

# 000 SPIKEGEN: DECOUPLED "RODS AND CONES" VISUAL 001 REPRESENTATION PROCESSING WITH LATENT GENER- 002ATIVE FRAMEWORK

006 **Anonymous authors**

007 Paper under double-blind review

## 010 ABSTRACT

013 The process through which humans perceive and learn visual representations in  
014 dynamic environments is highly complex. From a structural perspective, the human  
015 eye decouples the functions of cone and rod cells: cones are primarily responsible  
016 for color perception, while rods are specialized in detecting motion, particularly  
017 variations in light intensity. These two distinct modalities of visual information are  
018 integrated and processed within the visual cortex, thereby enhancing the robustness  
019 of the human visual system. Inspired by this biological mechanism, modern  
020 hardware systems have evolved to include not only color-sensitive RGB cameras  
021 but also motion-sensitive Dynamic Visual Systems, such as spike cameras. Building  
022 upon these advancements, this study seeks to emulate the human visual system  
023 by integrating decomposed multi-modal visual inputs with modern latent-space  
024 generative frameworks. We named it *SpikeGen*. We evaluate its performance  
025 across various spike-RGB tasks, including conditional image and video deblurring,  
026 dense frame reconstruction from spike streams, and high-speed scene novel-view  
027 synthesis. Supported by extensive experiments, we demonstrate that leveraging the  
028 latent space manipulation capabilities of generative models enables an effective  
029 synergistic enhancement of different visual modalities, addressing spatial sparsity  
030 in spike inputs and temporal sparsity in RGB inputs.

041 Figure 1: Overview of the motivation, task setups and main quantitative results of SpikeGen.

## 045 1 INTRODUCTION

047 Human vision is not the best at any single metric — bees can be tetrachromats (Kevan et al., 2001)  
048 and many flies see flicker at far higher rates than we do (Borst et al., 2010) — but it excels as  
049 a balanced, tightly coupled system that fuses rich low-level cues from different modalities with  
050 high-level semantics. This balance yields (i) broad color discrimination via trichromacy with fine  
051 color resolution (Horiguchi et al., 2013), (ii) robust perception of moving targets with preserved  
052 spatial detail through active eye movements and temporally tuned pathways (Conner, 1982), and (iii)  
053 powerful inference mechanism that “fills in” missing information under extreme conditions (e.g., low  
light, fast motion) (Chariker et al., 2016; 2018).

The quest to replicate such capabilities has driven innovations in both imaging hardware and computational models. In hardware, RGB cameras directly emulate the trichromatic properties of cone cells (Peterson, 2016), which are concentrated in the fovea to provide high spatial and color resolution but lack temporal sensitivity (Zhang et al., 2021a). Conversely, Dynamic Visual Systems (DVS) (Han et al., 2020) like spike cameras draw inspiration from rod cells — widely distributed outside the fovea — utilizing their continuous integration mechanism to achieve high temporal resolution for perceiving subtle light changes, albeit with trade-offs in color and spatial resolution (Marković et al., 2020). On the algorithmic front, Artificial Neural Networks (ANNs) have emerged as powerful tools for multimodal visual fusion. For instance, infrared imaging can detect heat sources in low-light but lacks color and texture details, while visible-light imaging provides high-resolution color information but falters in darkness. Fusion algorithms integrating these modalities have demonstrated significant utility in applications like nighttime security (Yuan et al., 2024).

Notably, the RGB and spike modalities are functionally decoupled. In the human visual system, the brain acts as a "model" that integrates information from both modalities while leveraging semantic knowledge to infer missing details. Inspired by this mechanism, our approach aims to develop a multimodal model that emulates key characteristics of the human visual system. **Reviewing current studies, when relying solely on the RGB modality, although achieving relative improvements over low - quality inputs, often results in inherent information loss that introduces ambiguities in the output (Chen et al., 2024; Chang et al., 2023; Chen et al., 2023a).** This phenomenon is known as the "sharpness trap" where overall contrast is enhanced without meaningful geometric recovery (i.e., preservation of fine structural features) (Jiang et al., 2021). Similarly, in tasks dominated by the spike modality — such as dense frame reconstruction — the outputs are typically grayscale and exhibit limited spatial resolution (e.g., 250×400). As a result, incorporating priors from complementary modalities can significantly improve performance. Prior work, such as the Self-supervised Spike-guided Deblurring Model (S-SDM) (Chen et al., 2024), has demonstrated that texture cues captured by spike cameras can guide models to prioritize structural accuracy over superficial sharpness. Furthermore, we argue that even blurry RGB frames may provide valuable guidance for dense frame reconstruction. Since individual frames in the raw spike stream are spatially sparse, insufficient spike activity leads to spatial uncertainty (Zhu et al., 2019; 2020; Zheng et al., 2023). In contrast, RGB frames preserve global spatial relationships among scene elements, thereby serving as a coarse yet effective constraint to mitigate such uncertainty. In conclusion, cross-modality processing exhibits greater potential, with recent successes extending to 3D vision tasks (e.g., multi-view spike stream for 3DGS (Guo et al., 2025; Dai et al., 2024)) further validating this trend.

Nevertheless, we observed a significant discrepancy between current approaches — such as S-SDM — and the human visual system. While existing methods rely on pixel-level self-supervised learning (SSL), the human visual system acquires information through latent representations without explicit pixel reconstruction. To bridge this gap, we propose ***SpikeGen***, a model featuring a latent generative architecture, for the following reasons: **(i)** Since the emergence of Latent Diffusion Models (LDM) (Rombach et al., 2022), operations in latent space have become an efficient paradigm for model training. In SpikeGen, we pre-train the spike encoder to align with the latent space of RGB Variational Autoencoder (VAE) (Kingma et al., 2013), achieving an 512x spatial-temporal downsampling. This substantially reduces computational overhead during training, particularly in terms of pixel-space loss computation, thereby enabling efficient pre-training on large-scale synthetic datasets (Deng et al., 2009). **(ii)** Pre-training in the latent space also improves adaptability to downstream tasks. Although pixel-level SSL methods such as Masked Autoencoders (MAE) (He et al., 2022) have proven effective, recent advances in DINO (Caron et al., 2021; Oquab et al., 2023) and Joint-Embedding Prediction Architectures (JEPA) (Assran et al., 2023; Drozdov et al., 2024) demonstrate superior generalization by operating in the embedding (i.e., latent) space. A key commonality among these approaches is their focus on capturing latent-level similarities rather than minimizing pixel-wise reconstruction errors, which helps mitigate issues such as the "sharpness trap." **(iii)** Most prior works are based on deterministic modeling frameworks (Chen et al., 2024; 2023a; Chang et al., 2023; Fan et al., 2024). In contrast, SpikeGen adopts a probabilistic framework by performing diffusion in the VAE latent space. This choice is motivated by that the scenarios we address inevitably involve information loss, whether due to blurring in RGB modalities or spatial sparsity in spike modalities. Diffusion models exhibit superior performance in similar cases, such as super-resolution (Moser et al., 2024; Gao et al., 2023) and denoising (Ho et al., 2020; Kawar et al., 2022), attributed to their enhanced recovery accuracy, particularly for detailed content like textures and artificial structures.

108 In summary, our key contributions are as follows:  
 109

- 110 We systematically reviewed the merits of the human visual system, identifying the functionally  
 111 decoupled nature of the human eye and cortical processing in latent space as  
 112 fundamental to this advancement. Inspired by these biological mechanisms, we propose a  
 113 novel processing pipeline compatible with dual RGB-spike modality, named *SpikeGen*.
- 114 To the best of our knowledge, our work represents a pioneering effort in leveraging a  
 115 latent-based generative model for such tasks. The rationale stems from both **efficiency and**  
 116 **effectiveness** considerations: latent-space operations enable an exceptional compression  
 117 ratio (512-fold) during training while circumventing common issues with pixel-space loss,  
 118 such as the "sharpness trap," which undermines the model's generalization capability.
- 119 We validate SpikeGen across multiple downstream tasks, including conditional image/video  
 120 deblurring, dense frame reconstruction from spike streams, and high-speed scene novel-  
 121 view synthesis. This comprehensive evaluation encompasses **all major tasks** in visual  
 122 spike stream & RGB processing, thereby strongly supporting our hypothesis regarding the  
 123 challenges inherent to these tasks and the corresponding methodological designs.

## 125 2 RELATED WORKS

127 **Visual Spike Stream Processing** Spike cameras are bio-inspired vision sensors that capture local  
 128 intensity changes asynchronously, emitting spike streams. Compared to traditional frame-based  
 129 cameras, they offer advantages such as high dynamic range (HDR), low power consumption, high  
 130 temporal resolution, and inherent data compression, making them ideal for high-speed dynamics  
 131 and challenging lighting conditions. Early research focused on texture recovery methods, like retina-  
 132 inspired sampling by Zhu et al (Zhu et al., 2019). More recently, deep learning has dominated the  
 133 transformation of spike data into dense images. Zhao et al. introduced Spk2ImgNet (Zhao et al., 2021)  
 134 for reconstructing dynamic scenes from spike streams. Spiking Neural Networks (SNNs) (Zhang  
 135 et al., 2023b) have also been applied for biologically plausible processing, with Zhao et al. developing  
 136 SSIR (Zhao et al., 2023) architectures. Fan et al. proposed STIR (Fan et al., 2024) for spatio-temporal  
 137 interactive learning to improve reconstruction efficiency. In image deblurring, Chen et al. developed  
 138 SpkDeblurNet (Chen et al., 2023b) and S-SDM (Chen et al., 2024) to enhance motion deblurring  
 139 using spike information. Spike cameras are also advancing 3D vision and scene perception, as shown  
 140 by Dai et al (Dai et al., 2024) (SpikeNVS) and Guo et al. (Guo et al., 2025)(SpikeGS).

141 **Latent Generation Models** Generative modelling has made significant progress, enabling high-  
 142 fidelity image synthesis and other complex data modalities. Diffusion models, pioneered by Denoising  
 143 Diffusion Probabilistic Models (DDPMs) Ho et al. (2020), achieve state-of-the-art results by pro-  
 144 gressively denoising signals from Gaussian noise. To address slow sampling speeds, Song et al. Song  
 145 et al. (2020) introduced Denoising Diffusion Implicit Models (DDIMs), which offer faster generation  
 146 with comparable quality. Latent Diffusion Models (LDMs) Rombach et al. (2022) operate in a learned  
 147 latent space, reducing computational demands. SDXL Podell et al. (2023) further improved LDMs  
 148 for high-resolution image generation. Auto-regressive models also benefit from latent representa-  
 149 tions; MaskGIT Chang et al. (2022) uses transformers for masked generative image modelling with  
 150 discrete latent codes. Recent research Li et al. (2024) explores autoregressive generation directly  
 151 from continuous features, eliminating the need for quantization.

152 **Self-Supervised Learning** Self-Supervised Learning (SSL) has long been a prominent research  
 153 topic. The success of MAE (He et al., 2022) and SimMIM (Xie et al., 2022) demonstrated the  
 154 effectiveness of Masked Image Modeling (MIM) in pixel space, prompting recent SSL approaches to  
 155 investigate MIM in latent space as a more efficient and effective alternative. Image Joint-Embedding  
 156 Prediction Architectures (i-JEPA) (Assran et al., 2023) represent a representative effort in this  
 157 direction. Concurrently, DINO (Caron et al., 2021) explored the potential of contrastive learning (CL)  
 158 in latent space by aligning semantically consistent representations of the same image under different  
 159 augmentations. iBot (Zhou et al., 2021) integrated the strengths of latent space modeling, MIM, and  
 160 CL into a unified framework, inspiring subsequent works such as DINOv2 (Oquab et al., 2023) and  
 161 DINOv3 (Siméoni et al., 2025), which have scaled up latent space SSL to the billion-parameter level  
 in terms of both data volume and model capacity.

162 3 METHODS  
163164 3.1 PRELIMINARY  
165166 **Visual Spike Stream** The imaging principle of spike cameras diverges from both the exposure-  
167 based mechanism of conventional RGB cameras and the differential approach of event cameras.  
168 A spike camera operates by integrating incoming light intensity until an accumulator reaches a  
169 predefined activation threshold, denoted as  $V_{th}$ . Upon reaching this threshold, a spike is emitted, and  
170 any surplus intensity  $I$  beyond the threshold is retained for the next integration cycle. If  $I_t$  represents  
171 the light intensity input at time step  $t$ , the value stored in the accumulator,  $A_t$  evolves according to:  
172

173 
$$A_t = (A_{t-1} + I_t) \bmod V_{th} \quad (1)$$

174 A spike for a pixel  $p$  at coordinates  $(i, j)$  occurs when the accumulated value plus the current input  
175 signal meets or exceeds the threshold  $V_{th}$ . This determines the binary spike value, indicating whether  
176 the brightness level was sufficient during the sampling interval. The formal definition is:  
177

178 
$$p_{i,j,t} = \begin{cases} 1, & \text{if } A_{t-1} + I_t \geq V_{th} \\ 0, & \text{otherwise} \end{cases} \quad (2)$$
  
179

180 Reconstructing dense frames from these spike streams traditionally employs methods like Texture  
181 From Interval (TFI) or Texture From Playback (TFP) (Zhu et al., 2019). TFI excels at capturing  
182 texture contours. In contrast, TFP reconstructs textures across varied dynamic ranges by adaptively  
183 modifying the time window size based on contrast levels. Let  $d_{i,j,t}$  be the temporal latency, i.e.,  
184 the time elapsed since the last spike at pixel  $(i, j)$  before time  $t$ . Let  $w$  denote the size of the time  
185 window and  $N_{i,j,w}$  be the total number of spikes accumulated for pixel  $(i, j)$  within that window.  
186 The expressions for TFI and TFP reconstructed texture  $P^t$  at time  $t$  are:  
187

188 
$$\text{TFI: } P_{TFI}^t = \frac{V_{th}}{d_{i,j,t}}, \quad \text{TFP: } P_{TFP}^t = \frac{N_{i,j,w}}{w} * C \quad (3)$$
  
189

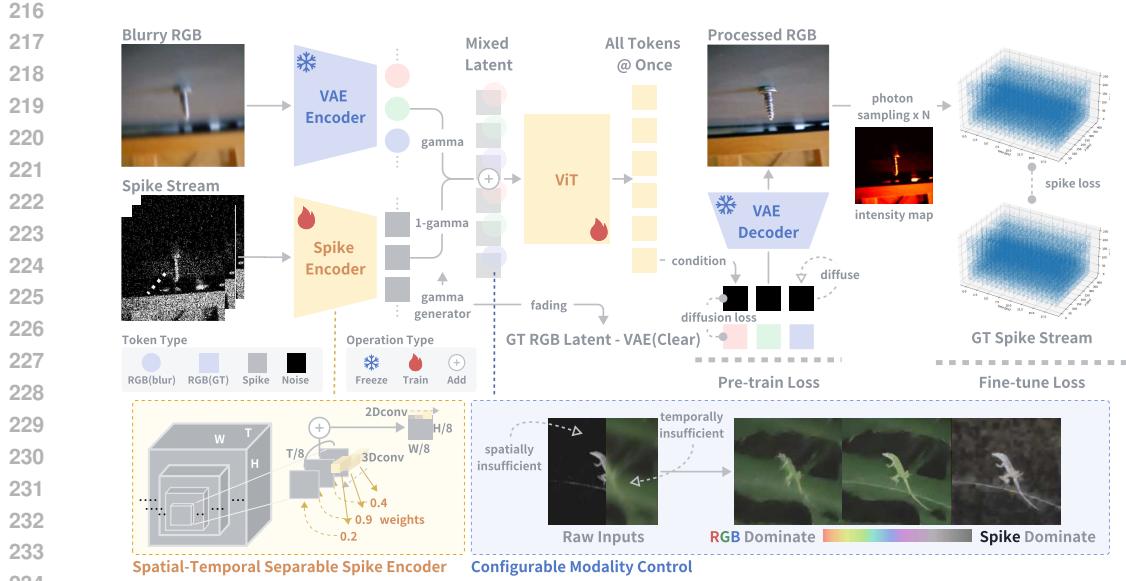

190 where  $C$  is a constant scaling factor for TFP.  
191192 **Latent Space Operation** Latent Diffusion Models (LDMs) (Rombach et al., 2022) are a type of  
193 latent space generative model designed for high-resolution image synthesis while being computa-  
194 tionally efficient. Instead of operating directly in the high-dimensional pixel space like traditional  
195 Diffusion Models, LDMs apply the diffusion process within the lower-dimensional latent space  
196 learned by a powerful pre-trained autoencoder (e.g., VAE (Kingma et al., 2013)). This autoencoder  
197 consists of an encoder  $\mathcal{E}(\cdot)$  that compresses the image  $x$  into a latent representation  $z = \mathcal{E}(x)$  and  
198 a decoder  $\mathcal{D}(\cdot)$  that reconstructs the image from the latent space  $\tilde{x} = \mathcal{D}(z)$  (Rombach et al., 2022).  
199 The diffusion model  $\epsilon_\theta$  is then trained solely within this latent space to denoise representations  $z_t$  at  
200 various noise levels  $t$ . This separation allows the computationally expensive training and sampling of  
201 the diffusion process to occur in a much more manageable space, focusing on semantic information  
202 rather than imperceptible pixel details.  
203The training objective for the Latent Diffusion Model is given by:  
204

205 
$$L_{LDM} := \mathbb{E}_{\mathcal{E}(x), \epsilon \sim \mathcal{N}(0,1), t} [\|\epsilon - \epsilon_\theta(z_t, t)\|_2^2]$$

206 Here,  $\epsilon$  is the noise sampled from a normal distribution,  $z_t$  is the noisy latent representation at timestep  
207  $t$ , and  $\epsilon_\theta(z_t, t)$  is the neural network predicting the noise added to  $z_t$ .  
208

## 3.2 SPIKEGEN: CONFIGURABLE DUAL MODALITY PRE-TRAIN

210 SpikeGen is developed by leveraging recent advancements in latent generation models. Specifically,  
211 we constructed a modified version of the Masked Auto-Regressive Model (MAR) (Li et al., 2024)  
212 to better suit our tasks. Similar to MAR, we encode RGB visual information via a Variational  
213 Autoencoder (VAE) (Kingma et al., 2013) and generate the conditioning input using a standard  
214 Vision Transformer (ViT) (Dosovitskiy et al., 2020) backbone. Subsequently, the conditioning input  
215 is processed through a compact Multi-Layer Perceptron (MLP), conducting a per-token diffusion  
process (Song et al., 2020) for decoding the latent representation (see Figure 2).  
216

**Figure 2: The Overall Pipeline of SpikeGen.** SpikeGen adopts a standard pre-training (self-supervised) and fine-tuning (task-dependent) pipeline. Specifically, visual information from two modalities is encoded, followed by the addition of the two latent representations. In this process,  $\gamma$  serves as a parameter to control the effective weight and is randomly sampled from the interval  $[0, 1]$ . Notice that during the pre-training phase, the diffusion loss is computed using the pre-extracted latent representation of the clear RGB image obtained via a Variational Autoencoder (VAE) (Kingma et al., 2013). The spike stream loss during the fine-tuning phase is calculated based on the given ground truth and the synthetic spike stream generated from the predicted RGB output.

**Diffusion with Decomposed Latent Condition** From a broader view, unlike the Masked Image Modelling (MIM) (He et al., 2022) strategies employed in MAR, we consider that both blurry RGB inputs (temporally insufficient) and spike inputs (spatially insufficient) represent forms of degradation. Consequently, the ViT in SpikeGen receives complete tokens from two encoders and generates conditions for the per-token diffusion. Since we do not need to predict new tokens from void, we have further streamlined the auto-regressive process of MAR into generating all tokens simultaneously. This enhances the efficiency during both training and inference (see Appendix Figure 6). We also found that this design did not affect the overall performance (see Appendix Table 7)

**Spatial-Temporal Separable Spike latent** Besides the Variational Autoencoder (VAE) utilized for encoding blurry RGB information, we developed a Spatial-Temporal Separable Spike (S3) Encoder. The S3 Encoder first applies a series of 3D convolutional blocks to transform the input spike stream from dimensions  $[B, 1, T, H, W]$  to  $[B, C_{out}, T/8, H/8, W/8]$  ( $C_{out} = 512$ ). These blocks progressively reduce the spatio-temporal resolution while increasing the channel depth, akin to the hierarchical structure employed in the UNet encoder. Following the temporal fusion stage, where the  $[B, C_{out}, T/8, H/8, W/8]$  features are processed to fuse information along the temporal dimension explicitly, we generate temporal attention weights for the features using two consecutive  $1 \times 1 \times 1$  3D convolutions. These attention weights are then multiplied element-wise with the features. The resulting weighted features are subsequently summed along the temporal dimension, collapsing it and producing a feature map of shape  $[B, C_{out}, H/8, W/8]$ . To further refine these spatially-resolved but temporally-fused features, a 2D convolution is applied, followed by a LayerNorm operation and a final LeakyReLU activation. When temporal fusion is active, the ultimate output of the S3 Encoder is a feature map of shape  $[B, C_{out}, H/8, W/8]$  (see Figure 2 and Appendix Table 5).

**Random Modality Dropout** To enable a configurable modality control after pre-training, we randomly assign the addition ratio of RGB latent (extracted by VAE encoder) and the spike latent (extracted by S3 encoder). The random ratio is denoted as  $\gamma$ , which is sampled from a Gaussian distribution with a mean of  $\mu = 0.5$  and a variance of  $\sigma^2 = 1$ , subsequently truncated to the interval

[0, 1]. This can be formally expressed as  $\gamma \sim \mathcal{N}_{[0,1]}(\mu = 0.5, \sigma^2 = 1)$ . The mixed latent,  $z_{mixed}$ , can then be calculated by the formula  $z_{mixed} = (1 - \gamma)z_{RGB} + \gamma z_{spike}$ . We intend to simplify the mixing strategy to enable better downstream usage. However, this indicates we cannot directly use the latent extracted from the clear RGB images as learning objectives. Instead, we colour fade the clear RGB images based on the  $\gamma$  value (higher fade intensity with increasing  $\gamma$ ). Let  $I_{clear}$  represent the original clear RGB image and  $I_{gray}$  be its corresponding grayscale version. The fade formula to obtain the faded image  $I_{faded}$  is as  $I_{faded} = (1 - \gamma) \cdot I_{clear} + \gamma \cdot I_{gray}$ . This ensures that when  $\gamma \rightarrow 1$  (spike latent becomes dominant),  $I_{faded}$  tends towards  $I_{gray}$ , and when  $\gamma \rightarrow 0$  (RGB latent is dominant),  $I_{faded}$  remains close to  $I_{clear}$ . This enables, when spike latent becomes the main content ( $\gamma$  is high), the model to focus more on texture reconstruction over precise colour prediction, as the learning objective  $I_{faded}$  will have reduced colour information (see Figure 2).

### 3.3 SPIKEGEN: TASK ADAPTATION

During pre-training, our loss is computed solely as the diffusion loss between the clear RGB latent and the latent predicted by SpikeGen. This significantly reduces computational costs when training on large-scale datasets. However, this latent alignment can underperform during fine-tuning, particularly with limited data, as it may not sufficiently guide the model to capture fine-grained details. For instance, the outdoor dataset (Ma et al., 2022) for 3D scene reconstruction contains merely 34 images per scene. A common strategy to mitigate this is to introduce pixel-space similarity measures during the fine-tuning phase; for example, models like SDXL (Podell et al., 2023) incorporate both MSE and perceptual losses calculated in the RGB pixel space. However, as downstream tasks for SpikeGen could lack clear RGB ground truth, we propose a spike-alignment strategy instead (see Figure 2). Specifically, the latent generated by SpikeGen is decoded back into the pixel space, yielding a predicted image  $I_{pred}$ . Based on the intensity of  $I_{pred}$ , we then generate a corresponding probability map  $P_{pred}$ . This process starts with min-max normalization and the  $I_{norm}$  image is convolved with a Gaussian kernel  $K_G$  (parameterized by  $\sigma_s$ ) to produce a smoothed version  $I_{smooth}$ . Finally,  $I_{smooth}$  undergoes gamma correction,  $P_{pred} = (I_{smooth})^{\gamma_c}$ , with a small amount of uniform random noise is added. Predicted spike stream can then be generated by sampling  $P_{pred}$ . The spike-alignment loss is computed by comparing the ground truth spike stream with the predicted spike stream.

## 4 EXPERIMENTS

We conducted comprehensive comparisons with more than 20 state-of-the-art baselines across 3 major visual spike & RGB processing tasks (conditional image/video deblurring, dense frame reconstruction from spike streams, and high-speed scene novel-view synthesis) to demonstrate the effectiveness and versatility of SpikeGen. We color-coded the performance in Table 1, 2, 3 with **Red (1st)**, **Blue (2nd)**. All the experiments follow the data usage and evaluation strategies used in S-SDM (Chen et al., 2024), STIR (Fan et al., 2024), and SpikeGS (Guo et al., 2025). See Appendix A for more details.

### 4.1 PRE-TRAINING

We performed pre-training on the complete training set of ImageNet (Deng et al., 2009) utilizing 8 A800 GPUs. We carefully tuned the hyperparameters to optimize the generation of synthetic data. Given the substantial volume of available data, we adopted a more aggressive blurring configuration and a sparser spike stream to enhance the learning challenge for the model. Specifically, we applied a  $40 \times 40$  blurring kernel and random sampled 8 from 64 generated spike frames per image. Through extensive pre-training, we anticipate that SpikeGen will exhibit robust generalization capabilities and successfully achieve the configurable modality conditioning discussed in Section 3.2. In Figure 3, we illustrate the generalization performance of SpikeGen on the ImageNet test set. Overall, even when RGB images are significantly blurred and spike information is relatively sparse, SpikeGen can effectively reconstruct artificial geometric shapes of objects (column 1, right) and natural fine structures (column 2, right). Furthermore, by controlling the injection of modalities, we showcased single-modal generalization capability (rows 3 and 4, left). When dual modalities collaborate, the model leverages their complementary strengths to achieve optimal results (row 5, left). We provided more visualization in Appendix C.2.

Figure 3: **Conditional Image Deblurring on Synthetic RGB-Spike Data.** For all our experiments, the input visual spike streams for SpikeGen are in binary format (0/1) without colour information. Here, for better visualization, row 2 (from top) of the left panel demonstrates the cut-out result of the RGB channels using 3 spike frames (results in row 4 used 8 frames as input). We also magnified a few results with highlighted detail for better comparison of the structural correctness (right panel).

Table 1: **Quantitative Results of Conditional Video Deblur Task.** The column colour reflects different thresholds when generating spike frames (code and value from S-SDM (Chen et al., 2024)). Higher thresholds produce spike frames with higher sparsity.

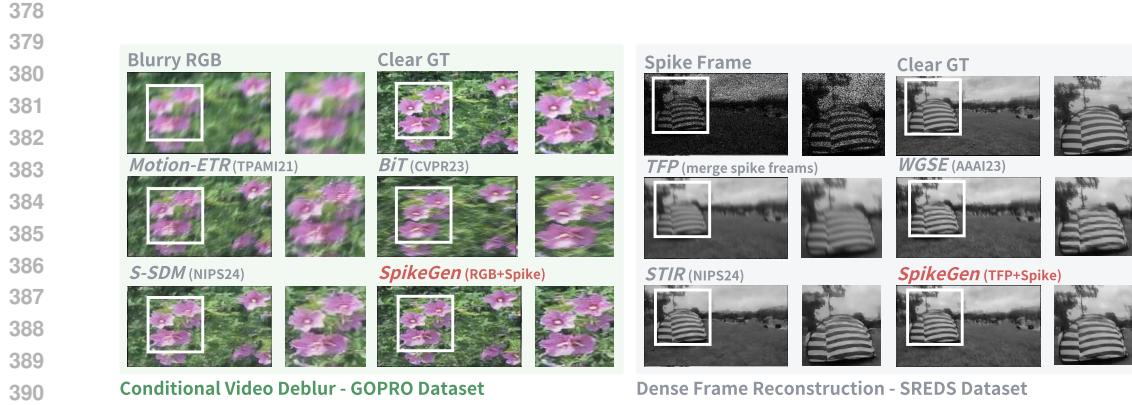

Dataset: <i>GOPRO</i> (Nah et al., 2017)

Furthermore, in terms of efficiency, we aim to evaluate whether the latent generation backbone selection in SpikeGen, combined with a non-autoregressive design (see Section 3.2), can reduce computational overhead. As shown in Table 7, our approach achieves a significant reduction in processing time without compromising performance.

## 4.2 FINE-TUNING GENERALIZATION

Given the extensive range of downstream experiments we have conducted, this section presents only the most concise and comparative results. For additional details, please refer to Appendix C.

**Conditional Image/Video Deblurring** We adhered to the same experimental setups as described in S-SDM (Chen et al., 2024) for this task. S-SDM generated paired blurry RGB-spike stream data based on the GOPRO dataset (Nah et al., 2017). Each blurry RGB input was converted by the SpikingSim simulator (Zhao et al., 2022) into an average of 98 spike frames (we use 8) with a spike threshold  $V_{th} = 1$  during training and  $V_{th} = 1/2/4$  during validation. As shown in the quantitative results presented in Table 1, SpikeGen significantly outperformed all baselines across all  $V_{th}$  configurations. Specifically, the relative improvement in PSNR increased from approximately 1 to approximately 3 as the spike guidance became sparser (higher  $V_{th}$ ). We attribute this phenomenon to two primary

**Figure 4: Mutual Guidance with Dual Modality Inputs.** The top panel presents the results obtained from both RGB-based deblurring methods and spike-RGB-based approaches. SpikeGen demonstrated superior performance compared to all competitors in terms of visual fidelity. The bottom panel illustrates the outcomes of various methods when only a limited number of spike frames (here, 16 frames) are available. SpikeGen addresses spatial ambiguity caused by spike sparsity by leveraging the merged result of spike frames (i.e., TFP) as a pseudo-dense modality.

**Table 2: Quantitative Results of Dense Frame Reconstruction Task.** The row color indicates the method type, with red denoting training-free methods, yellow representing event-based methods, and blue corresponding to spike-based methods.

Methods	Dataset: SREDS (Zhao et al., 2023)					Dataset: momVidar2021 (Zhu et al., 2020)	
	PSNR $\uparrow$	SSIM $\uparrow$	LPIPS $\downarrow$	NIQE $\downarrow$	BRISQUE $\downarrow$	NIQE $\downarrow$	BRISQUE $\downarrow$
TFP (ICME19) (Zhu et al., 2019)	25.35	0.69	0.26	5.97	43.07	9.34	45.20
TFI (ICME19) (Zhu et al., 2019)	18.50	0.64	0.26	4.52	44.93	10.10	58.31

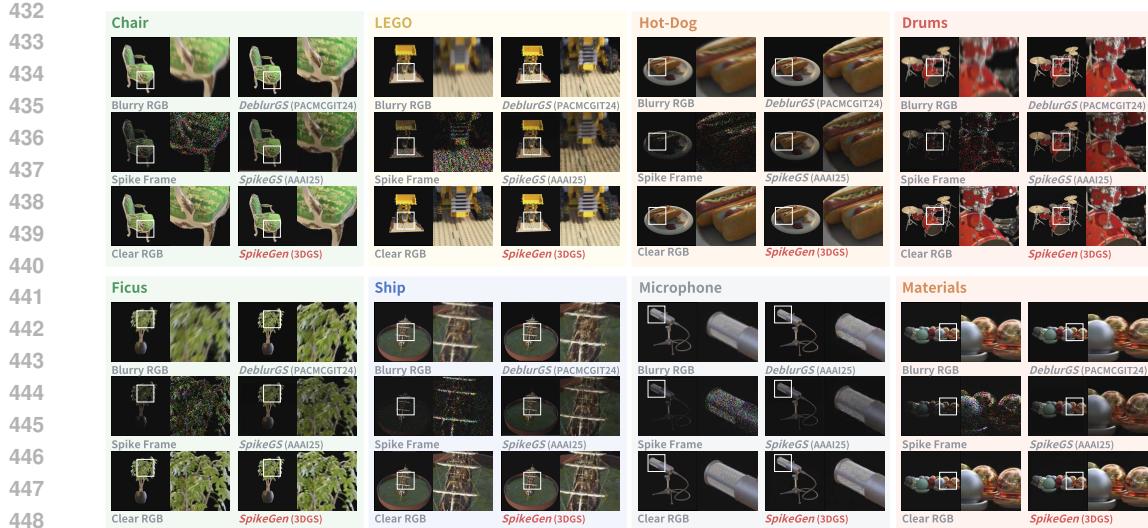

Figure 5: Qualitative Results of Novel View Synthesis Task.

**Dense Frame Reconstruction** As elaborated in Section 1, we posit that the spatial relationships embedded within dense RGB data, even when blurred, can address the sparsity inherent in spike streams. Consequently, validating this hypothesis on the dense frame reconstruction task holds merit. Following the experimental setups outlined in STIR (Fan et al., 2024), we utilized data from REDS (Xu et al., 2021) to synthesize a spike-based dataset (SREDS). Specifically, SREDS converts each RGB frame in REDS into 64 corresponding spike frames (we use 16) and further crops them into patches of size  $96 \times 96$ , resulting in a total of 21,840 patches. Additionally, the model was evaluated on the real-world dataset momVidReal2021 (Zhu et al., 2020). As demonstrated in Table 2 and Figure 4, SpikeGen exhibits superior performance, both in referenced metrics (PSNR, SSIM, and LPIPS (Zhang et al., 2018)) and no-reference metrics (NIQE (Mittal et al., 2012b) and BRISQUE (Mittal et al., 2012a)). A pivotal factor contributing to these results is the integration of Texture from Playback (TFP) (Zhu et al., 2019) as a pseudo grayscale image. TFP aggregates all spike frames within a fixed temporal window, akin to simulating shutter timing in conventional RGB cameras for spike streams. This approach enhances spatial richness at the expense of temporal resolution, thereby introducing blur. SpikeGen mitigates this limitation by reprocessing the raw spike streams to achieve high-quality reconstructions (see Appendix C.4 for ablation studies without TFP priors).

**High-speed Scene Novel-View Synthesis** Finally, we evaluated SpikeGen’s performance on the recently emerging task of high-speed scene novel-view synthesis. Our experimental setups were based on SpikeGS (Guo et al., 2025), which transformed the synthetic Blender datasets introduced in NeRF (Mildenhall et al., 2021) (for object-centric scenes) and DeblurNeRF (Ma et al., 2022) (for outdoor scenarios) into dual-modality pairs. As illustrated in Figure 5, while DeblurGS (Chen & Liu, 2024) demonstrates overall sharpness, it exhibits blurry details due to its reliance solely on the RGB modality. SpikeGS successfully recovers finer details; however, its optimization prioritizes texture repair using the binary spike stream at the expense of accurate color saturation matching to the ground truth RGB. In contrast, SpikeGen achieves an excellent qualitative balance and further validates its adaptability through quantitative results (see Table 3). Notably, despite being a two-stage method, SpikeGen outperforms other approaches, as evidenced by extra experiments comparing various two-stage methods (see Appendix C.5).

### 4.3 CONCLUSION

We propose **SpikeGen**, the first latent generative framework specifically designed for decoupled visual representation processing. We successfully pre-trained the model on more than one million images and demonstrated its broad applicability across diverse tasks, covering all major domains of joint spike stream and RGB visual processing. We believe this can serve as a foundation for advancing

486 latent generative modeling in neuromorphic vision, closely mirroring the human capacity to integrate  
 487 perception and imagination for multimodal visual processing in dynamic environments.  
 488

489 **5 ETHICS STATEMENT**

490  
 491 This paper presents work whose goal is to advance the field of Machine Learning. There are many  
 492 potential societal consequences of our work, none which we feel must be specifically highlighted  
 493 here.  
 494

495 **6 REPRODUCIBILITY STATEMENT**

496 To ensure the reproducibility of the computational experiments, we have provided the code in the  
 497 supplementary materials. Anonymous README file is also included. Detailed information regarding  
 498 the selected baselines, data usage, and codebases is presented in the Appendix.  
 499

756 **A EXPERIMENT SETUPS**  
757758 **A.1 BASELINES**  
759760 **Conditional Video Deblurring**  
761

- 762 Jin et al. (Jin et al., 2018) proposed LEVS, which tackled the extraction of a video sequence  
763 from a single motion-blurred image by proposing a deep learning scheme that sequentially  
764 reconstructs pairs of frames using loss functions invariant to their temporal order.
- 765 Zhang et al. (Zhang et al., 2021b) proposed MotionETR, focusing on recovering dense,  
766 potentially non-linear exposure trajectories from a motion-blurred image by proposing a  
767 novel motion offset estimation framework to model pixel-wise displacements over time.
- 768 Zhong et al. (Zhong et al., 2023) addressed real-world motion recovery from blur (joint  
769 deblurring and interpolation) by introducing a Blur Interpolation Transformer (BiT) that  
770 utilizes multi-scale residual Swin Transformer blocks and temporal supervision strategies.
- 771 Sun et al. (Sun et al., 2023) worked on event-based video frame interpolation with the  
772 capability of ad-hoc deblurring for both sharp and blurry input frames, using a bidirectional  
773 recurrent network (REFID) that adaptively fuses image and event information.
- 774 Xu et al. (Xu et al., 2021) tackled motion deblurring using real-world event data through a  
775 self-supervised learning framework (RED-Net) that leverages event-predicted optical flow  
776 for blur and photometric consistency constraints.
- 777 Chen and Yu (Chen & Yu, 2024) addressed event-based motion deblurring by proposing a  
778 Two-stage Residual-based Motion Deblurring (TRMD) framework, which first estimates an  
779 intensity residual sequence from events and then uses it to reconstruct sharp frames from the  
780 blurry image.
- 781 Chen et al. (Chen et al., 2023b) aimed at enhancing motion deblurring in high-speed scenes  
782 by proposing SpkDeblurNet, a model that leverages spike streams as auxiliary cues and  
783 employs content-aware motion magnitude attention and transposed cross-attention fusion  
784 for RGB-spike data integration.
- 785 Chen et al. (Chen et al., 2024) (SpikeReveal) focused on unlocking temporal sequences  
786 of sharp images from real blurry inputs assisted by spike streams, using a self-supervised  
787 spike-guided deblurring model (S-SDM) that explores theoretical relationships between the  
788 modalities.

790 **Dense Frame Reconstruction**  
791

- 792 Zhu et al. (Zhu et al., 2019) addressed visual texture reconstruction from spike streams by  
793 proposing a retina-inspired sampling method (TFP and TFI) and associated spike stream  
794 decoding techniques.
- 795 Zheng et al. (Zheng et al., 2021) tackled high-speed image reconstruction from spiking  
796 cameras by introducing novel models (TFSTP and TFMDSTP) based on the short-term  
797 plasticity (STP) mechanism of the brain.
- 798 Zhang et al. (Zhang et al., 2023a) focused on learning effective temporal-ordered representa-  
799 tions for spike streams by proposing a Wavelet-Guided Spike Enhancing (WGSE) paradigm  
800 that utilizes discrete wavelet transforms.
- 801 Zhao et al. (Zhao et al., 2021) developed Spk2ImgNet, a spike-to-image neural network,  
802 to learn the reconstruction of dynamic scenes from continuous spike streams generated by  
803 spiking cameras.
- 804 Zhao et al. (Zhao et al., 2023) proposed SSIR to addressed spike camera image reconstruction  
805 by employing deep Spiking Neural Networks (SNNs), aiming for comparable performance  
806 to state-of-the-art methods but with lower computational costs.
- 807 Fan et al. (Fan et al., 2024) tackled efficient image reconstruction for spiking cameras by  
808 proposing a spatio-temporal interactive reconstruction network (STIR) that jointly performs  
809 inter-frame feature alignment and intra-frame feature filtering in a coarse-to-fine manner.

- 810 Ercan et al. Ercan et al. (2024) aimed to improve event-based video reconstruction by  
811 proposing HyperE2VID, a dynamic neural network architecture that uses hypernetworks to  
812 generate per-pixel adaptive filters guided by a context fusion module.
- 813 • Weng et al. Weng et al. (2021) addressed event-based video reconstruction by proposing ET-  
814 Net, a hybrid CNN-Transformer framework designed to leverage both fine local information  
815 from CNNs and global context from Transformers.

### 817 Novel-View Synthesis

- 819 Kerbl et al. Kerbl et al. (2023) introduced 3D Gaussian Splatting for real-time, high-quality  
820 radiance field rendering by representing scenes as a collection of 3D Gaussians optimized  
821 from sparse points and rasterized efficiently.
- 822 • Ma et al. Ma et al. (2022) addressed the reconstruction of Neural Radiance Fields (NeRFs)  
823 from blurry images by proposing Deblur-NeRF, which simulates the blurring process using  
824 a deformable sparse kernel module within an analysis-by-synthesis framework.
- 825 • Chen and Liu Chen & Liu (2024) tackled 3D scene reconstruction using Gaussian Splat-  
826 tting from camera motion-blurred images (Deblur-GS) by jointly optimizing 3D Gaussian  
827 parameters and the camera’s motion trajectory during exposure time.
- 828 • Guo et al. Guo et al. (2024) proposed Spike-NeRF, the first Neural Radiance Field based  
829 method for 3D reconstruction and novel view synthesis of high-speed scenes using continu-  
830 ous spike streams from a moving spike camera, incorporating spike masks and a specialized  
831 loss function.
- 832 • Guo et al. Guo et al. (2025) developed SpikeGS to reconstruct 3D scenes from Bayer-pattern  
833 spike streams captured by a fast-moving bio-inspired camera by integrating spike data into  
834 the 3D Gaussian Splatting pipeline using accumulation rasterization and interval supervi-  
835 sion.

## 836 A.2 DATASETS

838 **Pre-Training** We utilize the complete training set from ImageNet (Deng et al., 2009) to synthesize  
839 spike-RGB pairs. ImageNet comprises 1,000 categories, with each category containing approximately  
840 1,000 RGB images, resulting in a total of roughly 1 million images. For each clear RGB image, we  
841 transform it into a blurred image and an 8-frame spike stream. The RGB blur kernel is configured as  
842  $40 \times 40$ , and the coverage rate of the spike stream is set to 0.1. The Dataset and Dataloader code are  
843 provided in the supplementary materials.

845 **Conditional Video Deblurring** To facilitate a quantitative analysis of our spike-assisted motion  
846 deblurring performance, we constructed a synthetic dataset leveraging the commonly adopted GO-  
847 PRO (Nah et al., 2017) dataset. The process commenced with the application of the XVFI (Sim  
848 et al., 2021) interpolation algorithm, which served to augment the video data by generating seven  
849 additional intermediate frames between every pair of successive sharp images. For the creation of  
850 spike streams that faithfully mimic real-world sensor data, the interpolated video sequences were  
851 first spatially downscaled to a  $320 \times 180$  resolution, followed by simulation using a dedicated spike  
852 simulator (Zhao et al., 2022). To replicate the effects of real-world motion blur, each blurry input  
853 frame was then synthesized through the averaging of 97 consecutive frames from these upsampled  
854 video sequences.

855 **Dense Frame Reconstruction** Following STIR (Fan et al., 2024), the SREDS dataset, a recently  
856 introduced collection that was synthesized from the established REDS (Xu et al., 2021) dataset. This  
857 dataset is organized into 240 distinct scenes for training and 30 separate scenes for testing. Each  
858 scene consists of 24 sequential frames, with every frame being accompanied by a corresponding  
859 spike stream ( $N=20$ ) that is centrally aligned to it. The spatial resolution for this data is  $1280 \times 720$   
860 pixels. In preparation for training, we crop each scene into non-overlapping patches of  $96 \times 96$  pixels,  
861 which yields a total of 21,840 patches. To evaluate our model’s effectiveness, we employ real-world  
862 captured data. This validation set includes the “momVidReal2021” (Zhu et al., 2020) publicly  
863 accessible dataset, which has a resolution of  $400 \times 250$  and features significant object and camera  
864 motion at high speeds (this dataset has also been previously employed in other studies).

**Novel-View Synthesis** We use the same dataset used in SpikeGS (Guo et al., 2025). It first contains the Blender dataset presented by NeRF (Mildenhall et al., 2021), this dataset comprises path-traced images of eight objects characterized by intricate geometry and realistic non-Lambertian materials. For six of these objects, viewpoints were sampled across the upper hemisphere, while the other two were rendered from viewpoints covering a full sphere. For every scene in this dataset, 100 views are rendered to serve as input and 200 views for testing purposes, all at an  $800 \times 800$  pixel resolution. The second one is the Blender dataset presented by DeblurNeRF (Ma et al., 2022). This dataset synthesized five distinct scenes, with multi-view cameras manually positioned to simulate realistic data capture conditions. To create images with camera motion blur, it first introduced random perturbations to the camera poses and then performed linear interpolation between the original and perturbed poses for each view; images rendered from these interpolated poses were subsequently blended in linear RGB space to form the final blurry images.

### A.3 METRICS

Several metrics are commonly used to evaluate the quality of images, differing in whether they require a reference (Full-Reference, FR) or operate without one (No-Reference, NR).

**Peak Signal-to-Noise Ratio (PSNR)** is an FR metric that measures image fidelity based on the Mean Squared Error (MSE) between a reference image  $I$  and a processed image  $K$ , both of size  $m \times n$ . A higher PSNR generally indicates better reconstruction quality. It is defined as:

$$MSE = \frac{1}{m \cdot n} \sum_{i=0}^{m-1} \sum_{j=0}^{n-1} [I(i, j) - K(i, j)]^2 \quad (4)$$

$$PSNR = 10 \cdot \log_{10} \left( \frac{MAX_I^2}{MSE} \right) \quad (5)$$

where  $MAX_I$  is the maximum possible pixel value of the image (e.g., 255 for 8-bit images).

**Structural Similarity Index Measure (SSIM)** is another FR metric designed to better align with human perception of image quality by considering changes in structural information, luminance, and contrast. For two image windows  $x$  and  $y$ , SSIM is calculated as:

$$SSIM(x, y) = \frac{(2\mu_x\mu_y + c_1)(2\sigma_{xy} + c_2)}{(\mu_x^2 + \mu_y^2 + c_1)(\sigma_x^2 + \sigma_y^2 + c_2)} \quad (6)$$

where  $\mu_x, \mu_y$  are the local means,  $\sigma_x^2, \sigma_y^2$  are the local variances,  $\sigma_{xy}$  is the local covariance, and  $c_1, c_2$  are small constants to stabilize the division. The overall SSIM is typically the average of local SSIM values. Higher SSIM values (closer to 1) indicate greater similarity.

**Learned Perceptual Image Patch Similarity (LPIPS)**, proposed by Zhang et al. (Zhang et al., 2018), is an FR metric that aims to better reflect human perceptual judgments by comparing deep features extracted from images using pre-trained convolutional neural networks. The distance  $d$  between a reference image  $x_0$  and a distorted image  $x$  is computed by summing the L2 distances of their feature activations  $\hat{y}^l, \hat{y}_0^l$  (normalized and channel-wise scaled by  $w_l$ ) across different layers  $l$  of a network:

$$d(x, x_0) = \sum_l \frac{1}{H_l W_l} \sum_{h,w} \|w_l \odot (\hat{y}_{hw}^l - \hat{y}_{0hw}^l)\|_2^2 \quad (7)$$

Lower LPIPS scores indicate higher perceptual similarity.

**Natural Image Quality Evaluator (NIQE)**, introduced by Mittal et al. (Mittal et al., 2012b), is an NR (blind) IQA metric. It operates by constructing a model based on natural scene statistics (NSS) extracted from a corpus of pristine natural images. The quality of a test image is then measured by the distance between the NSS features extracted from it and the pristine model. NIQE does not require training on human opinion scores of distorted images. Lower NIQE scores suggest better perceptual quality, closer to natural image statistics. The core idea involves fitting a multivariate Gaussian model to features derived from patches of natural images and then measuring the deviation of test image patch features from this model.

**Blind/Referenceless Image Spatial Quality Evaluator (BRISQUE)**, developed by Mittal et al. (Mittal et al., 2012a), is another NR IQA model that operates in the spatial domain. It quantifies the loss

918 of "naturalness" in an image by analyzing deviations in its locally normalized luminance coefficients  
919 (specifically, Mean Subtracted Contrast Normalized - MSCN coefficients) from statistical models of  
920 natural images. Features derived from the MSCN coefficient distributions are used to train a Support  
921 Vector Regressor (SVR) to predict a subjective quality score. Lower BRISQUE scores generally  
922 indicate better quality.

## 972 B TRAINING CONFIGURATIONS

974 All experiments were carried out on eight A800 GPUs, utilizing AdamW as the optimizer with  
 975 a weight decay rate of 0.05. The training schedule was configured to include a warm-up phase  
 976 (spanning 10% of the total epochs), during which the learning rate increased from 1e-8 to the target  
 977 value, followed by a cosine decay to a minimum learning rate of 1e-6.

### 979 B.1 MODEL

981 All the results are conducted with the same model hyperparameters listed in Table 4

## C ADDITIONAL RESULTS

### C.1 EFFICIENT LATENT PROCESSING WITHOUT AUTO-REGRESSION

As outlined in Section 3, our model emphasizes the integration and restoration of existing visual tokens rather than generating new tokens from void. In light of this focus, and to further enhance computational efficiency, we eliminated the autoregressive component that was present in the original MAR framework. It is important to note that this architectural modification does not compromise the model’s performance, as demonstrated in Table 7.

Table 7: Efficiency Comparison: SpikeGen vs. Diffusion Baselines

Dataset: ImageNet   Device: 1×NVIDIA A100 80G   Resolution: 256×256				
Backbone	time/256 images	PSNR	SSIM	LPIPS
<b>DIT-B</b> (100 × ViT steps) × 256 tokens	2min19s	18.11	0.59	0.28
<b>MAR-B</b> (64 × ViT steps + 100 × MLP steps) × gradually to 256 tokens	1min32s	18.79	0.65	0.21
<b>SpikeGen</b> (1 × ViT steps + 100 × MLP steps) × 256 tokens	2.7s	19.08	0.62	0.19

### C.2 GENERALIZATION ON IMAGENET

We present extra visualization results as an extended support for the discussion in Section 4.1.

### C.3 CONDITIONAL VIDEO DEBLURRING

As the conclusion elaborated in detail in the main text, introducing the spike modality can greatly alleviate the ambiguity of deblurring images, thus avoiding falling into the "sharpness trap" of single RGB modality deblurring. In Figure 8, we demonstrate that this property can be successfully transferred to downstream tasks. We can observe that, regardless of the sparsity of the introduced spikes (controlled by  $V_{th}$ ), the final deblurring results are superior to those relying on a single RGB modality. Moreover, as  $V_{th}$  decreases (indicating denser spike information), this improvement becomes more pronounced. From the visualization results, we can also see that although the overall texture is similar, introducing the spike modality can significantly enhance the restoration details.

### C.4 DENSE FRAME RECONSTRUCTION

We mentioned in the main text that using the results of TFP as pseudo-dense frames can significantly improve the performance of the model, and we further demonstrated this in Table 8. When relying solely on spike streams, the model has difficulty directly fusing spatially sparse binary spike streams. Especially when the number of spike frames is insufficient. However, simply increasing the number of spike frames means that the model needs to multiply the inference consumption. Therefore, using the results of TFP as pseudo-dense frames is a good balancing operation. When using 1/4 of the spike frames (we use 16 frames while STIR (Fan et al., 2024) uses 64 frames), we have improved

the performance of SpikeGen to the state-of-the-art level, even though the focus of our work is not on single-modal tasks. To further verify our conclusion, we conducted a more extreme comparison. In Figure 9, we further reduced the number of spike frames to 8. In this case, STIR is unable to restore the spatial details of the object, while our method can still maintain a certain level of detail restoration, such as the texture of the floor tiles.

### 1229 C.5 NOVEL-VIEW SYNTHESIS

1230 We mentioned in the main text that our method is not an end-to-end model similar to SpikeGS Guo et al. (2025). However, we believe that this two-stage method also has potential advantages. For 1231 example, it can better leverage pre-trained priors and decouple the complexity of optimizing texture 1232 and perceptual fidelity. Therefore, we also compared the effects of using other spike processors for 1233 two-stage reconstruction. As shown in Table 9, although this two-stage method is feasible, it is not 1234 easy to achieve stable excellence. In the Object data, since the background (pure black) and objects 1235 are relatively simple, the other two-stage methods also perform well. However, in outdoor scenes, due 1236 to the complex background and tiny components, the performance of the other two-stage methods 1237 is greatly affected, while SpikeGen can still maintain a relatively stable performance. We further 1238 presented all the test contents on the two datasets and the specific metrics of our method in Figure 10. 1239
