model's ability to understand and reason about the context of longer text. We use the test split of RACE, with RACE-H containing 3,498 examples and RACE-M containing 1,436 examples. The dataset is available at: https:// huggingface.co/datasets/ehovy/race.

• Question Answering (OpenBookQA): OpenBookQA (Mihaylov et al., 2018) is a dataset designed to evaluate a model's ability to answer scientific questions. It consists of two subsets: main and additional. The additional subset provides a 'fact1' field as a reference context, which contains core scientific facts related to the question. In our evaluation, we use the additional subset and treat 'fact1' as the contextual input for the model. We use the test split of the additional subset, which contains 500 examples. This task assesses the model's ability to recall and apply scientific knowledge in a reasoning context. The dataset is available https://huggingface.co/datasets/ at: allenai/openbookqa.

#### 2) Knowledge Hallucination Evaluation

To assess the extent of hallucinations generated by the model, we utilize the following task:

- HaluEval-Sum: HaluEval (Li et al., 2023a) is used to evaluate hallucinations in summaries generated by the model. This dataset includes 10,000 samples, where each sample consists of a document, a hallucinated summary, and a correct summary. The task involves determining whether a summary contains factual inconsistencies or hallucinations. The performance of the model is evaluated using two metrics: The dataset can be accessed at:
  - Arithmetic-mean accuracy (Acc-A): The mean accuracy for both hallucinated and correct summaries.
  - Harmonic-mean accuracy (Acc-H): The harmonic mean of the accuracy for hallucinated and correct summaries. Acc-H provides a more balanced view, penalizing imbalances between the two types of summaries.

The dataset can be accessed at: https: //github.com/RUCAIBox/HaluEval/blob/ main/data/summarization\_data.json.

#### 3) Factuality Evaluation

For evaluating factual consistency, we use the following datasets:

- **TruthfulQA:** TruthfulQA (Lin et al., 2022) is a dataset designed to test the truthfulness of language models. It consists of multiplechoice questions where the model must select the correct answer from a set of options. The dataset includes three metrics for evaluating the model's truthfulness. We use the validation split of the multiple-choice subset, which contains 817 examples. The dataset is available at:https://huggingface.co/ datasets/truthfulqa/truthful\_qa/ viewer/multiple\_choice.
- FACTOR (Wiki and News): The FACTOR dataset (Muhlgay et al., 2024) focuses on factual consistency, requiring the model to select the correct completion of a text from factual and non-factual alternatives. It includes two subsets: Wiki-FACTOR and News-FACTOR, with 2,994 and 1,036 examples, respectively. The task tests the model's ability

# to generate factually accurate outputs. The dataset is available at:https://github.com/ AI21Labs/factor/tree/main/data.

We conduct our experiments with the Llama family of models (Touvron et al., 2023a,b). The following baseline methods are used for comparison:

- **Greedy Decoding:** This baseline method selects the next token greedily by choosing the one with the highest probability at each step. It is the simplest form of decoding and serves as a baseline for comparison with more advanced methods.
- **DoLa:** DoLa (Chuang et al., 2024) is a contrastive decoding method that attempts to reduce hallucinations by contrasting the output distributions of different layers of the model. This method aims to enhance the factuality of the generated text by comparing the outputs from various layers. The method code is available at: https://github.com/ voidism/DoLa.
- Context-Aware Decoding (CAD): CAD (Shi et al., 2024) is a variant of contrastive decoding that involves two models: the first model, which has access to the full context during decoding, and the second model, which is the same architecture but lacks access to the additional context. By contrasting their outputs, CAD amplifies the difference in performance when the model has context, helping it focus more on the provided context. This improves the model's faithfulness, particularly when the context introduces new or contradictory information. The method code is available at: https://github.com/xhan77/ context-aware-decoding.
- Contrastive Decoding (CD): CD (Li et al., 2023b) is a well-established contrastive decoding method that contrasts the token distributions of models with different parameter scales. This approach aims to reduce hallucinations by comparing the outputs of smaller(7b) models with larger(13b), more powerful models. The method code is available at: https://github.com/XiangLi1999/ContrastiveDecoding.

Table 5: Inference time for different datasets using a single Tesla V100 (32GB) GPU.

| Dataset      | Number of Examples | Inference Time |  |
|--------------|--------------------|----------------|--|
| HellaSwag    | 10,042             | 82 m           |  |
| RACE-M       | 1,436              | 14 m           |  |
| RACE-H       | 3,498              | 52 m           |  |
| OpenBookQA   | 500                | 3 m            |  |
| TruthfulQA   | 817                | 18 m           |  |
| FACTOR-Wiki  | 2,994              | 40 m           |  |
| FACTOR-News  | 1,036              | 13 m           |  |
| HaluEval-Sum | 10,000             | 15 h           |  |

#### A.3 Computational Resources and Software Libraries

**Model and Computational Resources.** All experiments were conducted using the Llama<sup>2</sup>, Alpaca<sup>3</sup> and Llama2<sup>4</sup> models, both of which have 7 billion parameters. We test the inference experiments executed on a single Tesla V100 GPU (32GB) without GPU parallelism. The approximate runtime for inference on different datasets show in Table 5. **Software and Implementations.** We utilized Py-Torch<sup>5</sup> and Transformers<sup>6</sup> The Transformers

Torch<sup>5</sup>, and Transformers<sup>6</sup>. The Transformers library was modified to support head masking and attention map averaging. Additionally, Baukit<sup>7</sup> and lm-evaluation-harness<sup>8</sup> were used in our implementation. The modifications to the Transformers library primarily focused on adding a head\_mask attribute to control inducing heads and implementing attention map averaging.

This setup ensures that our experimental results are reproducible and that sufficient computational resources were allocated for evaluating model performance across multiple benchmarks.

For the reported experimental results, we set the random seed to 42 for all runs to ensure reproducibility. The results presented are based on the maximum performance observed across multiple runs with the same seed. Specifically, for each dataset, we ran experiments using a fixed seed and report the highest accuracy obtained across different validation or test splits. We emphasize that these results represent the best-performing configurations under this particular seed setting. Additionally, while the results are based on a single random seed for consistency, future work could

benefit from running experiments across multiple seeds to better assess the stability and reliability of the model's performance.

#### A.4 Identification of Inducing Heads

In this subsection, we focus on how to construct adversarial data using incorrect answer options from the original dataset. By utilizing these adversarial samples, we calculate the importance scores for attention heads that are crucial for predicting incorrect answers, referred to as "wrong heads." This process allows us to evaluate the impact of these heads on the model's performance in generating erroneous outputs. We directly utilize the other answer choices in the dataset (which are not the correct answer) and treat them as adversarial labels. Using the gradient-based importance scoring method, we compute the importance scores for each attention head that influences the model's decision towards a wrong answer. The higher the score, the more important that head is in contributing to the model's incorrect response. We then compute the average importance score for the heads corresponding to all adversarially constructed data and use this average score as the final importance score for the "wrong heads."

> In parallel, we also compute the importance scores for "right heads" using the original correct answers. These heads are critical in generating correct outputs, and their scores provide insights into the attention heads responsible for guiding the model toward accurate decisions.

The final inducing heads score is determined by combining the scores of both "right" and "wrong" heads. This allows us to identify which heads are most influential in guiding the model's decisions towards outputs. The optimal number of inducing heads is chosen based on the combined importance scores, as detailed in Section 4.2.

## B Parameter Settings Analysis and Hyperparameter Tuning

Table 3 has demonstrated the impact of selecting top-k inducing heads on model performance across different tasks. In this section, we provide a detailed account of the parameter configurations used in our experiments, including the hyperparameter values and their corresponding evaluation results. As shown in Table 6, we investigate the effect of the hyperparameter  $\alpha$  on model performance while Table 6: Ablation study showing the effect of Alpha on the evaluation results, with fixed Scale and Top-k.

| Task         | Alpha | Scale, | Evaluation |
|--------------|-------|--------|------------|
|              |       | Top-k  |            |

while keeping  $\alpha$  and Top-k fixed.

### **B.1** Effect of $\alpha$ (Alpha)

The  $\alpha$  parameter controls the relative weighting between the original model and the hallucinationinduced model during contrastive decoding (Equation 12). A higher  $\alpha$  amplifies the suppression of hallucinated outputs, while a lower  $\alpha$  allows more hallucination-driven tokens.

As seen in Table 6, the effect of  $\alpha$  on model performance varies by task. For example, in HellaSwag, increasing  $\alpha$  from 0.7 to 1.1 leads to a steady improvement, but further increases provide diminishing returns, with performance stabilizing around  $\alpha = 1.3$ . A similar trend is observed in Race Middle, where performance peaks at  $\alpha = 0.7$ , after which further increases cause a decline. In contrast, for TruthfulQA, a significantly larger negative value of  $\alpha = -6.0$  provides optimal performance. In our experiments, we found that a negative  $\alpha$  forces the model to prioritize the hallucinated outputs generated by the induced model over the original model's outputs. For TruthfulQA, this leads to a more effective combination of the original model and the inducing model outputs, improving the overall performance. For Factor tasks, the effect of changing  $\alpha$  was less pronounced, which may be due to the inducing hallucinations not being as contrast-effective in these tasks compared to others. This suggests that hallucinations induced in Factor tasks do not contribute as effectively to contrastive decoding, leading to relatively smaller performance improvements when adjusting  $\alpha$ .

#### **B.2** Effect of Scale Parameter

The Scale parameter *s* determines the weight of the discrepancy correction factor applied during inducing head selection (Equation 4). It adjusts how much difference in importance scores between correct and incorrect outputs influences the final inducing head score.

As shown in Table 7, the optimal Scale value varies in different tasks, with each task exhibiting a distinct best value for Scale s. Scale s effectively adjusts the importance scores of the inducing heads, which in turn influences the selection of more contrast-effective inducing heads. For instance, in the HellaSwag task, the performance peaks at s = 20, while in Race Middle, the best performance is achieved at s = 10. Compared to  $\alpha$ , the effect of s on performance is relatively subtle, as it primarily changes the scores used to

select inducing heads rather than directly impacting the final output. This indicates that while *s* changes the hallucination induction process by altering the selection of inducing heads, it does not drastically impact the model's overall contrastive decoding performance. 1033 1034 1035

The number of inducing heads (*Top-k*) plays a crucial role in determining the extent of hallucination induction and contrastive decoding effectiveness. As observed in Figure 2, different tasks achieve peak performance at different Top-k values. In HellaSwag selecting 30 inducing heads yields optimal results, whereas OpenBookQA performs best with 70 inducing heads. This suggests that different tasks have different sensitivities to hallucination induction, and optimal Top-k values should be determined based on task-relevant characteristics rather than a fixed number across all tasks.

As shown in Table 9, selecting an appropriate Top-k value improves the performance of the model on various tasks. For example, in *HellaSwag*, selecting 30 inducing heads yields the highest accuracy of 0.8423, while in *RACE High*, the optimal number of inducing heads is 70, resulting in an accuracy of 0.4637. In *OpenBookQA*, selecting 70 inducing heads also provides the best performance with an accuracy of 0.558. From the extent of the impact of varying the selected Top-k on performance,we confirm that Top-k selection plays a crucial role in optimizing the model's performance by effectively inducing hallucinations for contrastive decoding.

In tasks like *TruthfulQA*, the optimal Top-k selection varies depending on the evaluation metric. For instance, the MC1, MC2, and MC3 scores achieve peak values at Top-k = 70, which suggests that the inducing heads selected at this value help the model focus on the right hallucinations to improve factual correctness across the multiple-choice questions. Similarly, for *Race Middle*, the performance improves as Top-k increases, with 30 inducing heads yielding the best results. However, increasing Topk further leads to diminishing returns, emphasizing the importance of selecting an optimal number of heads for each task.

These findings suggest that while increasing the number of inducing heads can enhance performance up to a certain point, there exists an optimal threshold beyond which adding more heads does not yield further benefits. In fact, as the number of inducing heads continues to increase, the hallucinations inducing become less contrast-effective and can even lead to worse performance compared to the original model outputs. This indicates that hallucination induction should be balanced. An excessive number of inducing heads can introduce

Table 8: Final hyperparameter configurations for each task, optimized based on performance across evaluation metrics.

| Task         | Alpha | Scale | Top-k |
|--------------|-------|-------|-------|
| HellaSwag    | 1.1   | 20    | 30    |
| Race Middle  | 0.7   | 10    | 30    |
| Race High    | 1.3   | 50    | 70    |
| OpenBookQA   | 0.8   | 1     | 70    |
| TruthfulQA   | -6.0  | 10    | 70    |
| Factor News  | 0.38  | 10    | 70    |

noise, diluting the effectiveness of the contrastive decoding process. Therefore, it is crucial to finetune Top-k based on task-relevant characteristics to maintain the effectiveness of hallucination induction without surpassing the point of diminishing returns. The results with Llama2-7b are shown in Table 11. 1090

#### **B.4** Final Hyperparameter Selection

After extensive tuning, we summarize the optimal hyperparameter configurations in Table 8. These values were selected based on maximizing performance across all evaluation metrics while ensuring stable and reliable contrastive decoding.

Overall, our analysis highlights the importance of careful hyperparameter tuning in balancing hallucination induction and mitigation. The results demonstrate that an appropriate combination of  $\alpha$ , Scale, and Top-k effectively enhances model robustness in contrastive decoding, with different tasks requiring distinct configurations to achieve optimal performance.

#### C Additional Results and Analysis

#### C.1 Head Pruning Method in Our Experiments

In our experiments, the head-pruning method is 1114 implemented by directly setting the inducing heads 1115 to be inactive. This process effectively "prunes" the 1116 selected heads by disabling them in the attention 1117 mechanism. Specifically, this involves setting the 1118 attention values of the chosen inducing heads to 1119 zero, which ensures that these heads do not con-1120 tribute to the final output. As a result, the output 1121 from the pruned heads is excluded from the over-1122 all attention computation, effectively simulating a 1123 head pruning. This method serves as a baseline 1124 for comparison with the HICD method, where hal-1125 lucinations are induced by averaging the attention 1126 maps of selected heads. 1127

#### C.2 Spearman Correlation Coefficient r

1128

1129The Spearman correlation coefficient r is a non-<br/>parametric measure of statistical dependence be-<br/>tween two variables. It assesses how well the re-<br/>lationship between two variables can be described<br/>using a monotonic function. In the context of our<br/>study, we use the Spearman correlation coefficient

to quantify the relationship between the number of 1135 inducing heads and the performance of the down-1136 stream tasks. Specifically, we evaluate how the 1137 number of inducing heads affects the task perfor-1138 mance. A higher correlation coefficient indicates 1139 that the number of inducing heads have a stronger 1140 impact on task performance. We calculate r across 1141 different tasks to observe how the number of induc-1142 ing heads correlates with the performance metrics. 1143 The results are summarized in Figure 2. The cor-1144 relation values for each task are shown in Table 1145 10. 1146

#### D Inducing Head Analysis

#### D.1 Visualization of Importance Scores for Attention Heads

To identify the most relevant attention heads for inducing hallucinations, we visualize the importance scores for the attention heads, which are computed by combining the scores of right heads and wrong heads. These scores help us rank the heads from the most to the least important. Based on these rankings, we select the top-k heads to form the set of inducing heads.

The visualization of the importance scores, shown in Figure 7, illustrates the distribution of these scores across the heads. We use this scores to guide our selection of the top-k heads, where the most important heads are chosen for hallucination induction.

# D.2 Custom Metric for Inducing Head Selection

To evaluate the selection of inducing heads, we define a custom metric based on the overlap between the inducing heads and two key sets: the right heads and the wrong heads. Specifically, we aim to maximize the intersection between the inducing heads and the right heads while minimizing the intersection with the wrong heads.

The custom metric is computed as follows: for each set of inducing heads, we compute the overlap with the right and wrong heads sets and use these values to generate a score. Let  $H_r$  represent the set of right heads,  $H_w$  represent the set of wrong heads, and  $H_i$  represent the set of selected inducing heads. The custom metric score  $S_{metric}$  is computed as Equation 13.

$$S_{\text{metric}} = |H_i \cap H_r| - \beta \cdot |H_i \cap H_w| \quad (13) \quad 1181$$

Figure 7: Visualization of importance scores for attention heads, used to select the inducing heads.

ing heads.

Table 10: Spearman correlation coefficient r for various tasks.

| Task                | Spearman r |
|---------------------|------------|
| HellaSwag           | 0.2        |
| Race High           | 0.9429     |
| Race Middle         | 0.5429     |
| OpenBookQA          | 0.7714     |
| TruthfulQA (MC1)    | 0.4857     |
| TruthfulQA (MC2)    | 0.6571     |
| TruthfulQA (MC3)    | 0.8286     |
| Factor Wiki         | 0.4286     |
| Factor News         | 0.2571     |
| HaluEval-Sum(Acc-H) | 0.3127     |
| HaluEval-Sum(Acc-A) | 0.3512     |

1182 Where:

1183

1184

1185

1186

1187

1188

-  $|H_i \cap H_r|$  is the number of inducing heads that overlap with the right heads

-  $|H_i \cap H_w|$  is the number of inducing heads that overlap with the wrong heads

-  $\beta$  is a hyperparameter that controls the penalty for overlap with the wrong heads

This score is maximized when the inducing 1189 heads align well with the right heads and avoid 1190 overlap with the wrong heads. We evaluate this 1191 metric across different values of top-k and scale 1192 settings, and the results are shown in Figure 8. This 1193 evaluation shows that the best configurations, as 1194 determined by our metric, align with the configura-1195 tions yielding the best performance in our experi-1196 ments. 1197

**Comparison with Other** 

Hallucination-Inducing Methods

In this section, we compare HICD with several

other hallucination-inducing methods. The goal of

this comparison is to highlight the superior ability

of HICD to induce "contrast-effective" hallucina-

tions. The results are presented in Figure 2 and

• Prompt-based: In line with the idea of induc-

ing hallucinations, we leverage specially de-

signed prompts to directly compel the model

to generate fabricated information. We use the

prompt: "You are a helpful, respectful but not

honest assistant. You must generate false or

fabricated information. This is very important

to my career." This system prompt directs the

model to intentionally produce false informa-

tion, making it a useful tool for investigating

the effects of hallucinations. By prompting

the model in this manner, we can generate hal-

lucinated outputs that are systematically dif-

ferent from the model's original predictions,

which allows us to perform contrastive analy-

sis and study the impact of hallucinations on

• SH2-based: Inspired by (Kai et al., 2024),

which selects tokens with high informational

content and prepends them to the context.

By repeating these high-information tokens,

the model's attention is shifted towards them,

increasing their focus and improving the

model's accuracy. In contrast, we are inspired

by this idea, but we apply it in reverse. In-

stead of adding high-information tokens, we

prepend low-information, low-relevance to-

kens to the context. This forces the model

to shift its attention to these irrelevant to-

kens, which effectively induces hallucinations.

Then we apply contrastive decoding to com-

pare the hallucinated outputs with the original

model outputs, thus mitigating hallucinations

• PASTA-based: Based on the Attention Steer-

ing method from (Zhang et al., 2023a), the

PASTA-based method selects task-relevant

attention heads and increases the attention

weights of token positions corresponding to

key context information. This technique im-

proves the model's attention to critical sen-

tences or words, thus enhancing its contextual

faithfulness. Following the ideas in PASTA,

while preserving performance.

model performance.

we manipulate the attention weights of low-

information tokens, which have low relevance

to the task or correctness of the output. By in-

creasing the attention scores of low-relevance

tokens, we intentionally shift the model's

focus towards irrelevant or less informative

words. This dispersion of attention results in

the induction of hallucinations, as the model

starts to generate content based on these non-

essential tokens. We then apply contrastive

decoding to compare the hallucinated out-

puts with the original model's outputs, effec-

tively mitigating hallucinations while preserv-

• Cut-based: The Cut-based method directly ig-

nores the outputs of specific inducing heads by

masking them, effectively forcing the model

to disregard certain attention heads. This sim-

ple yet effective approach induces hallucina-

tions by removing the influence of particular

attention heads. After inducing hallucinations,

contrastive decoding is applied to compare the

hallucinated outputs with the original outputs.

As shown in Figure 2, in most tasks, the Cut-based

method (blue lines) exhibits weaker performance

in mitigating hallucinations at the optimal inducing

head number compared to the Ave-based approach

HICD (red lines). From the numerical results in

Table 3, HICD consistently outperforms both the

Prompt-based and the PASTA-based attention steer-

ing across all datasets. This is especially evident

in tasks that require contextual faithfulness, where

Although the SH2-based method for inducing

hallucinations outperforms HICD on specific fac-

tuality tasks—such as the TruthfulQA MC1 metric

and the FACTOR datasets-the overall results indi-

cate that HICD has greater potential for inducing

"contrast-effective" hallucinations. This advantage

allows HICD to effectively mitigate hallucinations

while maintaining superior performance across a

In-domain vs Out-of-domain Inducing

We analyze the performance of out-of-domain in-

ducing heads obtained from various datasets, with

respect to the same task. As shown in Figure 3,

the performance of these out-of-domain inducing

heads varies depending on the correlation between

the rankings of the inducing head scores. As the

wide range of evaluation tasks.

For example, the inducing heads from Race Middle, TruthfulQA, and HaluEval-Sum exhibit relatively high ranking similarity with OpenBookQA. This is evident from the data presented in Table 4, where the performance of the out-of-domain inducing heads from these datasets is closer to that of the in-domain OpenBookQA inducing heads compared to other out-of-domain heads.

On the other hand, the Factor News tasks, exhibit a relatively lower Spearman correlation with other tasks. This results in a more uniform performance across the out-of-domain inducing heads

from these datasets. This uniformity is accompanied by a notable gap in performance when compared to the in-domain inducing heads. In TruthfulQA task, out-of-domain heads from Factor News and Factor Wiki, which have lower correlations with in-domain heads, perform worse than other out-of-domain heads. At the same time, we observe that out-of-domain heads with a correlation greater than 50% with in-domain heads exhibit a relatively larger performance improvement compared to those with a correlation below 50%.

#### G Norm Analysis and Token Confidence

#### G.1 Norm-Based Analysis

In Transformer models, the attention mechanism is essential for selecting relevant information from the input sequence. While attention weights  $\alpha$  are commonly used to measure the relevance of each token, recent work shows that the norm of the transformed input vectors, f(x), also plays a significant role in determining the final attention output. Specifically, the attention mechanism computes the output as a weighted sum of the transformed input vectors, where the transformed vector  $f(x_j)$  is calculated by applying a learned transformation to the input token  $x_j$ , and the attention weight  $\alpha_{i,j}$  determines how much influence each token should have on the output:

$$y_i = \sum_{j=1}^n \alpha_{i,j} f(x_j) \tag{14}$$

In Equation 14,  $f(x_j)$  represents the transformed vector of input token  $x_j$ , and  $\alpha_{i,j}$  is the attention weight.

However, previous analyses based solely on attention weights  $\alpha$  overlook the critical role of  $f(x_j)$ . As demonstrated in (Kobayashi et al., 2020), the attention weight-based analysis is insufficient because it does not account for the fact that the transformed vectors can have varying magnitudes, even if the attention weight is large.

To address this, the norm-based analysis that incorporates both the attention weights and the norms of the transformed vectors. Based on norm-based analysis, the model not only controls the contribution of different tokens through attention weights  $\alpha$  but also regulates the contribution levels of frequently occurring, low-information tokens by controlling the norm of f(x). In this framework, the final attention is not only governed by the attention weights  $\alpha$ , but also by the magnitude of the transformed vectors  $f(x_j)$ .

This norm-based perspective helps to better understand how Transformer models attend to different tokens, especially in cases where attention weights alone would lead to misleading interpretations. By adjusting the norms of these transformed vectors, we can change the influence of frequent, low-information tokens, leading to a more effective and nuanced attention allocation.

#### G.2 Token Confidence and Key Tokens

In language models, the prediction of a token is typically driven by the context provided by previous tokens. The confidence of the model in its predictions can be quantified by the probability assigned to each token. We can define token confidence as the prediction probability of a token given its preceding context,  $p(\hat{x}_t) = p(\theta(\hat{x}_t|x < t))$ , where  $\hat{x}_t$ is the token at position t and x < t represents the context preceding it (Kai et al., 2024). 1376

1418

1419

1420

1421

1422

1423

1424

1425

Key tokens are defined as those that the model predicts with the lowest confidence. These tokens are the hardest for the model to predict and are considered to carry more semantic information, often representing critical content such as nouns, proper nouns, and adjectives. These tokens provide significant insight into the factual content of the text. The reasoning behind this is that tokens with lower confidence are harder for the model to infer, indicating that they are less predictable, and thus may contain more complex or factual information.

In contrast, high-confidence tokens, often function words such as prepositions or determiners, contribute less to the factual content of the sentence. They are generally easier for the model to predict, and their occurrence does not add much to the model's understanding of the facts.

Tokens with the highest informational content are those hardest to predict. The language model can benefit from giving more attention to these lowconfidence tokens, as they are more likely to carry factual information, thus improving the factuality of the generated text.

#### G.3 Saliency Matrix and Information Flow

We investigate the impact of attention map averaging on the model's outputs through the analysis of the saliency matrix I(i, j), where I(i, j) quantifies the importance of information flow from token i to token j (Wang et al., 2023). The results reveals that Ave Head allows the model to generate hallucinations that appear more "plausible."

Figure 9 provides further evidence supporting these observations. It shows how applying attention map averaging can alter the importance of information flow across tokens, thereby impacting the attention given to the tokens that need to be predicted based on the context, ultimately affecting the resulting outputs. The figure visualizes information flow, where the bottom row represents earlier tokens in the sentence and the top row represents later tokens.

Figure 9: Supplementary results showing the effect of different hallucination inducing methods on the information flow. This figure complements Figure 6, illustrating how Ave Head dispersion the attention distribution and enhances the effective of hallucinated outputs.

Table 12: Examples of contextual prediction and their corresponding information flow in Figure 9. The black portion of the text represents the context, and the blue portion shows the predicted tokens.
