Abstract

Annealed Importance Sampling (AIS) [27][13] is the gold standard for estimating partition functions or marginal likelihoods, corresponding to importance sampling over a path of distributions between a tractable base and an unnormalized target. While AIS yields an unbiased estimator for any path, existing literature has been limited to the geometric mixture or moment-averaged paths associated with the exponential family and KL divergence [13]. We explore AIS using q-paths, which include the geometric path as a special case and are related to the homogeneous power mean, deformed exponential family, and α-divergence [3].

1 Introduction

AIS [27][13] is a method for estimating intractable normalization constants, which considers a path of intermediate distributions πt(z) between a tractable base distribution π0(z) and unnormalized target πT(z). In particular, AIS samples from a sequence of MCMC transition operators Tt(z|zt−1) which leave each πβt(z) = πβt(z)/Zt invariant to estimate the ratio ZT/Z0. As shown in Algorithm 1 we can accumulate the importance weights wT t = w0 t = i=1 T tπt(zt−1)/πt−1(zt−1) along the path.

Taking the expectation of wT t over sampling chains yields an unbiased estimate of ZT/Z0 [27]. Similarly, Bidirectional Monte Carlo (BMC) [14][15] provides lower and upper bounds on the log partition function ratio log ZT/Z0 using AIS initialized with the base or target distribution, respectively.

AIS often uses a geometric mixture path with schedule {βt}t=0T to anneal between π0 and πT,

$$\tilde{\pi}_\beta(z) = \tilde{\pi}_0(z)^{1-\beta} \tilde{\pi}_T(z)^{\beta},$$

where $\pi_\beta(z) = \pi_\beta(z)/Z_\beta$ and $Z_\beta = \int \tilde{\pi}_0(z)^{1-\beta} \tilde{\pi}_T(z)^{\beta} dz$.

Alternative paths have been discussed in [13][12][10], but may not have closed form expressions for intermediate distributions. In this work, we propose to generalize the geometric mixture path [1] using the power mean [19][17][11]. or q-path,

$$\tilde{\pi}_\beta^{(q)}(z) = \left[ (1-\beta) \tilde{\pi}_0(z)^{1-q} + \beta \tilde{\pi}_T(z)^{1-q} \right]^{1/1-q}$$

As $q \to 1$, we recover the geometric mixture path as a special case. The power mean also contains as a special case the $q$-logarithm used in non-extensive thermodynamics [31][26][32], which allows us

*equal contribution

Algorithm 1: Annealed IS

for $i=1$ to $N$ do
\( z_0 \sim \pi_0(z) \)
\( w_0^{(i)} \leftarrow Z_0 \)
for $t=1$ to $T$ do
\( w_t^{(i)} \leftarrow w_{t-1}^{(i)} \frac{\tilde{\pi}_t(z_t^{(i)})}{\tilde{\pi}_{t-1}(z_{t-1}^{(i)})} \)
\( z_t^{(i)} \sim T_t(z_t^{(i)}) \)
end
return $Z_T/Z_0 \approx \frac{1}{N} \sum_N w_T^{(i)}$
to frame Eq. (2) in terms of the the q-exponential family [6]. Further, we draw connections with the α-integration of Amari [3,4] by showing that Eq. (2) minimizes a mixture of α-divergences as in [3]. We describe properties of the geometric and q-paths in Section 2 and Section 3 respectively.

2 Interpretations of the Geometric Path

We give three complementary interpretations of the geometric path defined in Eq. (1), which will have generalized analogues in Section 3.

Log Mixture Simply taking the logarithm of both sides of the geometric mixture (1) shows that \( \tilde{\pi}_\beta \) can be obtained by taking the log-mixture of \( \tilde{\pi}_0 \) and \( \tilde{\pi}_T \) with mixing parameter \( \beta \),

\[
\log \tilde{\pi}_\beta (z) = (1 - \beta) \log \tilde{\pi}_0 (z) + \beta \log \tilde{\pi}_T (z)
\]

(3)

where we may also choose to subtract a constant \( \log Z_\beta \) to enforce normalization.

Exponential Family Distributions along the geometric path may also be viewed as coming from an exponential family [9,16]. In particular, we use a base measure of \( \tilde{\pi}_0 (z) \) and sufficient statistics \( \phi(z) = \log \tilde{\pi}_T / \tilde{\pi}_0 \) to rewrite Eq. (1) as

\[
\pi_\beta (z) = \tilde{\pi}_0 (z) \exp \{ \beta \cdot \phi(z) - \psi (\beta) \}
\]

(4)

where the mixing parameter \( \beta \) appears as the natural parameter of the exponential family and \( \psi (\beta) := \log Z_\beta \). The log-partition function or free energy \( \psi (\beta) \) is convex in \( \beta \) and induces [4,29,9] a Bregman divergence over the natural parameter space equivalent to the KL divergence \( D_{KL}[\pi_\beta || \pi_\beta] \).

Variational Representation Grosse et al. [13] also observe that each \( \pi_\beta (z) \) can be viewed as minimizing a weighted sum of KL divergences to the (normalized) base and target distributions

\[
\pi_\beta (z) = \arg \min \limits_{r(z)} (1 - \beta) D_{KL}[r(z) || \pi_0 (z)] + \beta D_{KL}[r(z) || \pi_T (z)].
\]

(5)

While the optimization in Eq. (5) is over arbitrary \( r(z) \), the optimal solution is the geometric mixture with mixing parameter \( \beta \), which is a member of the exponential family in Eq. (4)[13][9].

3 Interpretations of the q-Path

To anneal between \( \tilde{\pi}_0 \) and \( \tilde{\pi}_T \), we consider the power mean with order parameter \( q \) in place of the geometric average in Eq. (1). Analogously to Sec. 2 above, our generalization is associated with the deformed log mixture, q-exponential family, and a variational representation using the α-divergence.

Power Means Kolmogorov [19] proposed a generalized notion of the mean using any monotonic function \( h(u) \), with \( h(u) = u \) corresponding to the arithmetic mean and

\[
\mu_h (\{ w_i, u_i \}) = h^{-1} \left( \sum_i w_i \cdot h(u_i) \right),
\]

(6)

where \( \mu_h \) outputs a scalar given a normalized measure \( \{ w_i \} \) over a set of elements \( \{ u_i \} \) [11]. The geometric and arithmetic means are homogeneous, meaning they have the linear scale-free property \( \mu_h (\{ c \cdot w_i, c \cdot u_i \}) = c \cdot \mu_h (\{ w_i, u_i \}) \). In order for the power mean to be homogenous, Hardy et al. [17] (pg. 68 or [3]) show that \( h(u) \) must be of the form

\[
h_q(u) = \begin{cases} 
  a \cdot u^{1-q} + b & q \neq 1 \\
  \log u & q = 1 
\end{cases}
\]

(7)

which we refer to as the q-power mean. Notable examples of the power mean include the arithmetic mean at \( q = 0 \), geometric mean as \( q \to 1 \), and the min or max operation as \( q \to \pm \infty \). For \( q = \frac{1+\alpha}{2} \), \( h_q(u) \) matches the α-representation of Amari [3,15,7].
Using the power mean to generalize geometric mean, we propose the $q$-path of intermediate unnormalized densities $\tilde{\pi}_\beta^{(q)}(z)$ for AIS. In App. A we show that for any choice of $a$ and $b$, $h_q(u)$ yields the same power mean

$$
\tilde{\pi}_\beta^{(q)}(z) = \begin{cases} 
\left[ (1 - \beta) \tilde{\pi}_0(z)^{1-q} + \beta \tilde{\pi}_T(z)^{1-q} \right]^{\frac{1}{1-q}} & q \neq 1 \\
\exp \left\{ (1 - \beta) \log \tilde{\pi}_0(z) + \beta \log \tilde{\pi}_T(z) \right\} & q = 1 ,
\end{cases}
$$

(8)

where we have chosen $\{u_1\} = \{1 - \beta, \beta\}$ and $\{u_i\} = \{\tilde{\pi}_0, \tilde{\pi}_T\}$ in $[6]$.

**Deformed Log Mixture** The deformed, or $q$-logarithm $[26]$, which plays a crucial role in non-extensive thermodynamics $[31, 32]$, is a particular special case of $h_q(u)$ in Eq. (16) with

$$
\ln_q(u) = \frac{1}{1-q}(u^{1-q} - 1), \quad \exp_q(u) = \left[ 1 + (1 - q) u \right]^{\frac{1}{1-q}},
$$

(9)

where we have also defined the $q$-exponential with \( \exp_q(u) = \ln_q^{-1}(u) \) and \( |x| = \max\{0, x\} \) ensuring \( g(u) \) is non negative. Note that \( \lim_{q \to 1} \ln_q(u) = \log u \) and \( \lim_{q \to 1} \exp_q(u) = \exp u \).

Applying $h_q(u) = \ln_q(u)$ to both sides of Eq. (6) or (8), we can write $\tilde{\pi}_\beta^{(q)}$ as a deformed log-mixture

$$
\ln_q \tilde{\pi}_\beta^{(q)}(z) = (1 - \beta) \ln_q \tilde{\pi}_0(z) + \beta \ln_q \tilde{\pi}_T(z)
$$

(10)

with mixing weight $\beta$. We also provide detailed derivations for Eq. (10) in App. B.1

**$q$-Exponential Family** The $q$-exponential in Eq. (9) may be used to define a $q$-exponential family of distributions $[6, 26]$. Using $\theta$ as the natural parameter,

$$
\pi_\theta^{(q)}(z) = \tilde{\pi}_0(z) \exp_q \{ \theta \cdot \phi_q(z) - \psi_q(\theta) \},
$$

(11)

which recovers the standard exponential family at $q \to 1$. In App. B.2 we show that the $q$-mixture $\pi_\beta^{(q)}$ in Eq. (8) can be rewritten in terms of the $q$-exponential family

$$
\pi_\beta^{(q)}(z) = \frac{1}{Z_\beta^{(q)}} \tilde{\pi}_0(z) \exp_q \{ \beta \cdot \ln_q \tilde{\pi}_T(z) / \tilde{\pi}_0(z) \} \quad Z_\beta^{(q)} = \int \tilde{\pi}_\beta^{(q)}(z) dz
$$

(12)

with sufficient statistic $\phi_q(z) = \ln_q \tilde{\pi}_T / \tilde{\pi}_0$ and natural parameter $\beta$. The expression in (12) might be used to directly estimate the normalization constant $Z_\beta^{(q)}$ via Monte Carlo approximation.

As for the standard exponential family, the $q$-free energy $\psi_q(\theta)$ in Eq. (11) is convex in $\theta$ and can be used to construct a Bregman divergence over normalized $q$-exponential family distributions $[6]$. However, to normalize (12) using the $q$-free energy, a non-linear mapping $\theta(\beta)$ between parameterizations is required. This delicate issue of normalization in the $q$-exponential family has been noted in $[22, 30, 26]$, and we provide more detailed discussion in App. B.3.
Variational Representation using the $\alpha$-Divergence  Since we do not have access to normalization constants in the AIS setting, we focus on the $\alpha$-divergence over unnormalized measures $\tilde{q}(z)$ and $\tilde{p}(z)$. We first recall the definition,

$$D_\alpha[\tilde{q}(z) : \tilde{p}(z)] = \frac{4}{(1-\alpha^2)} \left( \frac{1-\alpha}{2} \int \tilde{q}(z) \, dz + \frac{1+\alpha}{2} \int \tilde{p}(z) \, dz - \int \tilde{q}(z)^{1-\alpha} \tilde{p}(z)^{1+\alpha} \, dz \right)$$

which is an $f$-divergence for the generator $f(u) = \frac{4}{1-\alpha^2} \left( \frac{1-\alpha}{2} + \frac{1+\alpha}{2} u - u^{1+\alpha} \right)$. Note that $\lim_{\alpha \to 1} D_\alpha[\tilde{q}(z) : \tilde{p}(z)] = D_{KL}[\tilde{p}(z) : \tilde{q}(z)]$ and $\lim_{\alpha \to -1} D_\alpha[\tilde{q}(z) : \tilde{p}(z)] = D_{KL}[\tilde{q}(z) : \tilde{p}(z)]$. In App. C we follow similar derivations as Amari to show that, for $q = \frac{1+\alpha}{2}$, the $q$-path density $\tilde{\pi}_\beta^{(q)}$ minimizes the expected $\alpha$-divergence to the endpoints

$$\tilde{\pi}_\beta^{(q)}(z) = \arg \min_{\tilde{r}(z)} \left( 1 - \beta \right) D_\alpha[\tilde{\pi}_0(z) : \tilde{r}(z)] + \beta D_\alpha[\tilde{\pi}_T(z) : \tilde{r}(z)]$$

where the optimization is over arbitrary $\tilde{r}(z)$. This variational representation generalizes Eq. (5) since the KL divergence is recovered (with the order of the arguments reversed) as $\alpha \to 1$ or $q \to 1$.

Moment-Matching Procedures  At $q = 0$, the solution to the optimization corresponds to the arithmetic mean, or mixture distribution $\tilde{\pi}_\beta^{(0)}(z) = \frac{1}{2} \tilde{\pi}_0 + \frac{1}{2} \tilde{\pi}_1$. While the ‘moment-averaged’ AIS path appears related to the $q = 0$ case, we clarify in App. C that Grosse et al. restrict to optimization within an exponential family of distributions. Generalizing this approach to the $\alpha$-divergence, Bui follows Minka (Sec. 3.1-2) to derive the moment-matching condition

$$\tilde{r}_\alpha^{(q)}(z) := \arg \min_{\tilde{r}(z)} \left( 1 - \beta \right) D_\alpha[\tilde{\pi}_0(z) : \tilde{r}(z)] + \beta D_\alpha[\tilde{\pi}_T(z) : \tilde{r}(z)]$$

\[
\Rightarrow \mathbb{E}_{\tilde{r}(z)}[\phi(z)] = (1-\beta)\mathbb{E}_{\tilde{\pi}_0^{1-\alpha}}[\phi(z)] + \beta \mathbb{E}_{\tilde{\pi}_T^{1-\alpha}}[\phi(z)] \tag{15}
\]

where $\tilde{r}(z)$ comes from an exponential family with sufficient statistics $\phi(z)$. However, we note that our $q$-path is more general than these approaches, since the optimization in Eq. (13) is over all unnormalized distributions. Unlike the moment matching conditions above, our closed form expression for $\tilde{\pi}_\beta^{(q)}$ can be directly used as an energy function for MCMC sampling.

4 Experiments

We consider $q$-paths between $\pi_0 = \mathcal{N}(-4, 3)$ and $\pi_T = \mathcal{N}(4, 1)$ to estimate $Z_T/Z_0 = 1$, and use parallel runs of Hamiltonian Monte Carlo (HMC) to obtain accurate, independent samples from $\tilde{\pi}_T^{(q)}(z)$ linearly spaced between $\beta_0 = 0$ and $\beta_T = 1$. For all experiments, we use 10k samples from each intermediate distribution and average results across 20 seeds.

\footnote{We extend to unnormalized measures using $D_{KL}[\tilde{q}(z) : \tilde{p}(z)] = D_{KL}[\tilde{q}(z) : p(z)] - \int \tilde{q}(z) \, dz + \int \tilde{p}(z) \, dz$.}
In Fig. 2 we report BDMC upper and lower bound estimates of $\log Z_T/Z_1$ for various $q$ and $T$. We observe that the choice of $q$ can impact performance, with $q = 0.9$ obtaining tighter estimates at small $T$ and $q = 0.5$ converging more quickly as $T$ increases. Both outperform the baseline geometric path at $q = 1$. In Table 1 we estimate $Z_T/Z_0$ using AIS for $T = 100$, and observe that our $q = 0.9$ path can achieve a lower error than the geometric path.

Finally, in App. we provide additional analysis for annealing between two Student-$t$ distributions. The Student-$t$ family can be shown to correspond to a $q$-exponential family [21], with the same sufficient statistics as a Gaussian, and a degrees of freedom parameter $\nu$ that induces heavier tails and sets the value of $q$. As $q \to 1$ or $\nu \to \infty$, the standard Gaussian is recovered. In Fig. 3-4, we compare annealing between two Student-$t$ distributions in the $q = 2$ family to the Gaussian case of $q = 1$, and observe that the same $q$-path can induce different qualitative behavior based on properties of the endpoint distributions.

5 Conclusion

In this work, we propose $q$-paths to generalize the geometric mixture path commonly used in AIS, and show that modifying the path can improve AIS and BDMC for a fixed mixing schedule on a toy Gaussian example. We interpreted our $q$-paths using the deformed logarithm, $q$-exponential family, and $\alpha$-divergences, which may suggest further connections in non-extensive thermodynamics and information geometry. Choosing a schedule for a given $q$-path, understanding how the choice of $q$ depends on properties of the initial and target distributions, and exploring the use of $q$-paths in related methods such as the thermodynamic variational objective (TVO) [20, 9] remain interesting directions for future work.

References

A Abstract Mean is Invariant to Affine Transformations

In this section, we show that \( h_q(u) \) is invariant to affine transformations. That is, for any choice of \( a \) and \( b \),

\[
h_q(u) = \begin{cases} 
  a \cdot u^{1-q} + b & q \neq 1 \\
  \log u & q = 1 
\end{cases}
\]

(16)

yields the same expression for the abstract mean \( \mu_{h_q} \). First, we note the expression for the inverse \( h_q^{-1}(u) \) at \( q \neq 1 \)

\[
h_q^{-1}(u) = \left( \frac{u - b}{a} \right)^{\frac{1}{1-q}}.
\]

(17)

Recalling that \( \sum_i w_i = 1 \), the abstract mean then becomes

\[
\mu_{h_q}(\{w_i\}, \{u_i\}) = h_q^{-1} \left( \sum_i w_i h_q(u_i) \right)
\]

(18)

\[
= h_q^{-1} \left( a \left( \sum_i w_i u_i^{1-q} \right) + b \right)
\]

(19)

\[
= \left( \sum_i w_i u_i^{1-q} \right)^{\frac{1}{1-q}}
\]

(20)

which is independent of both \( a \) and \( b \).

B Derivations of the \( q \)-Path

B.1 Deformed Log Mixture

In this section, we show that the unnormalized ln mixture

\[
\ln_q \tilde{\pi}_\beta^{(q)}(z) = (1 - \beta) \ln_q \tilde{\pi}_0(z) + \beta \ln_q \tilde{\pi}_1(z)
\]

(21)

reduces to the form of the \( q \)-path intermediate distribution in (2) and (8). Taking \( \exp_q \) of both sides,

\[
\tilde{\pi}_\beta^{(q)}(z) = \exp_q \{ (1 - \beta) \ln_q \tilde{\pi}_0(z) + \beta \ln_q \tilde{\pi}_1(z) \}
\]

\[
= \left[ 1 + (1 - q) (\ln_q \tilde{\pi}_0(z) + \beta (\ln_q \tilde{\pi}_1(z) - \ln_q \tilde{\pi}_0(z))) \right]^{\frac{1}{1-q}}
\]

\[
= \left[ 1 + (1 - q) \frac{1}{1-q} \left( \tilde{\pi}_0(z)^{1-q} - 1 + \beta (\tilde{\pi}_1(z)^{1-q} - 1 - \tilde{\pi}_0(z)^{1-q}) \right) \right]^{\frac{1}{1-q}}
\]

\[
= \left[ 1 + \tilde{\pi}_0(z)^{1-q} - 1 + \beta \left( \tilde{\pi}_1(z)^{1-q} - \tilde{\pi}_0(z)^{1-q} \right) \right]^{\frac{1}{1-q}}
\]

\[
= \left[ \tilde{\pi}_0(z)^{1-q} + \beta \tilde{\pi}_1(z)^{1-q} - \beta \tilde{\pi}_0(z)^{1-q} \right]^{\frac{1}{1-q}}
\]

\[
= \left[ (1 - \beta) \tilde{\pi}_0(z)^{1-q} + \beta \tilde{\pi}_1(z)^{1-q} \right]^{\frac{1}{1-q}}
\]
B.2 \(q\)-Exponential Family

Here, we show that the unnormalized \(q\)-path reduces to a form of the \(q\)-exponential family

\[
\tilde{\pi}_q(z) = \left[ (1 - \beta)\tilde{\pi}_0(z)^{1-q} + \beta \tilde{\pi}_1(z)^{1-q} \right]^{\frac{1}{1-q}} \tag{22}
\]

\[
= [\tilde{\pi}_0(z)^{1-q} + \beta (\tilde{\pi}_1(z)^{1-q} - \tilde{\pi}_0(z)^{1-q})]^{\frac{1}{1-q}} \tag{23}
\]

\[
= \tilde{\pi}_0(z) \left[ 1 + \beta \left( \left( \frac{\tilde{\pi}_1(z)}{\tilde{\pi}_0(z)} \right)^{1-q} - 1 \right) \right]^{\frac{1}{1-q}} \tag{24}
\]

\[
= \tilde{\pi}_0(z) \left[ 1 + (1 - q) \beta \ln_q \left( \frac{\tilde{\pi}_1(z)}{\tilde{\pi}_0(z)} \right) \right]^{\frac{1}{1-q}} \tag{25}
\]

\[
= \tilde{\pi}_0(z) \exp_q \left\{ \beta \ln_q \left( \frac{\tilde{\pi}_1(z)}{\tilde{\pi}_0(z)} \right) \right\} \tag{26}
\]

Defining \(\phi(z) = \ln_q \frac{\tilde{\pi}_1(z)}{\tilde{\pi}_0(z)}\) and introducing a multiplicative normalization factor \(Z_q(\beta)\), we arrive at

\[
\pi_{q,\beta}(z) = \frac{1}{Z_q(\beta)} \tilde{\pi}_0(z) \exp_q \{ \beta \cdot \phi(z) \} \quad Z_q(\beta) := \int \tilde{\pi}_0(z) \exp_q \{ \beta \cdot \phi(z) \} \, dz. \tag{27}
\]

B.3 Normalization in \(q\)-Exponential Families

The \(q\)-exponential family can also be written using the \(q\)-free energy \(\psi_q(\theta)\) for normalization \([6, 26]\),

\[
\pi_q(\theta)(z) = \pi_0(z) \exp_q \{ \theta \cdot \phi(z) - \psi_q(\theta) \}. \tag{28}
\]

However, since \(\exp_q \{ x + y \} = \exp_q \{ y \} \cdot \exp_q \{ x / (1+(1-q)y) \}\) (see \([30]\) or App. \(D\) below) instead of \(\exp \{ x + y \} = \exp \{ x \} \cdot \exp \{ y \}\) for the standard exponential, we cannot easily move between these ways of writing the \(q\)-family \([22]\).

Mirroring the derivations of Naudts \([26]\) pg. 108, we can rewrite \((28)\) using the above identity for \(\exp_q \{ x + y \}\), as

\[
\pi_q(\theta)(z) = \pi_0(z) \exp_q \{ \theta \cdot \phi(z) - \psi_q(\theta) \} \tag{29}
\]

\[
= \pi_0(z) \exp_q \{ -\psi_q(\theta) \} \exp_q \left\{ \frac{\theta \cdot \phi(z)}{1 + (1 - q)(-\psi_q(\theta))} \right\} \tag{30}
\]

Our goal is to express \(\pi_q(\theta)(z)\) using a normalization constant \(Z_{q,\beta}^{(q)}\) instead of the \(q\)-free energy \(\psi_q(\theta)\). While the exponential family allows us to freely move between \(\psi(\theta)\) and \(\log Z_\theta\), we must adjust the natural parameters (from \(\theta\) to \(\beta\)) in the \(q\)-exponential case. Defining

\[
\beta = \frac{\theta}{1 + (1 - q)(-\psi_q(\theta))} \tag{31}
\]

\[
Z_{q,\beta}^{(q)} = \frac{1}{\exp_q \{ -\psi_q(\theta) \}} \tag{32}
\]

we can obtain a new parameterization of the \(q\)-exponential family, using parameters \(\beta\) and multiplicative normalization constant \(Z_{q,\beta}^{(q)}\),

\[
\pi_{q,\beta}(z) = \frac{1}{Z_{q,\beta}^{(q)}} \pi_0(z) \exp \{ \beta \cdot \phi(z) \} \tag{33}
\]

\[
= \pi_0(z) \exp \{ \theta \cdot \phi(z) - \psi_q(\theta) \} = \pi_q(\theta)(z). \tag{34}
\]

See Matsuzoe et al. \([22]\), Suyari et al. \([30]\), and Naudts \([26]\) for more detailed discussion of normalization in deformed exponential families.
C Minimizing \( \alpha \)-divergences

Amari \[3\] show that the \( \alpha \)-mixture \( \pi_{\alpha} \) minimizes the expected divergence to a single point for normalized measures. We repeat similar derivations but for the case of unnormalized \( \{ \hat{p}_i \} \) and \( \hat{r}(z) \)

\[
\hat{\pi}_{\alpha}(z) = \arg\min_{\hat{r}(z)} \sum_{i=1}^{N} w_i D_{\alpha}[\hat{p}_i(z) : \hat{r}(z)]
\]

(35)

where \( \hat{\pi}_{\alpha}(z) = \left( \sum_{i=1}^{N} w_i \hat{p}_i(z) \right)^{1-\alpha} \)

(36)

Proof.

\[
\frac{d}{dz} \sum_{i=1}^{N} w_i D_{\alpha}[\hat{p}_i(z) : \hat{r}(z)] = \frac{d}{dz} \frac{4}{1-\alpha^2} \sum_{i=1}^{N} w_i ( - \int \hat{p}_i(z) \frac{1-\alpha}{2} \hat{r}(z) \frac{1+\alpha}{2} dz + \frac{1+\alpha}{2} \int \hat{r}(z) dz )
\]

(37)

\[
0 = \frac{4}{1-\alpha^2} \left( - \frac{1+\alpha}{2} \sum_{i=1}^{N} w_i \hat{p}_i(z) \frac{1-\alpha}{2} \hat{r}(z) - \frac{1+\alpha}{2} \right)
\]

(38)

\[
\frac{2}{1-\alpha} = - \frac{2}{1-\alpha} \sum_{i=1}^{N} w_i \hat{p}_i(z) \frac{1-\alpha}{2} \hat{r}(z) - \frac{1+\alpha}{2}
\]

(39)

\[
\hat{r}(z) \frac{1-\alpha}{2} = \sum_{i=1}^{N} w_i \hat{p}_i(z) \frac{1-\alpha}{2}
\]

(40)

\[
\hat{r}(z) = \left( \sum_{i=1}^{N} w_i \hat{p}_i(z) \right)^{\frac{2}{1-\alpha}}
\]

(41)

This result is similar to a general result about Bregman divergences in Banerjee et al. \[8\] Prop. 1. although \( D_{\alpha} \) is not a Bregman divergence over normalized distributions.

C.1 Arithmetic Mean (\( q = 0 \))

The moment-averaging path from Grosse et al. \[13\] is not a special case of the \( \alpha \)-mean path of Amari \[3\]. While both minimize a convex combination of reverse KL divergences, Grosse et al. \[13\] minimize within the constrained space of exponential families, while Amari \[3\] optimizes over all normalized distributions.

More formally, consider minimizing the functional

\[
J[\rho] = (1-\beta) \int \pi_0(z) \log \frac{\pi_0(z)}{r(z)} dz + \beta \int \pi_1(z) \log \frac{\pi_1(z)}{r(z)} dz
\]

(42)

\[
= \text{const} - \int [(1-\beta)\pi_0(z) + \beta\pi_1(z)] \log r(z) dz
\]

(43)

We will show how Grosse et al. \[13\] and Amari \[3\] minimize (42).

Solution within Exponential Family Grosse et al. \[13\] constrains \( r(z) = \frac{1}{Z(\theta)} h(z) \exp(\theta^T g(z)) \) to be a (minimal) exponential family model and minimizes (43) w.r.t \( r \)’s natural parameters \( \theta \) (cf. \[13\] appendix 2.2):

\[
\theta^*_t = \arg\min_{\theta} J(\theta)
\]

(44)

\[
= \arg\min_{\theta} \left( - \int [(1-\beta)\pi_0(z) + \beta\pi_1(z)] [\log h(z) + \theta^T g(z) - \log Z(\theta)] dz \right)
\]

(45)

\[
= \arg\min_{\theta} \left( \log Z(\theta) - \int [(1-\beta)\pi_0(z) + \beta\pi_1(z)] \theta^T g(z) dz + \text{const} \right)
\]

(46)
where the last line follows because $\pi_0(z)$ and $\pi_1(z)$ are assumed to be correctly normalized. Then to arrive at the moment averaging path, we compute the partials $\frac{\partial J(\theta)}{\partial \theta_i}$ and set to zero:

$$\frac{\partial J(\theta)}{\partial \theta_i} = E_r[g_i(z)] - (1 - \beta) E_{\pi_0}[g_i(z)] - \beta E_{\pi_1}[g_i(z)] = 0$$ (47)

$$E_r[g_i(z)] = (1 - \beta) E_{\pi_0}[g_i(z)] - \beta E_{\pi_1}[g_i(z)]$$ (48)

where we have used the exponential family identity $\frac{\partial \log Z(\theta)}{\partial \theta_i} = E_r\theta[g_i(z)]$ in the first line.

**General Solution** Instead of optimizing in the space of minimal exponential families, Amari [3] instead adds a Lagrange multiplier to (43) and optimizes $r$ directly (cf. [3] eq. 5.1 - 5.12)

$$r^* = \arg\min_r J'[r]$$ (49)

$$= \arg\min_r J[r] + \lambda \left(1 - \int r(z)dz\right)$$ (50)

Eq. (50) can be minimized using the Euler-Lagrange equations or using the identity

$$\frac{\delta f(x)}{\delta f(x')} = \delta(x - x')$$ (51)

from [23]. We compute the functional derivative of $J'[r]$ using (51) and solve for $r$:

$$\frac{\delta J'[r]}{\delta r(z)} = -\int \left[(1 - \beta)\pi_0(z') + \beta\pi_1(z')\right] \frac{1}{r(z')} \frac{\delta r(z')}{\delta r(z)} dz' - \lambda \int \frac{\delta r(z')}{\delta r(z)} dz'$$ (52)

$$= -\int \left[(1 - \beta)\pi_0(z') + \beta\pi_1(z')\right] \frac{1}{r(z')} \delta(z - z') dz' - \lambda \int \delta(z - z') dz'$$ (53)

$$= - \left[(1 - \beta)\pi_0(z) + \beta\pi_1(z)\right] \frac{1}{r(z)} - \lambda = 0$$ (54)

Therefore

$$r(z) \propto \left[(1 - \beta)\pi_0(z) + \beta\pi_1(z)\right],$$ (55)

which corresponds to our $q$-path at $q = 0$, or $\alpha = -1$ in Amari [3]. Thus, while both Amari [3] and Grosse et al. [13] start with the same objective, they arrive at different optimum because they optimize over different spaces.

**D Sum and Product Identities for $q$-Exponentials**

In this section, we prove two lemmas which are useful for manipulation expressions involving $q$-exponentials, for example in moving between Eq. (29) and Eq. (30) in either direction.

**Lemma 1. Sum identity**

$$\exp_q\left(\sum_{n=1}^{N} x_n\right) = \prod_{n=1}^{N} \exp_q\left(\frac{x_n}{1 + (1 - q)\sum_{i=1}^{n-1} x_i}\right)$$ (56)

**Lemma 2. Product identity**

$$\prod_{n=1}^{N} \exp_q(x_n) = \exp_q\left(\sum_{n=1}^{N} x_n \cdot \prod_{i=1}^{n-1} (1 + (1 - q)x_i)\right)$$ (57)
D.1 Proof of Lemma 1

Proof. We prove by induction. The base case \((N = 1)\) is satisfied using the convention \(\sum_{i=a}^b x_i = 0\) if \(b < a\) so that the denominator on the RHS of Eq. (56) is 1. Assuming Eq. (56) holds for \(N\),

\[
\exp_q \left( \sum_{n=1}^{N+1} x_n \right) = \left[ 1 + (1 - q) \sum_{n=1}^{N+1} x_n \right]^{1/(1-q)}
\]

(58)

\[
= \left[ 1 + (1 - q) \left( \sum_{n=1}^N x_n + (1 - q)x_{N+1} \right) \right]^{1/(1-q)}
\]

(59)

\[
= \left[ \left( 1 + (1 - q) \sum_{n=1}^N x_n \right) \left( 1 + (1 - q) \frac{x_{N+1}}{1 + (1 - q) \sum_{n=1}^N x_n} \right) \right]^{1/(1-q)}
\]

(60)

\[
= \exp_q \left( \sum_{n=1}^N x_n \right) \exp_q \left( \frac{x_{N+1}}{1 + (1 - q) \sum_{n=1}^N x_n} \right)
\]

(61)

\[
= \prod_{n=1}^{N+1} \exp_q \left( \frac{x_n}{1 + (1 - q) \sum_{i=1}^{n-1} x_i} \right) \quad \text{(using the inductive hypothesis)}
\]

(62)

D.2 Proof of Lemma 2

Proof. We prove by induction. The base case \((N = 1)\) is satisfied using the convention \(\prod_{i=a}^b x_i = 1\) if \(b < a\). Assuming Eq. (57) holds for \(N\), we will show the \(N + 1\) case. To simplify notation we define \(y_N := \sum_{n=1}^N x_n \cdot \prod_{i=1}^{n-1} (1+ (1 - q)x_i)\). Then,

\[
\prod_{n=1}^{N+1} \exp_q (x_n) = \exp_q (x_1) \prod_{n=2}^{N+1} \exp_q (x_n)
\]

(63)

\[
= \exp_q (x_0) \prod_{n=1}^N \exp_q (x_n)
\]

(64)

\[
= \exp_q (x_0) \exp_q (y_N)
\]

(65)

\[
= \left[ \left( 1 + (1 - q) \cdot x_0 \right) \left( 1 + (1 - q) \cdot y_N \right) \right]^{1/(1-q)}
\]

(66)

Next we use the definition of \(y_N\) and rearrange

\[
\exp_q \left( x_0 + (1 + (1 - q) \cdot x_0) \left( x_1 + x_2 (1 + (1 - q) \cdot x_1) + ... + x_N \cdot \prod_{i=1}^{N-1} (1 + (1 - q) \cdot x_i) \right) \right)
\]

(67)

\[
= \exp_q \left( \sum_{n=0}^N x_n \cdot \prod_{i=1}^{n-1} (1 + (1 - q)x_i) \right)
\]

(68)

Then reindexing \(n \to n + 1\) establishes

\[
\prod_{n=1}^{N+1} \exp_q (x_n) = \exp_q \left( \sum_{n=1}^{N+1} x_n \cdot \prod_{i=1}^{n-1} (1 + (1 - q)x_i) \right).
\]

(69)
We can then write the multivariate Student-$t$ density, specified by a mean vector $\mu$, covariance $\Sigma$, and degrees of freedom parameter $\nu$, in $d$ dimensions, as

$$
t_{\nu}(x|\mu, \Sigma) = \frac{1}{Z(\nu, \Sigma)} \left[ 1 + \frac{1}{\nu} (x - \mu)^T \Sigma^{-1} (x - \mu) \right]^{-\left(\frac{\nu + d}{2}\right)} 
$$

(70)

where $Z(\nu, \Sigma) = \Gamma\left(\frac{\nu + d}{2}\right)/\Gamma\left(\frac{\nu}{2}\right) \cdot |\Sigma|^{-1/2} \nu^{-\frac{d}{2}} \pi^{-\frac{d}{2}}$. Note that $\nu > 0$, so that we only have positive values raised to the $-\left(\nu + d\right)/2$ power, and the density is defined on the real line.

The power function in (70) is already reminiscent of the $q$-exponential, while we have first and second moment sufficient statistics as in the Gaussian case. We can solve for the exponent, or order parameter $q$, that corresponds to $-\left(\nu + d\right)/2$ using $-\left(\frac{\nu + d}{2}\right) = \frac{1}{1-q}$. This results in the relations

$$
\nu = \frac{d - dq + 2}{q - 1} \quad \text{or} \quad q = \frac{\nu + d + 2}{\nu + d}
$$

(71)

We can also rewrite the $\nu^{-1} (x - \mu)^T \Sigma^{-1} (x - \mu)$ using natural parameters corresponding to $\{x, x^2\}$ sufficient statistics as in the Gaussian case (see, e.g., Matsuzoe and Wada [21] Example 4).

Note that the Student-$t$ distribution has heavier tails than a standard Gaussian, and reduces to a multivariate Gaussian as $q \to 1$ and $\exp_q(u) \to \exp(u)$. This corresponds to observing $n \to \infty$ samples, so that the sample mean and variance approach the ground truth [25].

### E.2 Annealing between 1-d Student-$t$ Distributions

Since the Student-$t$ family generalizes the Gaussian distribution to $q \neq 1$, we can run a similar experiment annealing between two Student-$t$ distributions. We set $q = 2$, which corresponds to $\nu = 1$ with $\nu = (3 - q)/(q - 1)$, and use the same mean and variance as the Gaussian example in Fig. 1 with $\pi_0(z) = t_{\nu=1}(-4, 3)$ and $\pi_1(z) = t_{\nu=1}(4, 1)$. 
We visualize the results in Fig. 4. For this special case of both endpoint distributions within a parametric family, we can ensure that the $q = 2$ path stays within the $q$-exponential family of Student-$t$ distributions. We make a similar observation for the Gaussian case and $q = 1$ in Fig. 3.

Comparing the $q = 0.5$ and $q = 0.9$ Gaussian path with the $q = 1.0$ and $q = 1.5$ path, we observe that mixing behavior appears to depend on the relation between the $q$-path parameter and the order of the $q$-exponential family of the endpoints.

As $q \to \infty$, the power mean (6) approaches the min operation as $1 - q \to -\infty$. In the Gaussian case, we see that, even at $q = 2$, intermediate densities for all $\beta$ appear to concentrate in regions of low density under both $\pi_0$ and $\pi_T$. However, for the heavier-tailed Student-$t$ distributions, we must raise the $q$-path parameter significantly to observe similar behavior.
