

# Targeted Advertising on Social Networks Using Online Variational Tensor Regression

Anonymous authors

Paper under double-blind review

## Abstract

This paper is concerned with online targeted advertising on social networks. The main technical task we address is to estimate the activation probability for user pairs, which quantifies the influence one user may have on another towards purchasing decisions. This is a challenging task because one marketing episode typically involves a multitude of marketing campaigns/strategies of different products for highly diverse customers. In this paper, we propose what we believe is the first tensor-based contextual bandit framework for online targeted advertising. The proposed framework is designed to accommodate any number of feature vectors in the form of multi-mode tensor, thereby enabling to capture the heterogeneity that may exist over user preferences, products, and campaign strategies in a unified manner. To handle inter-dependency of tensor modes, we introduce an online variational algorithm with a mean-field approximation. We empirically confirm that the proposed TensorUCB algorithm achieves a significant improvement in influence maximization tasks over the benchmarks, which is attributable to its capability of capturing the user-product heterogeneity.

## 1 Introduction

Online targeted advertising is one of the most interesting applications of machine learning in the Internet age. In a typical scenario, a marketing agency chooses a set of “seed” users from the nodes (i.e. users) of a social graph, and makes certain offers (e.g. coupons, giveaways, etc.), with the expectation that the seed users will influence their followers and spread the awareness on the product(s) or service(s) being promoted. An important question of interest is how to maximize the total purchases accrued over multiple marketing campaign rounds under a fixed budget (i.e. the number of seed users per round). This task is commonly referred to as (online) influence maximization (IM) in the machine learning community.

A key quantity of interest here is the **activation probability**  $\{p_{i,j}\}$ , where  $p_{i,j}$  is the probability of user  $i$  influencing user  $j$  into buying the products being advertised. Since  $\{p_{i,j}\}$  is unknown a priori, we are to repeatedly update the estimate after each marketing round, starting from a rough initial estimate based, for example, on demographic information. Many trials and errors are unavoidable especially in the beginning. After a sufficient number of trials, however, we can expect to have systematically better estimates for  $\{p_{i,j}\}$ . These characteristics make the *contextual bandits* (CB) framework (Abe et al., 2003; Li et al., 2010; Bouneffouf et al., 2020) a relevant and attractive solution approach. Here, the “bandit arms” correspond to the seed users to be selected. The “context” corresponds to information specific to the products being advertised and the users being targeted. The “reward” would be the number of purchases attained as a result of the influence of the selected seed users.

There are two mutually interacting sub-tasks in IM as discussed in the literature: One is how to choose the seed users when given  $\{p_{i,j}\}$ ; The other is how to estimate  $\{p_{i,j}\}$  given a seed selection algorithm, which is the focus of this paper. The approaches to the latter task can be further categorized into *direct* and *latent* modeling approaches. The direct approaches mainly leverage graph connectivity combined with simple features such as the number of purchases. Since transaction history is typically very sparse, the latent modeling approach has been attracting increasing attention recently. In this category, two major approaches

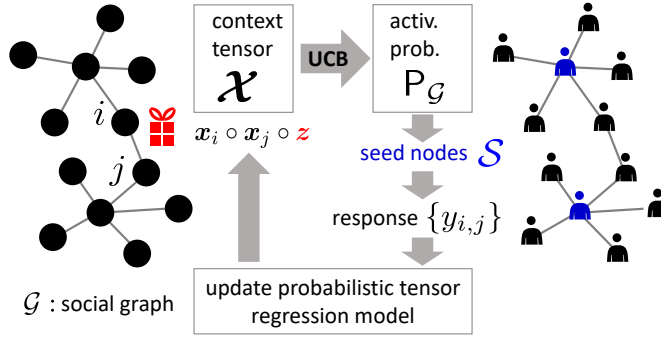

Figure 1: Overview of **TensorUCB** (simplest case). The context tensor encodes the features of user pairs and product/marketing strategy, and is used to estimate the activation probability matrix  $P_G = [p_{i,j}]$ . Based on observed user responses, the estimation model is updated.

have been proposed to date. One is *regression-based* (Vaswani et al., 2017; Wen et al., 2017) and the other is *factorization-based* (Wu et al., 2019; Wang & Chen, 2017; Barbieri et al., 2013). Although encouraging results have been reported in these works, there is one important limitation that restricts their usefulness in practice: *The lack of capability to simultaneously deal with heterogeneity over products and user pairs capturing their interactions*. This is critical since marketing campaigns typically include many different products and strategies applied to a diverse population.

To address this issue, we propose **TensorUCB**, a general tensor-based contextual bandit framework. Unlike the prior works, we use a tensor to represent the context information (“*context tensor*”), which makes it possible to handle *any* number of feature vectors in principle. Figure 1 illustrates our problem. The user context tensor  $\mathcal{X}$  is formed from three feature vectors in this simplest case: user feature vectors of the  $i$ - and  $j$ -th users and a product feature vector  $z$ . Then, the activation probability matrix  $P_G \triangleq [p_{i,j}]$  is estimated from  $\mathcal{X}$ . Here, we leverage a new online probabilistic tensor regression framework, and integrate the upper confidence bound (UCB) policy in a way analogous to the LinUCB algorithm (Li et al., 2010).

To the best of our knowledge, this is the first proposal of a contextual bandit framework extended to context tensors and applied to the task of IM. Our empirical results show that the proposed methods outperform baseline algorithms in the presence of product heterogeneity.

## 2 Related work

Prior works relevant to this paper can be categorized into three major areas: CB-based IM approaches, tensor bandits, and tensor regression.

**CB-based IM** Following the pioneering works by Valko et al. (2014) and Chen et al. (2016) that framed IM as an instance of the bandit problem, a few approaches have been proposed to incorporate contextual information. Vaswani et al. (2017) proposed **DILinUCB**, a contextual version of IM bandits, which uses user contextual features to learn  $p_{i,j}$  with linear regression. Wu et al. (2019) proposed **IMFB**, which exploits matrix factorization instead of linear regression. Unlike our work, in which a single susceptibility tensor  $\mathcal{W}$  is shared by all the nodes, their approaches give latent parameters to each network node, and thus, tends to require more exploration. Wen et al. (2017) proposed another regression-based approach **IMLinUCB** using edge-specific features, which can be difficult to obtain in practice. There also exist prior works that attempt to capture product features in addition to the user features. Saritaç et al. (2016) proposed **COIN**, which assumes a predefined partition of product features and does not directly use the users’ context vectors. Our framework automatically learns multiple patterns in different products as well as different users through multi-rank tensor regression. Chen et al. (2015) consider a topic distribution for the seed selection task, not for learning  $\{p_{i,j}\}$ .

**Tensor bandits** Apart from IM, bandits with structured arms are an emerging topic in the bandit research community. The majority of the studies consider the bilinear setting, which can be solved through low-rank matrix estimation or bilinear regression (Kveton et al., 2017; Zoghi et al., 2017; Katariya et al., 2017; Lu et al., 2018; Hamidi et al., 2019; Jun et al., 2019b; Lu et al., 2021). However, it is not clear how they can be extended to general settings having more than two contextual vectors which we are interested in. Azar et al. (2013) is among the earliest works that used higher order tensors in bandit research. However, their task is transfer learning among a multitude of bandits, which is different from ours. Recently, Hao et al. (2020) proposed a tensor bandit framework based on the Tucker decomposition (Kolda & Bader, 2009). However, their setting is *not contextual* and is not applicable to our task. Specifically, in our notation, their reward model is defined solely for  $\mathcal{X} = \mathbf{e}_{j_1}^1 \circ \dots \circ \mathbf{e}_{j_D}^D$ , where  $\mathbf{e}_{j_l}^l$  is the  $d_l$ -dimensional unit basis vector whose  $j_l$ -th element is 1 and otherwise 0. As a result of this binary input, the coefficient tensor  $\mathcal{W}$  is directly observable through the response  $u$ . In other words, the task is *not* a supervised learning problem anymore in contrast to our setting. To the best of our knowledge, our work is the first proposal of variational tensor bandits in the contextual setting.

**Tensor regression** We also believe this is the first work of contextual tensor bandits allowing an arbitrary number of tensor modes. For generic tensor regression methods, limited work has been done on *online* inference of *probabilistic* tensor regression. Most of the existing probabilistic tensor regression methods (e.g. (Zhao et al., 2014; Imaizumi & Hayashi, 2016; Guhaniyogi et al., 2017; Ahmed et al., 2020)) require either Monte Carlo sampling or evaluation of complicated interaction terms, making it difficult to directly apply them to online marketing scenarios. In contrast, we provide a tractable online updating equation based on a variational mean-field approximation. We believe **TensorUCB** is among the first works that explicitly derived an online version of probabilistic tensor regression.

### 3 Problem Setting

In the online influence maximization (IM) problem on social networks, there are three major design points, as illustrated in Fig. 1:

- Estimation model for  $y_{i,j}$  (user  $j$ ’s response by user  $i$ ’s influence).
- Scoring model for  $p_{i,j}$  (the probability that user  $i$  activates user  $j$ ).
- Seed selection model to choose the  $K$  most influential users, given  $\{p_{i,j}\}$ .

This paper deals with the first and the second tasks alone, following the existing IM literature (Wu et al., 2019; Vaswani et al., 2017; Wen et al., 2017; Saritaç et al., 2016). We formalize the first task as online probabilistic regression that takes a tensor as the contextual input (Sec. 4). The second task is handled by integrating the derived probabilistic model with the idea of UCB (Sec. 5). The third task is not within the scope of this paper. It takes care of the combinatorial nature of the problem and is known to be NP-hard (Kempe et al., 2003). We assume to have a black-box subroutine (denoted by **ORACLE**) that produces a near-optimal solution for a given  $\{p_{i,j}\}$ . In our experiments we use an  $\eta$ -approximation algorithm (Golovin & Krause, 2011) proposed by Tang et al. (2014).

Note that we do not explicitly model the dynamics of information diffusion. Instead, we learn the *latent* quantity  $p_{i,j}$  as a proxy for diffusion dynamics among the users. This is in contrast to the *direct* approaches (Bhagat et al., 2012; Li et al., 2013; Morone & Makse, 2015; Lei et al., 2015; Lu et al., 2015), as mentioned in Introduction.

#### 3.1 Data model

In addition to a social graph  $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ , where  $\mathcal{V}$  is the set of user nodes ( $|\mathcal{V}|$  is its size) and  $\mathcal{E}$  is the set of edges ( $|\mathcal{E}|$  is its size), we consider two types of observable data. The *first* is the contextual feature vectors, which are assumed to be *real-valued* column vectors:  $\phi_1 \in \mathbb{R}^{d_1}, \dots, \phi_D \in \mathbb{R}^{d_D}$ . Here,  $d_1$ , etc., denote the dimensionality and  $D$  is the number of the contextual feature vectors. In Fig. 1, we illustrated the case

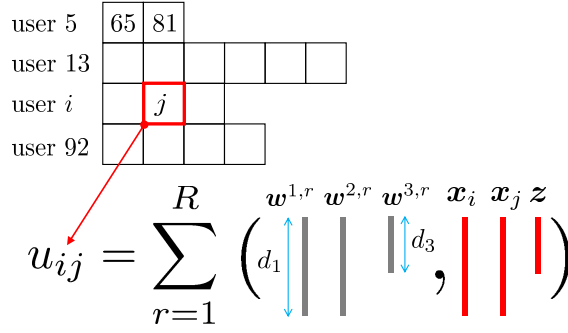

Figure 2: Illustration of data structure in one marketing round and the prediction model.  $\{5, 13, i, 92\}$  is the set of the seed nodes here.  $K = 4$  and  $D = 3$  are assumed.

where  $\phi_1 = \mathbf{x}_i$  and  $\phi_2 = \mathbf{x}_j$  for user features of the node pair  $(i, j)$ , and  $\phi_3 = \mathbf{z}$  characterizes the product or marketing strategy under consideration.

The *second* observable is the users’ response, denoted by  $y_{i,j} \in \{0, 1\}$ . Let us denote by  $i \Rightarrow j$  the event that “user  $i$  activates user  $j$  (into buying the product).”  $y_{i,j} = 1$  if  $i \Rightarrow j$  has occurred, and  $y_{i,j} = 0$  otherwise. Although activation is not directly measurable in general, a widely-used heuristic is the time-window-based method (Barbieri et al., 2013). Specifically, we set  $y_{i,j} = 1$  if user  $j$  bought the product after actively communicating with user  $i$  within a certain time window. Active communications include “likes,” retweeting, and commenting, depending on the social networking platform. The size of the time window is determined by domain experts and is assumed to be given.

### 3.2 Activation probability estimation problem

We consider the situation where a fixed number (denoted by  $K$ ) of seed users are chosen in each campaign round (“budgeted IM”). The seed nodes may have a different number of connected nodes, as illustrated in Fig. 2. Thus, the dataset from the  $t$ -th marketing round takes the following form (we use notation as summarized in Table 1):

$$\{(\phi_{t(k),1}, \dots, \phi_{t(k),D}, y_{t(k)}) \mid k = 1, \dots, n_t\}, \quad (1)$$

where  $n_t = \sum_{i \in \mathcal{S}_t} n_{\deg}(i)$ ,  $\mathcal{S}_t$  is the set of seed users chosen in the  $t$ -th marketing round ( $|\mathcal{S}_t| = K$ ) and  $n_{\deg}(i)$  is the node degree of the  $i$ -th node. In this expression, the identity of node pairs is implicitly encoded by  $k$ . In our solution strategy, the estimation model is updated as soon as a new sample comes in. So, it is more useful to “flatten”  $(t, k)$  into a single “time” index  $\tau$  when considering all the samples obtained up to the current time  $\tau$ , denoted as

$$\mathcal{D}_{1:\tau} \triangleq \{(\phi_{\tau',1}, \dots, \phi_{\tau',D}, y_{\tau'}) \mid \tau' = 1, \dots, \tau\}. \quad (2)$$

As a general rule, we use a subscript  $(t(k))$  or  $\tau$  to denote an *instance* of a random variable.

Our main task is to estimate the activation probability matrix  $\mathbf{P}_G \triangleq [p_{i,j}]$ , where we set  $p_{i,j} = 0$  for disconnected node pairs. As mentioned at the beginning of this section, the task is divided into two steps.

The *first* step (estimation model) is to learn a regression function to predict  $y_{i,j}$  from  $\phi_1, \dots, \phi_D$ . We call the output of the regression function the *response score*, and denote it by  $u_{i,j} \in \mathbb{R}$  to distinguish it from the binary response:

$$u_{i,j} = H_{\mathbf{W}}(\phi_1, \phi_2, \dots, \phi_D) + (\text{noise}), \quad (3)$$

where we assumed that  $\phi_1$  and  $\phi_2$  represent the feature vectors of nodes  $i$  and  $j$ , respectively.  $H_{\mathbf{W}}$  is a parametric model with  $\mathbf{W}$  being a random variable called the susceptibility tensor (defined in the next section). To systematically treat the uncertainty in the user response, we wish to learn a *probability distribution* of  $\mathbf{W}$

Table 1: Main mathematical symbols.

| symbol                   | definition   |
|--------------------------|--|
| $y_{i,j}$                | Binary user response about the event $i \Rightarrow j$       |
| $y_{t(k)}$               | $k$ -th observed response in the $t$ -th round               |
| $y_\tau$                 | User response observed at “time” $\tau$                      |
| $\bar{u}_{i,j}$          | Expected score (real-valued) for $y_{i,j}$                   |
| $p_{i,j}$                | Activation probability of the event $i \Rightarrow j$        |
| $\phi_l$                 | $l$ -th contextual vector in $\mathbb{R}^{d_l}$              |
| $\phi_{\tau,l}$          | $l$ -th contextual vector observed at “time” $\tau$          |
| $\mathbf{w}^{l,r}$       | Coefficient vector for $\phi_l$ of the $r$ -th tensor rank   |
| $\bar{\mathbf{w}}^{l,r}$ | Posterior mean of $\mathbf{w}^{l,r}$ (Eq. (15))              |
| $\Sigma^{l,r}$           | Posterior covariance matrix of $\mathbf{w}^{l,r}$ (Eq. (14)) |

and  $u_{i,j}$  explicitly, and eventually derive their *updating rule* to get a renewed estimate in every marketing round  $t$ .

In the *second* step (scoring model), once the distribution of  $u_{i,j}$  is obtained, the activation probability  $p_{i,j} \in [0, 1]$  is computed not only with the expectation  $\bar{u}_{i,j}$  but also with the variance through an appropriate mapping function that reflects the UCB policy.

## 4 Online variational tensor regression

When activation  $i \Rightarrow j$  occurs, we naturally assume that the activation probability depends on the feature vectors of the user pair *and* the product. One straightforward approach in this situation is to create a concatenated vector and apply, e.g., the LinUCB algorithm (Li et al., 2010). However, it is empirically well-known that such an approach is quite limited. For concreteness, consider the  $D = 3$  case in Fig. 1 again. The main issue is that it amounts to treating  $\mathbf{x}_i, \mathbf{x}_j, \mathbf{z}$  separately hence failing to model their *interactions*:  $H_{\mathbf{W}}$  in this approach would be  $\mathbf{w}_1^\top \mathbf{x}_i + \mathbf{w}_2^\top \mathbf{x}_j + \mathbf{w}_3^\top \mathbf{z}$ , and fitting the regression coefficients  $\mathbf{w}_1, \mathbf{w}_2, \mathbf{w}_3$  would result in giving the most weight on generally popular user and product types. This is not useful information in online advertising, as we are interested in analyzing what kind of *affinity* there might be in a specific combination of user pairs and products. The proposed tensor-based formulation allows dealing with such interactions while keeping the computational cost reasonable with a low-rank tensor approximation.

### 4.1 Tensor regression model

We instead assume to have the *context tensor* in the form

$$\mathcal{X} = \phi_1 \circ \phi_2 \circ \cdots \circ \phi_D, \quad (4)$$

where  $\circ$  denotes the direct product. For example, in the case shown in Fig. 1, the  $(i_1, i_2, i_3)$ -th element of  $\mathcal{X}$  is given by the product of three scalars:  $[\mathbf{x}_i \circ \mathbf{x}_j \circ \mathbf{z}]_{i_1, i_2, i_3} = x_{i, i_1} x_{j, i_2} z_{i_3}$ , where the square bracket denotes the operator to specify an element of tensors. Note that Eq. (4) includes the regression models in bilinear bandits (e.g. (Jun et al., 2019a)) and *non-contextual* tensor bandits (Hao et al., 2020) as special cases.

For the regression function  $H_{\mathbf{W}}$  in Eq. (3), we employ a tensor regression model as

$$H_{\mathbf{W}}(\phi_1, \dots, \phi_D) = (\mathbf{W}, \mathcal{X}), \quad (\mathbf{W}, \mathcal{X}) \triangleq \sum_{i_1, \dots, i_D} \mathcal{W}_{i_1, \dots, i_D} \mathcal{X}_{i_1, \dots, i_D}, \quad (5)$$

where  $(\cdot, \cdot)$  denotes the tensor inner product, and we call the regression coefficient  $\mathbf{W}$  the *susceptibility tensor*. For tractable inference, we employ the CP (canonical polyadic) expansion (Cichocki et al., 2016; Kolda & Bader, 2009) of order  $R$ , which simplifies Eq. (5) significantly:

$$\mathbf{W} = \sum_{r=1}^R \mathbf{w}^{1,r} \circ \mathbf{w}^{2,r} \circ \cdots \circ \mathbf{w}^{D,r}, \quad u_{i,j} = \sum_{r=1}^R \prod_{l=1}^D \phi_l^\top \mathbf{w}^{l,r} + (\text{noise}), \quad (6)$$

where  $^\top$  denotes the transpose. In the second equation above, the r.h.s. now involves only the vector inner product.  $R > 1$  gives the potential to capture the characteristics of multiple product types. Note that other tensor factorization methods such as Tucker and tensor-train do not yield the simple expression like Eq. (6), making the UCB analysis intractable.

Figure 2 illustrates one marketing round with  $K = 4$  and  $D = 3$ . Each seed user has a few connected users. For example, the 5th user is a “friend” of the 65th and 81st users. For a user pair  $(i, j)$ , the response score  $u_{i,j}$  is computed from  $\phi_1 = \mathbf{x}_i$ ,  $\phi_2 = \mathbf{x}_j$ , and  $\phi_3 = \mathbf{z}$  through Eq. (6).

## 4.2 Variational learning of susceptibility tensor

One critical requirement in CB-based IM is the ability to handle stochastic fluctuations of the user response. Here we provide a fully probabilistic online tensor regression model.

As the first step, let us formalize a batch learning algorithm, assuming that all the samples up to the  $\tau$ -th “time” are available at hand under the flattened indexing as in Eq. (2). Define  $\mathbf{x}_\tau \triangleq \phi_{\tau,1} \circ \cdots \phi_{\tau,D}$ . Typically,  $\phi_{\tau,1}$  and  $\phi_{\tau,2}$  are used for the node feature vectors, serving as the proxy for the node indexes. We employ Gaussian observation and prior models, which follow the standard CB approach except tensor-based parameterization:

$$p(u \mid \mathbf{x}, \mathbf{W}, \sigma) = \mathcal{N}(u \mid (\mathbf{W}, \mathbf{x}), \sigma^2), \quad p(\mathbf{W}) = \prod_{l=1}^D \prod_{r=1}^R \mathcal{N}(\mathbf{w}^{l,r} \mid \mathbf{0}, \mathbf{I}_{d_l}), \quad (7)$$

where  $p(\cdot)$  symbolically represents a probability distribution and  $\mathcal{N}(\cdot \mid (\mathbf{W}, \mathbf{x}), \sigma^2)$  denotes Gaussian with mean  $(\mathbf{W}, \mathbf{x})$  and variance  $\sigma^2$ . Also,  $u \in \mathbb{R}$  is the user response score (at any time and user pair), and  $\mathbf{I}_d$  is the  $d$ -dimensional identity matrix. Since  $\sigma^2$  is assumed to be given and fixed, which is a common assumption in the bandit literature,  $\mathbf{W}$  is the only model parameter to be learned.

Despite the apparent simplicity of Eq. (6), inter-dependency among the parameter vectors  $\{\mathbf{w}^{l,r}\}$  makes exact inference intractable. To address this issue, we introduce *variational tensor bandits* featuring variational Bayes (VB) inference (Bishop, 2006). The key assumption of VB is to assume the posterior distribution in a factorized form. In our case, the posterior of the susceptibility tensor  $\mathbf{W}$  is assumed to be:

$$Q(\mathbf{W}) = Q(\{\mathbf{w}^{l,r}\}) = \prod_{l=1}^D \prod_{r=1}^R q^{l,r}(\mathbf{w}^{l,r}). \quad (8)$$

We determine the distribution  $\{q^{l,r}\}$  by minimizing the Kullback-Leibler (KL) divergence:

$$Q = \arg \min_Q \text{KL}[Q \parallel Q_0], \quad \text{KL}[Q \parallel Q_0] \triangleq \int \prod_{l=1}^D \prod_{r=1}^R d\mathbf{w}^{l,r} Q(\mathbf{W}) \ln \frac{Q(\mathbf{W})}{Q_0(\mathbf{W})}, \quad (9)$$

where  $Q_0(\mathbf{W})$  is the true posterior. We, of course, do not know the exact form of  $Q_0(\mathbf{W})$ , but we do know that it is proportional to the product between the observation and prior models by Bayes’ theorem:

$$Q_0(\mathbf{W}) \propto p(\mathbf{W}) \prod_{\tau} p(y_{\tau} \mid \mathbf{x}_{\tau}, \mathbf{W}, \sigma). \quad (10)$$

Equation (9) is a functional optimization problem. Fortunately, the Gaussian assumption allows us to find an analytic form for the posterior. The result is simple:  $q^{l,r}(\mathbf{w}^{l,r}) = \mathcal{N}(\mathbf{w}^{l,r} \mid \bar{\mathbf{w}}^{l,r}, \Sigma^{l,r})$ , where

$$\bar{\mathbf{w}}^{l,r} = \sigma^{-2} \Sigma^{l,r} \sum_{\tau} \phi_{\tau,l} \beta_{\tau}^{l,r} y_{\tau}^{l,r}, \quad \Sigma^{l,r} = [\sigma^{-2} \sum_{\tau} \phi_{\tau,l} \phi_{\tau,l}^{\top} \gamma_{\tau,l} + \mathbf{I}_{d_l}]^{-1}. \quad (11)$$

Here we have defined

$$\beta_{\tau}^{l,r} \triangleq \prod_{l' \neq l} \phi_{\tau,l'}^{\top} \bar{\mathbf{w}}^{l',r}, \quad y_{\tau}^{l,r} \triangleq y_{\tau} - \sum_{r' \neq r} (\phi_{\tau,l}^{\top} \bar{\mathbf{w}}^{l,r'}) \beta_{\tau}^{l,r'}, \quad \gamma_{\tau,l} \triangleq \prod_{l' \neq l} \phi_{\tau,l'}^{\top} \langle \mathbf{w}^{l',r} (\mathbf{w}^{l',r})^{\top} \rangle_{\setminus (l,r)} \phi_{\tau,l}, \quad (12)$$

where  $\langle \cdot \rangle_{\setminus (l,r)}$  is the partial posterior expectation excluding  $q^{l,r}$ . Derivation of Eqs. (11)-(12) is straightforward but needs some work. See Appendix A for the details.

### 4.3 Mean-field approximation and online updates

Equations (11)-(12) have mutual dependency among the  $\{\mathbf{w}^{l,r}\}$  and need to be performed iteratively until convergence. This is numerically challenging to perform in their original form. In Eq. (11),  $\gamma_{\tau,l} \in \mathbb{R}$  plays the role of the sample weight over  $\tau$ 's. Evaluating this weight is challenging due to the matrix inversion needed for  $\Sigma^{l,r}$ . For faster and more stable computation suitable for sequential updating scenarios, we propose a mean-field approximation  $\langle \mathbf{w}^{l',r} (\mathbf{w}^{l',r})^\top \rangle_{\setminus(l,r)} \approx \bar{\mathbf{w}}^{l',r} (\bar{\mathbf{w}}^{l',r})^\top$ , which gives  $\gamma_{\tau,l} = (\beta_\tau^{l,r})^2$ . Intuitively, the mean-field approximation amounts to the idea ‘‘think of the others as given (as their mean) and focus only on yourself.’’ Using this, we have a simple formula for  $\Sigma^{l,r}$ :

$$\Sigma^{l,r} = \left[ \sigma^{-2} \sum_{\tau} (\beta_\tau^{l,r} \phi_{\tau,l}) (\beta_\tau^{l,r} \phi_{\tau,l})^\top + \mathbf{I}_{d_l} \right]^{-1}. \quad (13)$$

Unlike the crude approximation that sets the other  $\{\mathbf{w}^{l',r}\}$  to a given constant,  $\mathbf{w}^{l,r}$ 's are computed iteratively over all  $l, r$  in turn, and are expected to converge to a mutually consistent value. The variance is used for comparing different edges in the UCB framework. The approximation is justifiable since the mutual consistency matters more in our task than estimating the exact value of the variance. In Sec. 7, we will confirm that the variational tensor bandits significantly outperforms the baseline even under these approximations.

Now let us derive the online updating equations. Fortunately, this can be easily done because  $\bar{\mathbf{w}}^{l,r}$  in Eq. (11) and  $\Sigma^{l,r}$  in Eq. (13) depend on the data only through the summation over  $\tau$ . For any quantity defined as  $A_{\tau+1} \triangleq \sum_{s=1}^{\tau} a_s$ , we straightforwardly have an update equation  $A_{\tau+1} = A_\tau + a_\tau$  in general. Hence when a new sample  $(\mathcal{X}_\tau, y_\tau)$  comes in: First,  $\Sigma^{l,r}$  can be updated as

$$(\Sigma^{l,r})^{-1} \leftarrow (\Sigma^{l,r})^{-1} + (\beta^{l,r}/\sigma)^2 \phi_{\tau,l} \phi_{\tau,l}^\top, \quad \Sigma^{l,r} \leftarrow \Sigma^{l,r} - \frac{\Sigma^{l,r} \phi_{\tau,l} \phi_{\tau,l}^\top \Sigma^{l,r}}{(\sigma/\beta^{l,r})^2 + \phi_{\tau,l}^\top \Sigma^{l,r} \phi_{\tau,l}}, \quad (14)$$

where the second equation follows from the Woodbury matrix identity (Bishop, 2006). Second, for the posterior mean  $\bar{\mathbf{w}}^{l,r}$ , with the updated  $\Sigma^{l,r}$ , we have

$$\mathbf{b}^{l,r} \leftarrow \mathbf{b}^{l,r} + \phi_{\tau,l} \beta^{l,r} y_\tau, \quad \bar{\mathbf{w}}^{l,r} = \sigma^{-2} \Sigma^{l,r} \mathbf{b}^{l,r}. \quad (15)$$

Equations (14)-(15) are computed over all  $(l, r)$  until convergence. Note that when  $R = D = 1$ , these update equations essentially derive the ones used in LinUCB (Li et al., 2010) as a special case.

## 5 Tensor UCB Algorithm

This section presents **TensorUCB**, based on the online probabilistic tensor regression framework in Sec. 4.

### 5.1 Predictive distribution

With the posterior distribution  $Q(\mathcal{W}) = \prod_{l,r} q^{l,r}$ , we can obtain the predictive distribution of the user response score  $u$  for an *arbitrary* context tensor  $\mathcal{X} = \phi_1 \circ \dots \circ \phi_D$  as

$$p(u | \mathcal{X}, \mathcal{D}_{1:\tau}) = \int \mathcal{N}(u | (\mathcal{W}, \mathcal{X}), \sigma^2) Q(\mathcal{W}) d\mathcal{W}. \quad (16)$$

Despite  $Q(\mathcal{W})$  being a factorized Gaussian, this integration is intractable. We again use the mean-field approximation when applying the Gaussian marginalization formula (see, e.g., Sec. 2.3.3 of (Bishop, 2006)). The resulting predictive distribution is also a Gaussian distribution  $p(u | \mathcal{X}, \mathcal{D}_t) = \mathcal{N}(y | \bar{u}(\mathcal{X}), \bar{s}^2(\mathcal{X}))$  with

$$\bar{u}(\mathcal{X}) = (\bar{\mathcal{W}}, \mathcal{X}) = \sum_{r=1}^R \prod_{l=1}^D (\bar{\mathbf{w}}^{l,r})^\top \phi_l, \quad \bar{s}^2(\mathcal{X}) = \sigma^2 + \sum_{r=1}^R \sum_{l=1}^D (\beta^{l,r} \phi_l)^\top \Sigma^{l,r} (\beta^{l,r} \phi_l). \quad (17)$$

Notice that the predictive mean  $\bar{u}(\mathcal{X})$  is simply the inner product between the posterior mean  $\bar{\mathcal{W}}$  and the input tensor  $\mathcal{X}$ , which is a typical consequence of the mean-field approximation. We also see that the predictive variance  $\bar{s}^2$  depends on the context tensor  $\mathcal{X}$ , and some users/products may have greater uncertainty in the expected score  $\bar{u}$ . We leave the detail of the derivation of Eq. (17) to Appendix B.

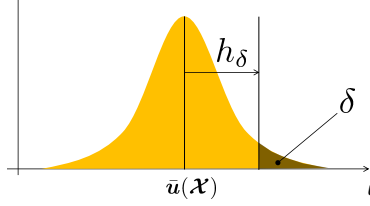

Figure 3: Illustration of Gaussian tail probability and its upper confidence bound.

## 5.2 Upper confidence bound

To transform  $\bar{u}$  into the activation probability, we adopt the well-known UCB strategy. Thanks to the predictive distribution being Gaussian, we can straightforwardly provide the upper confidence bound corresponding to a tail probability.

We start with Markov's inequality that holds for any non-negative random variable  $v$  and any  $r > 0$ :

$$\mathbb{P}(v \geq r) \leq \frac{\langle v \rangle}{r}, \quad (18)$$

where  $\mathbb{P}(\cdot)$  is the probability that the argument holds true and  $\langle \cdot \rangle$  is the expectation. Although the response score  $u$  can be negative, we can use Markov's inequality by setting  $v = e^{\lambda u}$ :

$$\mathbb{P}(e^{\lambda u} \geq e^{\lambda h}) = \mathbb{P}(u \geq h) \leq \frac{\langle e^{\lambda u} \rangle}{e^{\lambda h}}. \quad (19)$$

Here we note that  $\langle e^{\lambda u} \rangle$  is the definition of the moment generating function, and a well-known analytic expression is available for the Gaussian distribution (17):

$$\langle e^{\lambda u} \rangle = \exp \left( \lambda \bar{u}(\mathcal{X}) + \frac{1}{2} \lambda^2 \bar{s}^2(\mathcal{X}) \right). \quad (20)$$

The inequality (19) now reads

$$\mathbb{P}(u \geq h) \leq \exp \left( \lambda (\bar{u}(\mathcal{X}) - h) + \frac{1}{2} \lambda^2 \bar{s}^2(\mathcal{X}) \right). \quad (21)$$

Here, recall that  $\lambda$  is *any* positive number. The idea of Chernoff bound is to exploit the arbitrariness of  $\lambda$  to get the tightest bound. It is an elementary calculus problem to get the minimum of the r.h.s. of Eq. (21). The minimum is achieved at  $\lambda = (h - \bar{u})/\bar{s}^2$ , yielding the Chernoff bound of Gaussian:

$$\mathbb{P}(u \geq h) \leq \exp \left( -\frac{(h - \bar{u}(\mathcal{X}))^2}{2\bar{s}^2(\mathcal{X})} \right). \quad (22)$$

Now let us assume that the tail probability  $\mathbb{P}(u \geq h)$  on the l.h.s. equals to  $\delta$ , and denote the corresponding upper bound by  $h_\delta + \bar{u}$ , as illustrated in Fig. 3. Solving the equation  $\delta = \exp(-h_\delta^2/[2\bar{s}^2(\mathcal{X})])$ , we have

$$h_\delta = \sqrt{-2 \ln \delta} \times \bar{s}(\mathcal{X}). \quad (23)$$

This is the upper confidence bound we wanted. Since  $\sigma^2$  has been assumed to be a constant and  $(\beta^{l,r} \phi_l)^\top \Sigma^{l,r} (\beta^{l,r} \phi_l) \geq 0$  in Eq. (17), it suffices to use

$$p_{i,j} = J(\bar{u}(\mathcal{X}) + \text{UCB}(\mathcal{X})), \quad \text{UCB}(\mathcal{X}) \triangleq c \sum_{r=1}^R \sum_{l=1}^D \sqrt{(\beta^{l,r} \phi_l)^\top \Sigma^{l,r} (\beta^{l,r} \phi_l)}, \quad (24)$$

where we assumed that  $\mathcal{X}$  is between the  $i$ - and  $j$ -th nodes,  $J(\cdot)$  is a (typically sigmoid) function that maps a real value onto  $[0, 1]$ , and  $c > 0$  is a hyperparameter. Again,  $D = R = 1$  reproduces LinUCB (Li et al., 2010).

**Algorithm 1** TensorUCB for contextual influence maximization ( $D = 3$  case)

---

**Input:**  $K, \sigma, R$  and  $c > 0$ . Subroutine **ORACLE**.  
Initialize  $\{\Sigma^{l,r}, \mathbf{w}^{l,r}\}$  and  $\{p_{i,j}\}$ .  
**for**  $t = 1, 2, \dots, T$  **do**  
  Receive product context  $\phi_3$  of this round.  
   $\mathcal{S}_t \leftarrow \text{ORACLE}(\{p_{i,j}\}, K)$   
  Receive response from users connected to  $\forall i \in \mathcal{S}_t$ .  
  **for**  $k = 1, \dots, n_t$  **do**  
    Retrieve user feature vectors  $\phi_1, \phi_2$  from  $k$ .  
    Update  $\{\bar{\mathbf{w}}^{l,r}\}$  and  $\{\Sigma^{l,r}\}$  with  $(\mathcal{X}_{t(k)}, y_{t(k)})$ .  
  **end for**  
  **for**  $(i, j) \in \mathcal{E}$  **do**  
    Set  $\phi_1 = \mathbf{x}_i$ ,  $\phi_2 = \mathbf{x}_j$ , and  $\mathcal{X} = \phi_1 \circ \phi_2 \circ \phi_3$   
    Compute  $p_{i,j} = J(\bar{\mathbf{u}}(\mathcal{X}) + \text{UCB}(\mathcal{X}))$   
  **end for**  
**end for**

---

**5.3 Algorithm summary**

We summarize the proposed **TensorUCB** algorithm in Algorithm 1 in the simplest setting with  $D = 3$ . Compared with the existing budgeted IM works using linear contextual bandits, **TensorUCB** has one extra parameter,  $R$ , the rank of CP expansion (6).  $R$  can be fixed to a sufficiently large value within the computational resource constraints, typically between 10 and 100. As shown in Fig. 5 later, the average regret tends to gradually improve as  $R$  increases up to a certain value. Except for the first several values as in Fig. 5, changes are typically not drastic.

As for the other three “standard” parameters: The budget  $K$  is determined by business requirements.  $\sigma^2$  is typically fixed to a value of  $\mathcal{O}(1)$  such as 0.1. Note that  $\sigma^2$  is also present in other linear contextual bandit frameworks but they often ignore it by assuming unit variance.  $c$  needs to be chosen from multiple candidate values (see Sec. 7), which is unavoidable in UCB-type algorithms. For initialization of the online algorithm,  $\Sigma^{l,r}$  is typically set to  $\mathbf{I}_{d_l}$  and  $\mathbf{w}^{l,r}$  can be the vector of ones.  $\{p_{i,j}\}$  can be random numbers for connected edges and 0 otherwise.

Since our algorithm does not need explicit matrix inversion, the complexity per update can be evaluated as  $\mathcal{O}(RDd^2)$ , where  $d \triangleq \max_l d_l$ . Note that, if we vectorized  $\mathbf{W}$  to use standard vector-based inference algorithms, the complexity would be at least  $\mathcal{O}((\prod_l d_l)^2)$ , which can be prohibitive. The vectorized model also hurts interpretability as it breaks natural groupings of the features.

**6 Regret analysis**

We leverage the predictive distribution (17) to evaluate the regret bound of **TensorUCB**. Let  $f(\mathcal{S}, \mathbf{P}_{\mathcal{G}})$  be the total number of influencees activated for a selected seed set  $\mathcal{S}$  based on the activation probabilities  $\mathbf{P}_{\mathcal{G}}$ . Suppose that **ORACLE** is an  $\eta$ -approximation algorithm (Golovin & Krause, 2011). In the CB-based IM literature, a scaled version of regret is typically used as the starting point (Wen et al., 2017; Vaswani et al., 2017; Chen et al., 2016):

$$R_T^\eta = \frac{1}{\eta} \sum_{t=1}^T \mathbb{E}[f(\mathcal{S}^*, \mathbf{P}_{\mathcal{G}}^*) - f(\mathcal{S}_t, \mathbf{P}_{\mathcal{G}}^*)], \quad (25)$$

where  $\mathbf{P}_{\mathcal{G}}^* = [p_{i,j}^*]$  is the ground truth of the activation probability matrix and  $\mathcal{S}^* = \text{ORACLE}(\mathbf{P}_{\mathcal{G}}^*, K)$ . The expectation  $\mathbb{E}(\cdot)$  is taken over the randomness of seed selection by the **ORACLE**. Let  $\mathbf{P}_{t,\mathcal{G}} = [p_{t,i,j}]$  be the estimated activation probability matrix at the  $t$ -th round. Assume that there exists a constant  $B$  such that

$$f(\mathcal{S}_t, \mathbf{P}_{t,\mathcal{G}}) - f(\mathcal{S}_t, \mathbf{P}_{\mathcal{G}}^*) \leq B \sum_{i \in \mathcal{S}_t, j \sim i} |p_{t,i,j} - p_{i,j}^*| \quad (26)$$

for any  $\mathbf{P}_{\mathcal{G}}^*, \mathcal{S}_t$ , and that  $\|\beta^{l,r} \phi_l\| \leq 1$  holds for all  $(l, r)$ . Then the following theorem holds:

**Theorem 1.** *Assuming that  $\text{UCB}(\mathcal{X})$  in Eq. (24) is exact, the upper regret bound of **TensorUCB** is evaluated as*

$$R_T^\eta \leq \mathcal{O}\left(\frac{cB}{\eta} |\mathcal{V}| DR \sqrt{\frac{TKd \ln\left(1 + \frac{TK}{d\sigma^2}\right)}{\ln\left(1 + \frac{1}{\sigma^2}\right)}}\right). \quad (27)$$

The proof is given in Appendix C. Although the complexity can depend on assumed scenarios, this bound is at least comparable to the ones reported in the literature: **IMFB** (Wu et al., 2019), **DILinUCB** (Vaswani et al., 2017), and **IMLinUCB** (Wen et al., 2017) reported the regret bounds of  $\mathcal{O}(d|\mathcal{V}|^{\frac{5}{2}}\sqrt{T})$ ,  $\mathcal{O}(d|\mathcal{V}|^2\sqrt{T})$ , and  $\mathcal{O}(d|\mathcal{V}|^3\sqrt{T})$ , respectively.

## 7 Experiments

This section reports on empirical evaluation of **TensorUCB**. Our goal is to illustrate how it captures users’ heterogeneity as the tensor rank  $R$  increases (Fig. 5), to show its advantage in the presence of product/user heterogeneity (Fig. 4), and to examine its computational overhead (Fig. 6).

### 7.1 Datasets and baselines

We used two publicly available datasets with significantly different levels of product heterogeneity: *Digg* (Hogg & Lerman, 2012a;b) records users’ voting history to posted news stories and has  $|\mathcal{V}| = 2843$ ,  $|\mathcal{E}| = 75895$ , and 1000 stories. *Flixster* (Zafarani & Liu, 2009) records users’ movie rating history and has  $|\mathcal{V}| = 29384$ ,  $|\mathcal{E}| = 371722$ , and 100 movies. In both, we removed isolated or unreachable nodes and those with less than 50 interactions in the log. Activation is defined as voting for the same article (*Digg*), or as watching or liking the same movie within 7 days (*Flixster*).

Baseline methods were carefully chosen to comprehensively cover the major existing latent-modeling IM frameworks (see Introduction): Matrix factorization-based **IMFB** (Wu et al., 2019), linear-regression-based **DILinUCB** (Vaswani et al., 2017), edge-based-regression **IMLinUCB** (Wen et al., 2017), and clustering-based **COIN** (Saritaç et al., 2016), all of which have been introduced in Sec. 2, in addition to **Random**, which selects the seeds for a given round randomly.

All the experiments used  $K = 10$ . **ORACLE** was implemented based on (Tang et al., 2014) with  $\eta = 1 - \frac{1}{e} - 0.1$ . For **TensorUCB**, we fixed  $\sigma^2 = 0.1$  and the hyper-parameters  $R$  and  $c$  were optimized using an initial validation set of 50 rounds. As the performance metric, we reported the average cumulative expected regret  $\frac{1}{t} R_t^\eta$  computed at each round. We reported on regret values averaged over five runs. We used the interaction logs to compute the ground truth activation probabilities  $\{p_{ij}^*\}$  and  $f(\mathcal{S}, \mathbf{P}_{\mathcal{G}})$ . We created the item features  $\mathbf{z}$  using log-likelihood maximization as suggested in (Barbieri et al., 2013).

To avoid pathological issues due to the non-smoothness of categorical variables, we created user and item features using linear embeddings. Our preliminary study showed that categorical features such as ZIP code and product categories lead to too much variance that washes away the similarity between users and between products. For generating user features, we employed the Laplacian Eigenmap (Belkin & Niyogi, 2002) computed from the social graph  $\mathcal{G}$ , which is included in both *Digg* and *Flixster* datasets. For product features, we employed a probabilistic topic model (see, e.g. (Steyvers & Griffiths, 2007)) with the number of topics being 10. In this model, an item is viewed as a document in the “bag-of-votes” representation. Specifically, its  $i$ -th dimension represents whether the  $i$ -th user voted for the item. The intuition is that two articles should be similar if they are liked by a similar group of people. As a result, each item is represented by a 10-dimensional real-valued vector, which corresponds to a distribution over the 10 latent topics identified. Once the item feature vectors are computed on a held-out dataset, they are treated as a constant feature vector for each item.

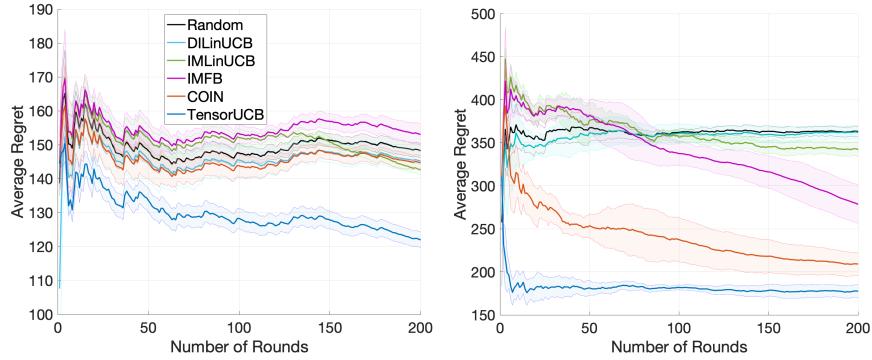

Figure 4: Average cumulative regret for Digg (top) and Flixster (bottom). Best viewed in colors.

## 7.2 Comparison of cumulative regret

As mentioned in Sec. 1, our original motivation for the tensor-based formulation is to capture the heterogeneity over different products/items. To validate this, we simulated marketing campaigns such that a new product is randomly picked at each campaign round  $t$ . For parameter tuning,  $c$  was chosen from  $\{10^{-3}, 10^{-2}, 10^{-1}, 1\}$ , while  $R$  was chosen in the range of  $1 \leq R \leq 50$ . We used the sigmoid function for  $J(\cdot)$  in Eq. (24).

Figure 4 compares **TensorUCB** against the baselines on Digg and Flixster. As is clearly shown, **TensorUCB** significantly outperforms the baselines. The difference is striking in Flixster. In this dataset, there are only 100 items (movies). Interestingly, **TensorUCB** captures the majority of the underlying preference patterns with only about 10 rounds of explorations. This is in sharp contrast to the “slow starter” behavior of **COIN** and **IMFB**. On the other hand, the Digg dataset includes as many as 1 000 items, and the interaction patterns in it may not have been fully explored in the relatively small number of rounds. This is consistent with the relatively small margin in the upper figure. Even in that case, however, **TensorUCB** captures underlying user preferences much more quickly than any other methods.

In Flixster, **COIN** exhibits a relatively similar behavior to **TensorUCB**. **COIN** partitions the feature space at the beginning. In Flixster, the number of items is comparable to the number of training rounds, which was 50 in our case. Thus the initial partitioning is likely to have captured a majority of patterns, while it is not the case in Digg.

In Digg, we see that a few baselines underperform **Random**. For example, **IMFB** is beaten by **Random** in Digg (top) while it can eventually capture some of the underlying user preference patterns in Flixster (bottom). Since **IMFB** does not use the product features, the product heterogeneity in Digg apparently fools the model into inaccurately adjusting the parameters. It is encouraging that **TensorUCB** stably achieves better performance even under rather challenging set-ups as in Digg, indicating its usefulness in practice.

## 7.3 Dependency on tensor rank

Since **TensorUCB** uses the specific parameterization of CP expansion (6), it is interesting to see how the result depends on the tensor rank  $R$ . Figure 5 shows how the average regret behaves over the first several values of  $R$  on Digg. To facilitate the analysis, we randomly picked a single item (story) at the beginning and kept targeting the item throughout the rounds. In the figure, we specifically showed the first five  $R$ ’s, where the change in the average regret was most conspicuous. In this regime, the average regret tends to improve as  $R$  increases. Depending on the level of heterogeneity of the data, it eventually converges at a certain  $R$  up to fluctuations due to randomness. The intuition behind Eq. (6) was that  $R = 1$  amounts to assuming a single common pattern in the user preference while  $R > 1$  captures *multiple* such patterns. This result empirically validates our modeling strategy.

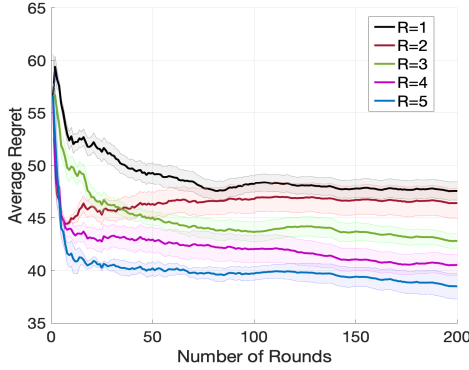

Figure 5: Average cumulative regret of **TensorUCB** computed on Digg with different  $R$ s. Best viewed in colors.

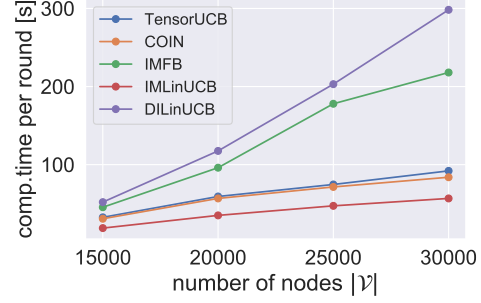

Figure 6: Computational time per round averaged over 200 rounds on Flixster. Best viewed in colors.

#### 7.4 Comparison of computational cost

Finally, Fig. 6 compares the computation time per round on Flixster, measured on a laptop PC (Intel i7 CPU with 32 GB memory). Error bars are negligibly small and omitted for clearer plots. To see the dependency on the graph size, we randomly sampled the nodes to create smaller graphs of  $|\mathcal{V}| \approx 25\,000, 20\,000, 15\,000$ . As shown in the figure, the computation time scales roughly linearly, which is understandable because the graph is quite sparse and the most nodes have a node degree that is much smaller than  $|\mathcal{V}|$ . **IMLinUCB** is fastest but significantly under-performed in terms of regrets in Fig. 4. **TensorUCB** is comparable to **COIN** and much faster than **IMFB** and **DILinUCB**. These results validate that **TensorUCB** significantly outperforms the baselines without introducing much computational overhead.

## 8 Concluding remarks

We have proposed **TensorUCB**, a tensor-based contextual bandit framework, which can be viewed as a new and natural extension of the classical UCB algorithm. The key feature is the capability of handling any number of contextual feature vectors. This is a major step forward in the problem of influence maximization for online advertising since it provides a practical way of simultaneously capturing the heterogeneity in users and products. With **TensorUCB**, marketing agencies can efficiently acquire common underlying knowledge from previous marketing campaigns that include different advertising strategies across different products. We empirically confirmed a significant improvement in influence maximization tasks, attributable to its capability of capturing and leveraging the user-product heterogeneity.

## Appendix

### A Derivation of posterior distribution

This section explains how to solve Eq. (9). The key idea of VB is to look at individual components  $\{q^{l,r}\}$  of  $Q$  one by one, keeping all the others fixed. For instance, for a particular pair of  $(l, r) = (3, 2)$ , the minimization problem of Eq. (8) reads

$$\min_{q^{3,2}} \left\{ \int d\mathbf{w}^{3,2} q^{3,2} \ln q^{3,2} - \int \prod_{l=1}^D \prod_{r=1}^R d\mathbf{w}^{l,r} q^{l,r} \ln Q_0(\mathbf{w}) \right\},$$

where  $Q_0$  has been defined in Eq. (10). The main mathematical tool to solve this functional optimization problem is calculus of variations. A readable summary can be found in the appendix of Bishop (Bishop, 2006). Apart from deep mathematical details, its operational recipe is analogous to standard calculus. What we do is analogous to differentiating  $x \ln x - ax$  to get  $\ln x + 1 - a$ , and equating it to zero. For a general  $(l, r)$ , the solution is given by:

$$\ln q^{l,r} = \text{const.} + \langle \ln Q_0(\mathbf{w}) \rangle_{\setminus(l,r)}, \quad (\text{A.1})$$

$$\langle \ln Q_0(\mathbf{w}) \rangle_{\setminus(l,r)} \triangleq \int \prod_{l' \neq l} \prod_{r' \neq r} d\mathbf{w}^{l',r'} q^{l',r'} \ln Q_0(\mathbf{w}), \quad (\text{A.2})$$

where  $\text{const.}$  is a constant and  $\langle \cdot \rangle_{\setminus(l,r)}$  denotes the expectation by  $Q(\{\mathbf{w}^{l,r}\})$  over all the variables except for the  $(l, r)$ .

#### A.1 Solution under the Gaussian model

Now let us derive an explicit form of the posterior. Using Eq. (10) for  $Q_0$  together with Eq. (7) in Eq. (A.1), we have

$$\ln q^{l,r} = \text{const.} - \frac{1}{2} (\mathbf{w}^{l,r})^\top \mathbf{w}^{l,r} - \frac{1}{2\sigma^2} \sum_{\tau} \langle \{y_{\tau} - (\mathbf{w}, \mathbf{x}_{\tau})\}^2 \rangle_{\setminus(l,r)}. \quad (\text{A.3})$$

The expression (6) allows writing the last term in terms of  $\{\mathbf{w}^{l,r}\}$ :

$$\begin{aligned} \langle \{y_{\tau} - (\mathbf{w}, \mathbf{x}_{\tau})\}^2 \rangle_{\setminus(l,r)} &= \text{const.} - 2\mathbf{w}^{l,r\top} \phi_{\tau,l} \beta_{\tau}^{l,r} y_{\tau}^{lr} \\ &\quad + \mathbf{w}^{l,r\top} \phi_{\tau,l} \phi_{\tau,l}^\top \mathbf{w}^{l,r} \prod_{l' \neq l} \phi_{\tau,l'}^\top \langle \mathbf{w}^{l',r} \mathbf{w}^{l',r\top} \rangle_{\setminus(l,r)} \phi_{\tau,l'}, \end{aligned} \quad (\text{A.4})$$

where  $\beta_{\tau}^{l,r}$  and  $y_{\tau}^{lr}$  have been defined in Eq. (12).

Equations (A.3) and (A.4) imply that  $\ln q^{l,r}$  is quadratic in  $\mathbf{w}^{l,r}$  and thus  $q^{l,r}$  is Gaussian. For instance, for  $(l, r) = (3, 2)$ , collecting all the terms that depend on  $\mathbf{w}^{3,2}$ , we have

$$\ln q^{3,2} = \text{const.} + (\mathbf{w}^{3,2})^\top \frac{1}{\sigma^2} \sum_{\tau} (\beta_{\tau}^{3,2} \phi_{\tau,3}) y_{\tau}^{3,r} - \frac{1}{2} (\mathbf{w}^{3,2})^\top \left\{ \mathbf{I}_d + \frac{1}{\sigma^2} \sum_{\tau} (\beta_{\tau}^{3,2} \phi_{\tau,3}) (\beta_{\tau}^{3,2} \phi_{\tau,3})^\top \right\} \mathbf{w}^{3,2}.$$

By completing the square, we get the posterior covariance matrix  $\Sigma^{3,2}$  and the posterior mean  $\bar{\mathbf{w}}^{3,2}$  as

$$\Sigma^{3,2} = \left\{ \mathbf{I}_d + \frac{1}{\sigma^2} \sum_{\tau} (\beta_{\tau}^{3,2} \phi_{\tau,3}) (\beta_{\tau}^{3,2} \phi_{\tau,3})^\top \right\}^{-1}, \quad \bar{\mathbf{w}}^{3,2} = \frac{1}{\sigma^2} \Sigma^{3,2} \sum_{\tau} (\beta_{\tau}^{3,2} \phi_{\tau,3}) y_{\tau}^{3,r}, \quad (\text{A.5})$$

which are the (batch-version of) solution given in the main text.

## B Derivation of the predictive distribution

This section explains how to perform the integral of Eq. (16) under

$$Q(\mathcal{W}) = \prod_{l=1}^D \prod_{r=1}^R \mathcal{N}(\mathbf{w}^{l,r} \mid \bar{\mathbf{w}}^{l,r}, \Sigma^{l,r}). \quad (\text{B.6})$$

We first integrate w.r.t.  $\mathbf{w}^{1,r}$ . By factoring out  $\mathbf{w}^{1,r}$  from the tensor inner product as  $(\mathcal{W}, \mathcal{X}) = \sum_r (\phi_1 b^{1,r})^\top \mathbf{w}^{1,r}$ , we have

$$I_1 \triangleq \int \prod_{r=1}^R d\mathbf{w}^{1,r} \mathcal{N}(\mathbf{w}^{1,r} \mid \bar{\mathbf{w}}^{1,r}, \Sigma^{1,r}) \mathcal{N}(u \mid (\mathcal{W}, \mathcal{X}), \sigma^2) = \mathcal{N}(u \mid u_1, \sigma_1^2),$$

where  $b^{1,r} \triangleq (\phi_2^\top \mathbf{w}^{2,r}) \cdots (\phi_D^\top \mathbf{w}^{D,r})$  and

$$u_1 = \sum_{r=1}^R (\phi_1^\top \bar{\mathbf{w}}^{1,r}) b^{1,r}, \quad \sigma_1^2 = \sigma^2 + \sum_{r=1}^R (b^{1,r} \phi_1)^\top \Sigma^{1,r} (b^{1,r} \phi_1).$$

To perform the integral we used the well-known Gaussian marginalization formula. See, e.g., Eqs. (2.113)-(2.115) in Sec. 2.3.3 of Bishop (2006).

Next, we move on to the  $l = 2$  terms, given  $I_1$ . Unfortunately, due to the nonlinear dependency on  $\mathbf{w}^{2,r}$  in  $\sigma_1^2$ , the integration cannot be done analytically. To handle this, we introduce a mean-field approximation in the same spirit of that of the main text:

$$\sigma_1^2 \approx \sigma^2 + \sum_{r=1}^R (\beta^{1,r} \phi_1)^\top \Sigma^{1,r} (\beta^{1,r} \phi_1), \quad (\text{B.7})$$

where  $\mathbf{w}^{2,r}, \dots, \mathbf{w}^{D,r}$  have been replaced with their posterior means  $\bar{\mathbf{w}}^{2,r}, \dots, \bar{\mathbf{w}}^{D,r}$ . The definition of  $\beta_{\tau}^{l,r}$  is given by Eq. (12). We do this approximation for all  $\sigma_1^2, \dots, \sigma_D^2$  while keeping  $u_1, \dots, u_D$  exact.

As a result, after performing the integration up to  $l = k$ , we have a Gaussian  $\mathcal{N}(u \mid u_k, \sigma_k^2)$ , where

$$u_k = \sum_{r=1}^R \prod_{l=1}^k (\phi_l^\top \bar{\mathbf{w}}^{l,r}) \prod_{l'=k+1}^D (\phi_{l'}^\top \mathbf{w}^{l',r}), \quad \sigma_k^2 = \sigma^2 + \sum_{l=1}^k \sum_{r=1}^R (\beta^{l,r} \phi_l)^\top \Sigma^{l,r} (\beta^{l,r} \phi_l). \quad (\text{B.8})$$

By continuing this procedure, we obtain the predictive mean and the variance in Eq. (17).

## C Derivation of the regret bound

This section derives the upper bound given in Theorem 1 on the scaled regret defined in Eq. (25).

### C.1 Relationship with confidence bound

In addition to the 1-norm bounded smoothness condition (26), we make a common assumption called the monotonicity. For a seed user set  $\mathcal{S}$ , the monotonicity states that, if  $p_{i,j} \leq p'_{i,j}$  for all  $(i, j)$ , we have  $f(\mathcal{S}, \mathbf{P}_{\mathcal{G}}) \leq f(\mathcal{S}, \mathbf{P}'_{\mathcal{G}})$ . Let  $\mathbf{P}_{t,\mathcal{G}} = [p_{t,i,j}]$  be an estimate of the activation probabilities at the  $t$ -th round. Based on the monotonicity condition and the property of the ORACLE's seed selection strategy, Wu et al. (2019) argued that the instantaneous regret (25) is upper-bounded as

$$\frac{1}{\eta} \mathbb{E} [f(\mathcal{S}^*, \mathbf{P}_{\mathcal{G}}^*) - f(\mathcal{S}_t, \mathbf{P}_{\mathcal{G}}^*)] \leq \frac{1}{\eta} \mathbb{E} [f(\mathcal{S}_t, \mathbf{P}_{t,\mathcal{G}}) - f(\mathcal{S}_t, \mathbf{P}_{\mathcal{G}}^*)]$$

with probability  $1 - \delta$ , where  $\delta$  is the tail probability chosen in the UCB approach. Since  $K \ll |\mathcal{V}|$  in general, it is possible for the event that may occur with possibility  $\delta$  to play a significant role in the cumulative regret. Fortunately, Lemma 2 of (Wen et al., 2017) guarantees that its contribution can be bounded by  $\mathcal{O}(1)$ , according to Wu et al. (2019).

Combining with the smoothness condition (26) and the expression of UCB presented in the main text, we have

$$R_T^\eta \leq \frac{cB|\mathcal{V}|}{\eta} \sum_{t=1}^T \sum_{k=1}^K \sum_{l=1}^D \sum_{r=1}^R \kappa_{t(k),l,r} + \mathcal{O}(1), \quad (\text{C.9})$$

$$\kappa_{t(k),l,r} \triangleq \sqrt{(\beta_{t(k)}^{l,r} \phi_{t(k),l})^\top \Sigma_{t(k)}^{l,r} (\beta_{t(k)}^{l,r} \phi_{t(k),l})}, \quad (\text{C.10})$$

where we have used the “ $t(k)$ ” notation introduced in Sec. 3.2 in the main text. Here,  $\Sigma_{t(k)}^{l,r}$  is the covariance matrix computed using the data up to the  $k$ -th seed node in the  $t$ -th round.  $\beta_{t(k)}^{l,r}$  and  $\phi_{t(k),l}$  are defined similarly. The summation over  $j$  in Eq. (26) produces a constant of the order of node degree, which is bounded by  $|\mathcal{V}|$ .

Now our goal is to find a reasonable upper bound of  $\kappa_{t(k),l,r}$ . This term has appeared in the definition of the confidence bound  $\text{UCB}(\mathcal{X})$  in the main text. This is reminiscent of the regret analysis of vector contextual bandits (Dani et al., 2008; Chu et al., 2011; Abbasi-Yadkori et al., 2011), in which the analysis is reduced to bounding the vector counterpart of  $\kappa_{t(k),l,r}$ .

### C.2 Bounding confidence bound

Now that the cumulative scaled regret is associated with  $\kappa_{t(k),l,r}$ , let us prove the following Lemma, which supports the regret bound reported in the main text:

**Lemma 1.** *Under the assumption  $\|\beta_{t(k)}^{l,r} \phi_{t(k),l}\| \leq 1, \forall l, r, t, k$ ,*

$$\sum_{t,k,l,r} \kappa_{t(k),l,r} \leq R \sqrt{\frac{TKD \sum_l d_l \ln \left(1 + \frac{TK}{d_l \sigma^2}\right)}{\ln \left(1 + \frac{1}{\sigma^2}\right)}}, \quad (\text{C.11})$$

$$\leq DR \sqrt{\frac{TKd \ln \left(1 + \frac{TK}{d \sigma^2}\right)}{\ln \left(1 + \frac{1}{\sigma^2}\right)}}, \quad (\text{C.12})$$

where  $d \triangleq \max_l d_l$ .

(Proof) Under the  $t(k)$ -notation, the updating equation for the covariance matrix looks like

$$(\Sigma_{t(k+1)}^{l,r})^{-1} = (\Sigma_{t(k)}^{l,r})^{-1} + \left(\frac{\beta_{t(k)}^{l,r}}{\sigma}\right)^2 \phi_{t(k),l} \phi_{t(k),l}^\top, \quad (\text{C.13})$$

which leads to an interesting expression of the determinant:

$$\det |(\boldsymbol{\Sigma}_T^{l,r})^{-1}| = \prod_{t=1}^{T-1} \prod_{k=1}^K \left( 1 + \frac{\kappa_{t(k),l,r}^2}{\sigma^2} \right). \quad (\text{C.14})$$

This follows from repeated applications of the matrix determinant lemma  $\det |\mathbf{A} + \mathbf{a}\mathbf{b}^\top| = \det |\mathbf{A}|(1 + \mathbf{b}^\top \mathbf{A}^{-1} \mathbf{a})$  that holds for any vectors  $\mathbf{a}, \mathbf{b}$  and invertible matrix  $\mathbf{A}$  as long as the products are well-defined. Equation (C.14) implies  $\det |\boldsymbol{\Sigma}_{t(k)}^{l,r}| \leq 1$ . By the assumption  $\|\beta_{t(k)}^{l,r} \boldsymbol{\phi}_{t(k),l}\| \leq 1$ , we have  $\kappa_{t(k),l,r} \leq 1$ .

Interestingly, the cumulative regret (C.9) can be represented in terms of the determinant. Using an inequality

$$b^2 \leq \frac{1}{\ln(1 + \sigma^{-2})} \ln(1 + \frac{b^2}{\sigma^2}), \quad (\text{C.15})$$

that holds for any  $b^2 \leq 1$ , we have

$$\begin{aligned} \sum_{t=1}^T \sum_{k=1}^K \sum_{l=1}^D \sum_{r=1}^R \kappa_{t(k),l,r} &\leq \left[ TKDR \sum_{t,k,r,l} \kappa_{t(k),l,r}^2 \right]^{\frac{1}{2}}, \\ &\leq \left[ TKDR \sum_{t,k,r,l} \frac{\ln(1 + \frac{\kappa_{t(k),l,r}^2}{\sigma^2})}{\ln(1 + \sigma^{-2})} \right]^{\frac{1}{2}}, \end{aligned} \quad (\text{C.16})$$

$$= \left[ TKDR \sum_{r,l} \frac{\ln \det |(\boldsymbol{\Sigma}_T^{l,r})^{-1}|}{\ln(1 + \sigma^{-2})} \right]^{\frac{1}{2}}, \quad (\text{C.17})$$

where the last equality follows from Eq. (C.14).

The determinant is represented as the product of engenvales. Since the geometrical mean is bounded by the arithmetic mean, we have

$$\det |(\boldsymbol{\Sigma}_T^{l,r})^{-1}|^{\frac{1}{d_l}} \leq \frac{1}{d_l} \text{Tr}[(\boldsymbol{\Sigma}_T^{l,r})^{-1}], \quad (\text{C.18})$$

$$= 1 + \frac{1}{d_l \sigma^2} \sum_{t=1}^{T-1} \sum_{k=1}^K \|\beta_{t(k)}^{l,r} \boldsymbol{\phi}_{t(k),l}\|^2, \quad (\text{C.19})$$

$$\leq 1 + \frac{(T-1)K}{d_l \sigma^2}, \quad (\text{C.20})$$

where the second equality is by Eq. (C.13) and the last inequality is by the assumption  $\|\beta_{t(k)}^{l,r} \boldsymbol{\phi}_{t(k),l}\| \leq 1$ . Finally, we have

$$\begin{aligned} \sum_{t,k,r,l} \kappa_{t(k),l,r} &\leq \left[ \frac{TKDR^2}{\ln(1 + \sigma^{-2})} \sum_{l=1}^D d_l \ln \left( 1 + \frac{(T-1)K}{d_l \sigma^2} \right) \right]^{\frac{1}{2}}, \\ &\leq \left[ \frac{TKDR^2}{\ln(1 + \sigma^{-2})} \sum_{l=1}^D d_l \ln \left( 1 + \frac{TK}{d_l \sigma^2} \right) \right]^{\frac{1}{2}}, \end{aligned} \quad (\text{C.21})$$

which completes the proof.  $\square$
