Abstract

Federated Learning (FL) under distributed concept drift is a largely unexplored area. Although concept drift is itself a well-studied phenomenon, it poses particular challenges for FL, because drifts arise staggered in time and space (across clients). Our work is the first to explicitly study data heterogeneity in both dimensions. We first demonstrate that prior solutions to drift adaptation, with their single global model, are ill-suited to staggered drifts, necessitating multiple-model solutions. We identify the problem of drift adaptation as a time-varying clustering problem, and we propose two new clustering algorithms for reacting to drifts based on local drift detection and hierarchical clustering. Empirical evaluation shows that our solutions achieve significantly higher accuracy than existing baselines, and are comparable to an idealized algorithm with oracle knowledge of the ground-truth clustering of clients to concepts at each time step.

1 Introduction

Federated learning (FL) [25, 31] is a popular machine learning (ML) paradigm that enables collaborative training without sharing raw training data. FL is crucial in the era of pervasive computing, where massive IoT and mobile phones continuously generate relevant ML data that cannot be easily shared due to privacy and communication constraints. Existing FL solutions generally assume the training data comes from a stable underlying distribution, and the training data in the past is sufficiently similar to the test data in the future. This assumption is often violated in the real world, where the underlying data distribution is non-stationary and constantly evolves. For instance, user sentiment and preference change drastically due to external environments such as the pandemic and macroeconomics [14, 24]. Data collected by cameras are also subject to various data changes such as unexpected weather and novel objects, which can lead to significant ML model performance losses [2, 38].

This concept drift problem [42] in streaming data has been studied extensively in a centralized learning environment [13, 39]. These centralized solutions, however, cannot address the fundamental challenges of concept drifts in FL where data is heterogeneous over time and across different clients. When different clients experience the data drift at different times, no single global model can perform well for all clients. Similarly, when multiple concepts exist simultaneously, no centralized training decision works well for all clients. Several recent works have recognized the problem of FL under concept drift and proposed solutions that adapt learning rates or add regularization terms [8, 9, 17, 29]. Although these solutions perform better than drift-oblivious algorithms such as FedAvg [31], the solutions still use a single global model for all clients, and hence fail to address the aforementioned fundamental challenges of heterogeneity over time and across clients.
We present the first FL solution that employs multiple models to address FL under distributed concept drift. Our solution aims to create one model for each new concept so that all clients under the same concept can train that model collaboratively, similar to what is done for personalized or clustered FL [11 15 17 30 35]. We introduce two new algorithms for client clustering to address the challenges of distributed concept drift. Our first algorithm, FedDrift-Eager, is a specialized algorithm that creates models based on drift detection. FedDrift-Eager is effective if new concepts are introduced one at a time. Our second algorithm, FedDrift, is a general algorithm that isolates drifted clients and conservatively merges clients via hierarchical clustering, so that FedDrift can effectively handle general cases where an unknown number of new concepts emerge simultaneously.

We empirically evaluate our solution, comparing against state-of-the-art centralized concept drift solutions (KUE [6] and DriftSurf [39]) and a recent FL solution that adapts to concept drifts (Adaptive-FedAvg [7]). Our results show that (i) FedDrift-Eager and FedDrift consistently achieve much higher and more stable model accuracy than existing baselines (average accuracy 93% vs. 88% for the best baseline, across six dataset/ drift combinations); (ii) FedDrift performs much better than FedDrift-Eager when multiple new concepts are introduced at the same time; and (iii) our solution achieves a similar model accuracy as Oracle (94% accuracy), an idealized algorithm that knows the timing and distribution of concept drifts. On the real-world drift in the FMoW dataset [24], FedDrift achieves 64% accuracy vs. 58% accuracy for the best baseline.

2 Problem Setup

We consider a FL setting with $P$ clients, assumed to be stateful and participating at each round, and a central server that coordinates training across the clients. Training data are decentralized and arriving over time. The data $S_c(t)$ at each client $c = 1, 2, \ldots, P$ and each time $t = 1, 2, \ldots$ are sampled from a distribution (concept) $P_c(x, y)$. We consider that data may be non-IID in two dimensions, varying across clients and time. We say that there is a concept drift at time $t$ and at client $c$ if $P_c(t) \neq P_c(t-1)$.

The multiple-model FL problem is to learn a set of global models, and a time-varying clustering of clients. For notation, we denote the global models as $h_m$ for $m \in [M]$, where $M$ is the number of models at a given time (and can vary over time). We denote the cluster identities by one-hot vectors $w_c(t)$, where $w_{c,m}(t) = 1$ when the client $c$ at time $t$ uses model $h_m$ for inference; we denote $h_{w_c(t)}$ to represent the unique model $h_m$, where $w_{c,m}(t) = 1$. The objective is to minimize over all time $t$,

$$\sum_{c=1}^{P} \mathbb{E}_{(x,y) \sim \mathcal{P}_c(t)} [\ell(h_{w_c(t)}(x), y)].$$  

In presenting our multiple-model solution, we assume that there is one concept and one model at time 1, and show in §4 how to learn the cluster identities $w_c(\tau)$ for each time $\tau > 1$ as new data arrive. Given the cluster identities, learning the set of global models from the clients’ data is by continuously retraining via FedAvg [31] within each cluster, which is described precisely in Appendix B.

3 Motivation

The prior work on drift adaptation in FL has considered only restrictive settings such as (i) drifts occurring simultaneously in time (e.g., Figure 1 (left)), where a centralized approach works well [4],
or (ii) drifts with only minor deviations from a majority concept (e.g., Figure 1(right)), where updates from drifting clients are suppressed and the minority concept goes unlearned [9,29]. Our work is the first to explicitly study the more general settings arising in distributed drifts, with heterogeneous data across clients and over time.

Consider the distributed drift pattern depicted in Figure 2. This is representative of an emerging trend (e.g., a breaking news event) that affects different clients at different times (e.g., due to their lag in learning of the news). For example, consider a next word prediction app in the period when “war” emerges as the popular next word after “Ukraine” or “slap” emerges after “Will Smith”. Even for this simple case of a single staggered transition between two concepts, prior work results in significant accuracy loss. In particular, their use of a single global model (and at best a single global drift detection test) results in poor accuracy during the transition period (time steps 4–8 in Figure 2, see Figure 5(left) in §5). We also consider more challenging cases, as depicted in Figure 5 where multiple concepts emerge at the same time and concept drifts may be recurring (a.k.a. periodic).

To demonstrate the challenge of distributed drift in real-world data, we consider the Functional Map of the World (FMoW) dataset adapted from the WILDS benchmark [10,24]. The task is to classify the building type or land use from a satellite image, where images are over 5 major geographical regions (Africa, Americas, Asia, Europe, and Oceania) and across 16 years. Concept drift due to human activity and environmental processes degrades predictive accuracy over time. For the 10 most common classes, Figure 4 shows how the class distribution in Africa changes more rapidly over time, such as a reduction in places of worship and an increase in single-unit residential buildings. However, the class distribution viewed globally is relatively slow-changing. Our evaluation shows that the model trained on the global dataset only achieves 48% accuracy on Africa after the major drift at 2014, compared to 60% on the rest of the world. This real-world example highlights the necessity to mitigate concept drift differently across regions, and existing centralized solutions cannot address this fundamental challenge.

4 Clustering Algorithms

In §4.1, we handle the case where only one new concept emerges at a time. Then in §4.2 we give an algorithm that handles the general case where multiple new concepts may emerge simultaneously.

4.1 Special Case: One New Concept at a Time

When a new concept emerges, the clients that observe the drift should be split off to a new cluster to start training a new model. In Algorithm 1 (FedDrift-Eager), we apply a drift detection test locally at each client, and create a new cluster for all clients that detect a new concept.

There are many drift detection tests in the literature [1,12,18,23,32,34,39]. The particular test in this paper is not our focus and for simplicity we consider a test of the form $\ell_{c,m}^m > \ell_{c,m}^{m-1} + \delta$ where the loss degrades by a set threshold $\delta$. However, the desired condition for creating a new model should check only for drifts that correspond to a concept previously unobserved and ill-suited for all existing models. Hence, in Algorithm 1 the drift detection test compares against the best performing model.

---

**Algorithm 1 FedDrift-Eager at time $\tau$**

$\ell_{c,m}^{(\tau)} \leftarrow$ loss of model $h_m$ on client data $S_c^{(\tau)}$

$w_{c,m}^{(\tau)} \leftarrow 1\{m = \arg \min_m \ell_{c,m}^{(\tau)}\}$

if $\min_m \ell_{c,m}^{(\tau)} > \min_m \ell_{c,m}^{(\tau-1)} + \delta$ at any client $c$

then // create one model for all drifted clients

$M \leftarrow M + 1$

Initialize a new global model $h_M$

$w_{c,M}^{(\tau)} \leftarrow 0$; $w_{c,M}^{(\tau)} \leftarrow 1$

---
Algorithm 1 groups all drifting clients in one cluster. However, under the drift in Figure 3 in which concepts B and C emerge simultaneously, this sub-optimally trains a single model for both concepts.

4.2 General Case

When drifts to new concepts are detected at multiple clients, in general we do not know whether the drifts all correspond to one or multiple concepts (or even zero in the event of false positives in detection). We designed Algorithm 2 (FedDrift) for clustering in the face of this uncertainty. For each client that detects drift to a new concept, Algorithm 2 conservatively isolates the clients to individual clusters, and then merges clusters corresponding to the same concept slowly and safely over time by iteratively applying classical hierarchical agglomerative clustering.

Hierarchical clustering is generally specified by a distance function and a stopping criterion. The distance between clusters \( D(i, j) \) based on the loss degradation of model \( h_i \) over a subsample of the data associated with the cluster for model \( h_j \) (and vice versa for symmetry). This distance corresponds to the magnitude of drift between the concepts for each cluster, analogous to the drift detection condition for splitting clusters. Hence, we naturally re-use the drift detection threshold \( \delta \) to represent the tolerance level up to which clusters can be merged, avoiding the addition of another hyperparameter.

One subtlety to Algorithm 2 is that the hierarchical clustering is iteratively run at every time step, because the cluster distances vary with time. A simpler alternative would be to only try merging newly created clusters of local models after one time step of training. However, at that one time step, even models corresponding to the same concept may fail to merge given the limited sample size and limited number of training iterations. In other words, while the models are still warming-up, they may still be separated by a distance exceeding \( \delta \), but as the models converge over time, the distance may drop below \( \delta \), which iterative merging accounts for. A more complete description of Algorithm 2 is described in Appendix C.

5 Experimental Results

We empirically demonstrate that FedDrift-Eager and FedDrift are more effective than prior centralized drift adaptation and achieve high accuracy comparable to an oracle algorithm in the presence of distributed drifts. Our evaluation covers the synthetic drifts in Figures 2 and 3 which (i) occur across clients with staggered timing, (ii) correspond to different concept changes across different clients, and (iii) involve recurring concepts (e.g., the sequence A–B–C–D–A). The 2-concept and 4-concept drift patterns are generated for the datasets SINE, CIRCLE, SEA, and MNIST, described in Appendix D. We also evaluate on the real-world drift in the FMoW dataset.

We compare against the following baselines. First, the Oblivious algorithm learns a single model with FedAvg. Second, we consider drift adaptation algorithms applied at the server on top of FedAvg: the drift detection method DriftSurf, two ensemble methods KUE and AUE, and a Window method that forgets data older than one time step. Third, Adaptive-FedAvg is an FL algorithm that learns a single model and adapts to drifts by centrally tuning the learning rate based on the variability across updates. Fourth, we compare to static FL clustering algorithms IFCA and CFL, which we extend to the time-varying setting by adding a window method (more variations reported in Appendix E). Fifth, Oracle has oracle access to the ground-truth clustering at training time.

In Table 1 we report the average test accuracy across clients and time. Across the 2-concept drift datasets, we observe that the multiple-model algorithms FedDrift-Eager and FedDrift outperform prior centralized solutions. In Figure 5(left), the accuracy is broken down per time step on CIRCLE-2,
where we observe that centralized algorithms particularly suffer during the transition period—when both concepts simultaneously exist, there is no single model that is an accurate fit at all clients. Even the ensemble algorithm (KUE) has poor performance because any new model added is updated by each client, and during the transition period, there is no model trained solely over data from the second concept. FedDrift-Eager and FedDrift learn models specialized for the second concept immediately after it emerges, and learn to apply the appropriate model at each client during the transition, matching the performance of Oracle. On the other hand, while the clustering algorithms IFCA and CFL could flexibly employ specialized models across clients, they do sub-optimally and their accuracy is overall behind (details in Appendix A.2). For the case of CFL, its iterative cluster splitting reacts quickly, but creates excessive models for a staggered concept drift without unification.

For the 4-concept drift, the accuracy per time step on MNIST-4 is shown in Figure 5 (right). We refer to the clustering learned by FedDrift in Figure 6 in which each cell indicates the model ID, and the background color indicates the ground-truth concept. We observe that at time 3, a local model is created for 5 of the 6 drifted clients, and by time 5, under iterative hierarchical clustering, a distinct model is learned for each concept with no excess models. The accuracy of FedDrift is close to Oracle throughout, with a gap at time 3 when each local model is created. Meanwhile, for FedDrift-Eager, just one model is initially created for both the yellow and green concepts, and its accuracy takes longer to recover. The performance of the centralized baselines never recover.

Finally, we discuss the drift in the real-world FMoW dataset where we observe FedDrift has superior performance. The authors of the WILDS benchmark primarily make note of the performance loss of a globally trained model on data from Africa over time [24]. We observe FedDrift successfully adapts to the local drift, switching the model applied at Africa at year 2014, the time with a significant increase in single-unit residential buildings in Figure 4 in §3. Instead of creating a new model for 2014, we find FedDrift joins the cluster for Oceania where a local model was previously created, and stays at that cluster for 2014 and 2015, before then splitting into a new individual cluster for 2016 and 2017. We also observe that FedDrift detects a drift at 2015 for both Europe and the Americas, creating two more local models that contribute to higher accuracy. Meanwhile, FedDrift-Eager similarly adapts to the change in Africa yielding a performance benefit, but it does not adapt well to the simultaneous drift for Europe and the Americas. Both FedDrift and FedDrift-Eager outperform the centralized adaptation baselines which fail to adapt to the drift when viewed globally (c.f. Figure 4).

To conclude, our evaluation under distributed drifts staggered in time and space demonstrates that FedDrift-Eager and FedDrift achieve accuracy significantly higher than existing baselines and comparable to an idealized algorithm with oracle knowledge of the ground-truth clustering.

A Related Work

Concept drift refers to a change over time in the joint distribution $\mathcal{P}(x, y)$. By decomposing the joint distribution $\mathcal{P}(x, y) = \mathcal{P}(x)\mathcal{P}(y|x)$, we distinguish between drifts where only $\mathcal{P}(x)$ changes versus drifts where the feature-to-label mapping $\mathcal{P}(y|x)$ changes. Under the former case (which goes by the names virtual drift [40], covariate drift [37], and feature-distribution skew [22]) a single model can perform well despite change (although achieving fast convergence in an FL setting still requires a specialized strategy; e.g., FedProx [27]). But under the latter case where the feature-to-label mapping changes (real drift or concept drift [40]), lower loss can often be obtained by using specialized models for different concepts.

Concept drift has been studied extensively in the centralized setting for decades. We refer the reader to the surveys by Gama et al. [13] and Lu et al. [28]. As discussed in §1 directly applying centralized adaptation to a single global model in FL is not well-suited for distributed concept drifts with heterogeneous data across time and clients. Furthermore, centralized ensemble methods that use multiple models for adapting to drift also suffer, because the models in an ensemble are distinguished solely over time, and do not account for heterogeneity across clients—in response to a localized data drift, any newly created global model is trained over a mixture of concepts. We demonstrate this in our experimental evaluation, where we compare against state-of-the-art algorithms such as DriftSurf [39] and KUE [6].

Drift in FL, on the other hand, has so far seen only preliminary study. One line of work considers the setting where there is one concept in the system to be learned (either like the example in Figure 1(right) when a minority of clients drift, or when clients observe the main concept under random noise), and seek to speed up the convergence of a model for that one concept by suppressing clients with heterogeneous data via regularization [9, 17] or drift detection [29]. When it comes to adapting to a new concept over time, we are only aware of two works, and both only consider drifts with uniform timing like the example in Figure 1(left). First, Casado et al. [8] consider only the virtual drift setting (where the labeling $\mathcal{P}(y|x)$ is fixed and only $\mathcal{P}(x)$ changes) and uses drift detection to partition data from distinct concepts, in order to train a single model accurately in the course of revisiting each partition (i.e., rehearsal). Second, Canonaco et al. [7] propose Adaptive-FedAvg, in which the server tunes the learning rate used by all clients as a function of the variability across updates, with the goal of reacting fast when drift occurs while also achieving stable performance in the absence of drift. In our experimental evaluation, we compare against Adaptive-FedAvg.

Our solution to drift in FL relies on learning multiple models, which has been studied in prior work on personalized FL and clustered FL. Clients with similar data can be grouped into clusters, where each cluster of clients is associated with a global model that they collaboratively train [4, 11, 15, 16, 30, 35]. As we extend the problem of data heterogeneity in FL with an additional dimension of time, we train multiple models with the algorithm in Appendix B, which is heavily inspired by the prior clustering algorithms IFCA [16] and HypCluster[30]. This serves as the starting point of our solution, where our main contribution is the creation of new clusters as new concepts arrive over time. Finally, our solution in §4 to handle an unknown number of concepts relies on hierarchical clustering, which has been studied in FL (in the static case) previously by Briggs et al. [4]. In the prior work, the clustering is based on clients’ local updates, and it is unclear how to set the distance threshold at which to stop merging. In contrast, an advantage of our approach is that the stopping criterion is identical to the drift detection threshold, which has an intuitive interpretation of performance loss.

B Multiple-Model Training in FL

Distributed concept drift often means that multiple concepts are present simultaneously, necessitating the need for multiple-model training. In §4 we presented algorithms to learn a time-varying clustering of clients, where each cluster is associated with a global model. In this section, we show how train models for each cluster in Algorithm 5.

We define a time step as the granularity at which new data may arrive at a client. A time step may consist of multiple communication rounds. The set of data arriving at client $c$ and time $t$ is denoted by $S_{c}^{(t)}$. The global models being trained are denoted by $h_{m}$ for $m \in [M]$, where $M$ is the total number of models at a given time. Each model is trained by a cluster of clients, where the clustering may vary over time as concept drifts occur. The cluster identity of client $c$ at time $t$ is denoted by the
one-hot vector \( w_c^{(t)} \), where \( w_{c,m}^{(t)} = 1 \) when assigned to the cluster associated with model \( h_m \) and 0 otherwise. The cluster identities \( w_c^{(t)} \) indicate whether the data \( S_c^{(t)} \) that arrived at client \( c \) at time \( t \) are sampled when computing a local update to the global model \( h_m \). Further, the cluster identity of a client at a given time indicates which model is used for inference.

Within each time, the training of the global models in Algorithm 3 is equivalent to Federated Multiple-model training at time \( \tau \) where

\[
\tilde{F}_c(\tau)(h_m) = \sum_{c=1}^{P} \tilde{w}_{c,m}^\tau F_c(\tau)(h_m)
\]

where \( F_c(\tau) \) denotes the local objective function on client \( c \), and the normalized weight is defined as

\[
\tilde{w}_{c,m}^\tau = \frac{\sum_{t=1}^{T} w_{c,m}^{(t)} N_c^{(t)}}{\sum_{c=1}^{P} \sum_{t=1}^{T} w_{c,m}^{(t)} N_c^{(t)}}.
\]

In the ideal case where each cluster maps to one concept in the system, each \( h_m \) is specialized for each concept that is sampled from a unique data distribution \((P(x, y))\), and these \( h_m \) form a strong solution to our overall objective in \S 2. This ideal solution is the Oracle algorithm in our evaluation in \S 5, and we empirically demonstrate in \S 5 that our proposed solutions achieve comparable accuracy.

---

**Algorithm 3** Multiple-model training at time \( \tau \)

**Input:** Cluster identities \( w_{c,m}^{(t)} \)

for each round \( i = 1, 2, \ldots, R \) do

for each client \( c = 1, 2, \ldots, P \) and each model \( m = 1, 2, \ldots, M \) in parallel do

\( h_{c,m} \leftarrow \text{LOCALUPDATE}(c, h_{c,m}, \{w_{c,m}^{(t)}\}_{t=1}^{T}) \)

for each model \( m = 1, 2, \ldots, M \) do

\( h_m \leftarrow \frac{\sum_{c=1}^{P} h_{c,m} \sum_{t=1}^{T} w_{c,m}^{(t)} N_c^{(t)}}{\sum_{c=1}^{P} \sum_{t=1}^{T} w_{c,m}^{(t)} N_c^{(t)}} \)

**LOCALUPDATE** \((c, h_{c,m}, \{w_{c,m}^{(t)}\}_{t=1}^{T})\):

for each local step \( j = 1, 2, \ldots, K \) do

\( b \leftarrow \text{random minibatch of size } B \) from \( \{ \cup_{t=1} T w_{c,m}^{(t)} \}

\( h_m \leftarrow h_m - \eta \nabla \ell(h_m; b) \)

return \( h_m \)

Note that, as stated, each client \( c \) in Algorithm 3 retains its complete history of both the cluster indicators \( w_{c,m}^{(t)} \) and the local data arrivals \( S_c^{(t)} \). To reduce this overhead, each client could instead maintain just a sliding window of the most recent time steps, as long as the window suffices for the minibatch sampling in LOCALUPDATE.

In setting up the problem of distributed concept drift in FL (\S 3), we separated it into two components: (i) determining the time-varying clustering of clients in response to concept drifts, which is then used as input for (ii) the multiple-model training in Algorithm 3. Suppose, hypothetically, that there is a global model already initialized for each concept up to some moderate accuracy. In this restrictive setting, Algorithm 3 can be used to determine the cluster identities for each new time step. Each client tests the global models from the previous time step over its newly arrived data and chooses to identify with the model with the best loss (breaking ties randomly). The setting considered encompasses time steps involving drifts that occur between concepts known to the system; e.g., the later stages of a staggered drift from concept A to concept B after some clients have already observed concept B (Figure 2). However, Algorithm 3 does not have any mechanism to spawn new clusters or determine the number of clusters. In \S 4, we presented clustering algorithms that can spawn clusters over time to react to drifts to new concepts.
C Detailed Description of FedDrift

In this section, we give a more complete presentation of Algorithm FedDrift first described in §4.2.

Under distributed drift in FL, data are heterogeneous both over time and across clients, where the concept at each time and client is the ground-truth clustering that we seek to learn. Ideally, the models trained by each cluster correspond 1-to-1 to the concepts present in the system. Specifically, we want to avoid two miss-clustering problems: (P1) spawning multiple clusters that correspond to a single concept, because then each model would be trained over only a subset of the relevant data, not taking full advantage of collaborative training, and (P2) merging clients corresponding to multiple concepts into a single cluster (model poisoning).

Algorithm 2 incorporates a bottom-up technique that isolates clients that detect drift (addressing P2) and iteratively merges clusters corresponding to the same concept (addressing P1) by leveraging hierarchical clustering.

The generic hierarchical clustering procedure is specified by a distance function over the set of elements to be clustered and a stopping criterion, and at each step until the stopping criterion is met, merges the two closest clusters, where the distance between clusters of multiple elements is commonly defined to be the maximum distance between their constituents (known as a max-linkage clustering). Algorithm 2 merges clusters as shown in Algorithm 5, combining two clusters (which in our case is unknown), or an upper limit on the distance between clusters to stop merging. By our identification of the cluster distance as a magnitude of drift, we re-use the drift detection condition (although not identical due to the bias of concept associated with h).

Algorithm 5. Merge(i, j, D)

Add a new model $h_k$ ∈ $h_i \sum_{c,t} w_c^{(i)} N_t^{(i)} + h_j \sum_{c,t} w_c^{(j)} N_t^{(j)}$ $\sum_{c,t} w_c^{(i)} N_t^{(i)} + \sum_{c,t} w_c^{(j)} N_t^{(j)}$
\[ w_c^{(i)} = w_c^{(i)} + w_c^{(j)} \text{ for all } c, t \]
\[ D(k, l) = \max(D(i, l), D(j, l)) \text{ for all } l \]
Delete models $h_i, h_j$

To specify a distance function for hierarchical clustering, Algorithm 2 first aggregates at the server the loss estimates $L_{ij}$ of the model $h_i$ evaluated over a subsample of the data associated with the cluster for model $h_j$. Then the distances between each cluster are initialized as $D(i, j) = \max(L_{ij} - L_{ji}, L_{ji} - L_{jj}, 0)$. The first term $L_{ij} - L_{ji}$ measures the loss degradation of model $h_i$ when evaluated over the data associated with $h_j$, relative to the loss over its own data. We informally interpret this difference as the magnitude of drift between the concept associated with $h_i$ to the concept associated with $h_j$, analogous to the drift detection condition (although not identical due to the bias of $L_{ii}$ measuring a model’s accuracy over its own training data). The term $D(i, j)$ is defined to be symmetric by also accounting for the magnitude of the drift $L_{ji} - L_{jj}$ in the reverse direction from concept $j$ to concept $i$.

In addition to defining the cluster distances $D(i, j)$, employing hierarchical clustering also requires setting a stopping criterion. Typically, that corresponds to specifying either the desired number of clusters (which in our case is unknown), or an upper limit on the distance between clusters to stop merging. By our identification of the cluster distance as a magnitude of drift, we re-use the drift detection threshold $\delta$ to also represent the tolerance level up to which clusters can be merged in Algorithm 2, which avoids introducing another hyperparameter.

In Algorithm 2, both creating new clusters and merging existing clusters are based on the observed difference of the models’ accuracy across two samples of data. For the clustering to accurately distinguish concepts, we assume that relevant changes in the concepts are manifested in the degradation of a model’s predictive accuracy, and that the local sample size is sufficient for statistical significance—the same assumptions necessary for prior drift detection tests [18, 32, 34, 39].

1 More precisely, at client $c$, the data clustered to $h_i$ are sampled proportionate to the size of the local dataset relative to the global dataset for $h_j$, $\sum_t w_{c,t} N_t^{(i)} / \sum_{c'} \sum_t w_{c',t} N_t^{(i)}$.

2 We note that $D(i, j)$ is not necessarily a true distance function as there is no guarantee that it satisfies the triangle inequality.
The hierarchical clustering strategy of Algorithm 2 allows it to adaptively determine the appropriate number of clusters even when an unknown number of new concepts emerge at a time, but it also incurs additional computational resources relative to Algorithm 1. Algorithm 2 creates more global models $M_c$ (instead of just $M$) adding to the communication cost of sending $O(MP)$ models. Additionally, the hierarchical clustering adds an $O(M^2\log M)$ time complexity at the server at every time step (using a heap data structure for finding the minimum pairwise distance). In Appendix E we discuss how we might restrict Algorithm 2 to create fewer overall models for higher efficiency.

Similar to Algorithm 3, each client $c$ could maintain $w_{c,m}^{(t)}$ and $s_{c}^{(t)}$ for just a sliding window of the most recent time steps, as long as the window suffices for Algorithm 2’s subsampling step.

D Datasets and Experimental Parameters

We consider concept drift with respect to the following datasets previously used in the concept drift and personalized FL literature [1, 5, 7, 29, 39]: SINE and CIRCLE [33] which each have 2 defined concepts, and SEA [3] and MNIST [26], which have up to 4 concepts. In SINE, the first concept is a decision boundary of the sine curve $x_2 < \sin(x_1)$ for data points sampled from the unit square, and the second concept reverses the direction (swapping the labels). In CIRCLE, the two concepts are each decision boundaries of two different circles in the unit square, representing a smaller concept change than SINE. The first circle is centered at $(0.2, 0.5)$ with radius 0.15 and the second circle is centered at $(0.6, 0.5)$ with radius 0.25. In SEA, each concept corresponds to a shifted hyperplane. Each point in SEA has three attributes in $[0, 10]$, where the label is determined by $x_1 + x_2 \leq \theta_j$, where $j$ corresponds to 4 concepts, $\theta_A = 9, \theta_B = 8, \theta_C = 7, \theta_D = 9.5$. (The third attribute $x_3$ is not correlated with the label.) In SEA, at every concept there is noise in the observed labels, where the label is swapped with 10% chance for each data point independently. In MNIST, concept A corresponds to the original labeling of the hand-drawn digits, and under each other concept, the labels of two of the digits are swapped (B swaps digits 1 and 2, C swaps digits 3 and 4, and D swaps digits 5 and 6).

Experiments are run using the FedML framework [19]. For each of the synthetic datasets in our experiments, the training data are distributed across 10 clients and arrive over 10 time steps. The partition of the data at each client and time is a constant 500 number of samples from the concept corresponding to the concept drift patterns in Figures 2 and 3 in §1. SINE and CIRCLE each have two defined concepts, and we generate partitions of the data under the 2-concept staggered drift of Figure 2, while SEA and MNIST have more defined concepts, and we generate partitions under both the 2-concept and 4-concept drift patterns of Figures 2 and 3.

In our experimental results, after training at each time $\tau$ we report the test accuracy over the data at $\tau + 1$. For clarification, in reporting the accuracy at the last time step 10, we test over an 11th sample of data at each client that is from the same concept observed during training at time 10. We report the accuracy averaged across all clients and all time steps (omitting the time of except for the times of drift. We omit the times of drift because there is no chance for a client to adapt to the drift yet, and all algorithms suffer from the inevitable performance loss. By omitting the time of drift, we eliminate the noise from beneficial clustering mistakes if by chance a client was clustered to the model appropriate for the test data after the drift. For completeness, the results averaging over all time steps including drifts are in Appendix E. Each experiment is run for 5 trials, and we report the mean and the standard deviation.

We also evaluate on the real-world drift in the Functional Map of the World (FMoW) dataset included in the WILDS benchmark [10, 24]. The learning task is to classify the land use or building type from satellite images, which has significant practical relevance, “aiding policy and humanitarian efforts in applications such as deforestation tracking, population density mapping, crop yield prediction, and other economic tracking applications” [24]. Each image is RGB and square with a width of 224 pixels. The WILDS benchmark is not explicitly posed as a drift adaptation problem that we study in this paper, but instead as a drift robustness problem, and so they originally partitioned the data into train/validation/test splits. For our evaluation, we re-partition the dataset, distributing training data across 5 clients arriving over 9 time steps, using the metadata annotation of each image by region (Africas, Americas, Asia, Europe, Oceania) and year. The first 8 years from 2002–2009 have much fewer images collected, which we group into one time step, and then we treat each year from 2010–2017 as one time step each. The partition of the data at each client and time step is a subsample
of up to 1000 images at the 10 classes that are the most common (counting across all regions and years). The test data evaluated for the last time step are a disjoint subsample also from the same year 2017 as the training data. Figure 3 in §3 depicts how the data drifts gradually over time, where the development of new infrastructure is a result of social, political, economic, and environmental factors. Viewed globally, the drift is small. Koh et al. [24] write: “intriguingly, a large subpopulation shift across regions only occurs with a combination of time and region shift.” Further, they call for solutions that “can leverage the structure across both space and time” and also hypothesize a benefit to “potentially transfer knowledge of other regions with similar economies and infrastructure” which we empirically confirm where FedDrift clusters Africa and Oceania together for years 2014–2015.

Across all algorithms we evaluate, the algorithms that learn a single model use FedAvg for training, and the clustering algorithms that learn multiple models use Algorithm 3 in Appendix B for training (which reduces to FedAvg when there is one cluster). For all the experiments on synthetic datasets, the models trained under each algorithm are fully connected neural networks with a single hidden layer of size $2d$ where $d$ is the number of features. On the FMoW dataset, each algorithm trains ResNet18 models pretrained on ImageNet [20]. The training parameters used in our experiments are shown in Table 2. For efficiency of the larger FMoW experiments, we reduce to 10 rounds and batch size 32—we observe that this suffices by convergence of the training accuracy.

Regarding the learning rate selection, first we discuss all algorithms excluding Adaptive-FedAvg. We searched for learning rates of the form $10^{-a}$ for $a = 1, 2, 3, 4$, for each dataset, and found that $\eta = 10^{-2}$ was the best for SINE-2, CIRCLE-2, SEA-2, and SEA-4, that $\eta = 10^{-3}$ was best for MNIST-2 and MNIST-4, and that $\eta = 10^{-4}$ was best for FMoW. (This held for both of the two extremes among our baselines, Oblivious and Oracle, and we apply the same learning rate across all the algorithms. For FMoW, there is no known Oracle, so we searched only using the Oblivious baseline.) Also note that for computing the LOCAL UPDATE at each client, we use the implementation of Adam in PyTorch with the options weight decay = $10^{-3}$ and amsgrad = True. We treat Adaptive-FedAvg separately, because it uses SGD with its own internal learning rate scheduler as its mechanism to react to drifts. We found that the initial learning rate of $10^{-2}$ was the best for each dataset with the exception of SINE-2, instead using $10^{-1}$. (This higher learning rate explains the high standard deviation in the reported accuracy of Adaptive-FedAvg on SINE-2.)

Next, we report the selection of the drift detection threshold $\delta$ in the algorithms DriftSurf, FedDrift-Eager, and FedDrift. While the optimal $\delta$ is expected to vary across datasets, even for a fixed dataset, different algorithms can peak in performance at varying $\delta$. The performance of each of these three algorithms for each dataset across $\delta$ in the range 0.02, 0.04, . . . , 0.20 is shown in Figure 7. To not bias towards any one algorithm, the experimental results are reported for each algorithm and dataset using its best $\delta$. (The $\delta$ used for the FedDrift-C variant discussed in Appendix E is identical to that used for FedDrift.) However, using a fixed $\delta = 0.04$ for FedDrift-Eager and FedDrift makes at most a 1 pp difference in the results reported in Table 1 (on one trial).

For all other hyperparameters of the algorithms we evaluate, we follow the parameter choices stated in the original papers, with the following exceptions: for DriftSurf we use $r = 3$ (which performed better than their suggested $r = 4$); for CFL we use $\gamma = 0.1$ (for which there is no default, but is shown to be a good setting from Theorem 1 and Figure 3 of their paper [35] given that the number of distinct concepts at a time is at most 5 across all evaluated datasets); and for AUE we use $K = 5$ as the total ensemble size (compared to the $K = 10$ in their paper they consider over a significantly longer time horizon). In reporting FMoW results, for training efficiency, we further restrict to a total ensemble size of 4 for AUE and KUE.

Furthermore, for the FMoW dataset, which has more than one distinct data distribution at the initial time step unlike the remaining datasets, we use a different initialization of IFCA variants and FedDrift. For IFCA variants, clients initially self-select among 5 cluster centers instead of being all assigned to a single cluster. For FedDrift, clients are initialized to a local model each, which can be merged starting at the next time step. (If we instead initialize all clients to a single cluster that can later be split, we observed the average test accuracy of FedDrift is 64.46%, or 0.45 pp worse.)

Finally, regarding the model training in Algorithm 3 at time $\tau$, we apply one optimization for efficiency to only train models that are currently clustered to. (Although note that any such models
are still retained by FedDrift-Eager and FedDrift in order to react to recurring drifts even if they are not actively being trained.)

E Additional Experimental Results

We present additional experimental results on more baseline algorithms and on variants of our algorithms restricted to limited memory or communication.

Additional Baseline Algorithms. The additional algorithms presented in this appendix are:

- **Four traditional drift adaptation algorithms.** AUE-PC is a variation of the ensemble method AUE with the ensemble weights set *per-client*. Window-2 is a window method like Window, except that it forgets data older than two time steps instead of one. Weighted-Linear and Weighted-Exp also forget older data like window methods, but do so more gradually by down-weighting older data with either linear or exponential decay.

- **The FL clustering algorithm CFL [35].** In extending the original static algorithm to our time-varying setting, we also consider a variant CFL-W, in which during training, each client samples only from the window of the newest data arriving at each time.

- **Three variations of the IFCA clustering algorithm [16] that we considered for extending the original algorithm to the time-varying setting.** First, IFCA(T) is exactly Algorithm 4 in §B, which defines cluster identities for each client and each time, in order to associate the data within a client that are heterogeneous over time across multiple clusters. IFCA(T) chooses the cluster identity once per *time step* (where time steps consist of multiple communication rounds)—this differs from the original algorithm described by Ghosh et al. [16], which recomputes the cluster identity once per *round*. Second, IFCA does the per-round clustering; more precisely, for each time step τ, the cluster identity $w^{(τ)}_{c,m}$ is recomputed at every round under the same equation used at the beginning of the time step in Algorithm 4. Third, IFCA-W is a variant of IFCA that trains only over the most recent data arrivals at each time, and the cluster identities of data from previous time steps are forgotten. In general, the IFCA-based algorithms require the number of clusters as input, which we provide as oracle knowledge—either 2 or 4 depending on the total number of concepts over time in each dataset. This gives IFCA-based algorithms an advantage over all other algorithms we evaluate, which do not know the number of clusters a priori. For the initialization of all three variations, at time 1 and round 1, all clients are assigned to a single cluster, matching the assumption we made for FedDrift and FedDrift-Eager in §4. The exception to this initialization strategy is on FMoW, where the total number of concepts is not known, and the concept at time 1 across clients is not identical; for this dataset, we instead initialize all IFCA-based algorithms with a total of 5 clusters (matching the number of regions), and where each client identifies with the best-performing randomly initialized model (same as the original paper).

- **A more communication-efficient variant of FedDrift.** FedDrift-C is the algorithm referred to in the last paragraph of §4 that is restricted to introducing one new global model per time step. More details on this algorithm are described later in this section.

- **Sliding window variants of FedDrift-Eager and FedDrift.** FedDrift-Eager-W and FedDrift-W are restricted to using only the most recent time step of data $S^{(τ)}_c$ and cluster identities $w^{(τ)}_{c,m}$.

- **A baseline sliding window variant Oracle-W, which has oracle access to the ground-truth clustering but only uses the most recent time step of data in training.**

In general, we use the -W suffix in the name of an algorithm to indicate a limited memory of a window of one time step. This memory restriction reduces the number of samples used for training at a time and might reduce the accuracy achievable under ground-truth clustering (Oracle-W vs. Oracle). Yet, the window is not strictly a drawback: (i) forgetting the older data builds in a passive adaptation to drift and (ii) in our setting it also guarantees that each client’s training data at a step are all drawn from the same distribution—this is why we also investigate -W variants when extending the prior static clustering algorithms CFL and IFCA to our setting when data arrive over time.
where at each client, the model used for inference corresponds to the observed concept in the most
recently arrived training data. Note that for the real-world gradual drifts in FMoW, the ground-truth
accuracy averaged over all time steps including drifts is shown in Table 4. In this latter table, note
the times of drift when all algorithms suffer from the performance loss. For completeness, the test
averaged across all clients and time steps, but omitting the times of drifts. As noted in §5, we omit
Table 3 (extending Table 1 in §5) shows the test accuracy of all algorithms,

Test Accuracy Results. Table 3 (extending Table 1 in §5) shows the test accuracy of all algorithms, averaged across all clients and time steps, but omitting the times of drifts. As noted in §5, we omit the times of drift when all algorithms suffer from the performance loss. For completeness, the test accuracy averaged over all time steps including drifts is shown in Table 4. In this latter table, note that Oracle and Oracle-W suffer a performance loss too at the time of drift. Under the test-then-train evaluation, Oracle has access to the concept ID of the data at training time but not at test time, where at each client, the model used for inference corresponds to the observed concept in the most recently arrived training data. Note that for the real-world gradual drifts in FMoW, the ground-truth is unknown, so we omit results for Oracle. Furthermore, because drifts occur gradually and there is no oracle knowledge of their timing, we report identical test accuracy results on FMoW in Tables 3 and 4 averaging across all clients and time steps.

Based on these tables, we make the following observations on the additional algorithms. The AUE-PC variant of AUE extends the model weights in the ensemble method to be individualized per-client,
based on the performance of each model over each client’s local data (as opposed to weights chosen based on the aggregate performance at the server). This additional flexibility leads to only a marginal accuracy improvement over AUE across all datasets. While it is generally valuable for clients at different stages of a staggered drift to use different models for inference, the more fundamental obstacle is that each global model trained by AUE-PC is updated by all clients. In the course of the 2-concept staggered drift, all of the models in the ensemble are trained either over a mixture of data from both concepts or solely from the first concept, and there is no accurate model available that is a good fit for the second concept.

The Window-2 algorithm and the weighted sampling algorithms Weighted-Linear and Weighted-Exp are techniques for forgetting older data, but less abruptly compared to Window-1, and in general they all perform similarly. On the sharp drift of SINE-2, the fastest forgetting algorithm Window performs the best of these. On the other hand, on the 4-concept drift of MNIST-4 in which the time axis does not well separate different concepts, the slowest forgetting algorithm Weighted-Linear performs best. Meanwhile, the performance of all four algorithms are close on the SEA datasets, which have greater overlap between the concepts.

The clustering algorithms CFL and CFL-W start with each client in one cluster, and recursively split clusters over rounds and over time based on the intra-cluster similarity of their local updates. We observe that the CFL-W variant is the better-performing of the two on each dataset except MNIST-4 (which is also the only dataset where Oblivious outperforms Window), and is a consequence of the passive drift adaptation of its sliding window which forgets older data. The performance of CFL-W is relatively high on SINE-2 and CIRCLE-2. As an example, the clustering learned on SINE-2 is shown in Figure 8. We observe that, for the first 6 time steps, it correctly distinguishes the two concepts by using distinct models. The disadvantage of the clustering of CFL-W is that it creates excess models for the same concept and does not take full advantage of collaborative training. At time 5, it is limited to splitting its cluster for model 0 when the green concept occurs, but cannot merge the drifted clients to the existing cluster created for the green concept at the previous time step. This limitation of only being able to subdivide existing clusters, but not merge clusters or re-assign clients to existing clusters results in poor performance on more complex drifts.

For IFCA, IFCA-W, and IFCA(T), the clustering is pre-initialized with a random model for each concept that can occur over time for each dataset. In general, we observe that this is not a reliable method for reacting to drift. All the IFCA variants perform well under the sharp label-swap drift of SINE-2. When the new concept occurs, the drifted clients cluster to the second model, and the learned clustering matches the ground-truth. On CIRCLE-2, we found that IFCA and IFCA(T) learned the correct clustering in 2 out of 5 trials, and otherwise used only a single model in the other 3 trials. IFCA-W learned the correct clustering in 1 out of 5 trials. (Note the high standard deviation in Table 3.) Across the SEA and MNIST datasets, none of the three algorithms ever used more than a single model (with one exception—on SEA-4, in 1 out of 5 trials, IFCA-W used a distinct model for the yellow concept). For the SEA and MNIST datasets, we observe that the IFCA and IFCA(T) degrade to the Oblivious algorithm, and that IFCA-W degrades to the Window algorithm. On the FMoW dataset, we observe again that random initialization can sometimes address drift, but unreliably: in 1 out of 5 trials each for all IFCA variants, a separate model is used for the Africa region at later time steps. (However, the IFCA variants are among the worst performing in our evaluation because their random initialization precludes the pre-trained ImageNet initialization we use for other algorithms.)
The authors of the original paper on IFCA note that the accuracy of the clustering is sensitive to the initialization of the models, and propose random restarts to address this issue, but restarts do not translate well to the time-varying setting we study. In our work, FedDrift-Eager and FedDrift address the initialization problem by using drift detection to deal with new concepts as they occur and to cultivate new clusters.

For FedDrift-Eager-W and FedDrift-W, restricting to a window has minimal impact on the accuracy for the SEA dataset. There is a significant loss of accuracy for the MNIST dataset relative to the non-windowed versions, but note that the same significant loss occurs when going from Oracle to Oracle-W, so this loss is a result of windowing, not specific to our algorithm. Indeed, the accuracy of FedDrift-W is quite close to Oracle-W.

The communication-efficient FedDrift-C. As noted in §4 one of the drawbacks of FedDrift is that it can create more models $M$ compared to FedDrift-Eager, adding to the communication cost of sending $O(MP)$ models. The goal is to only use a number of global models close or equal to the number of distinct concepts, and while FedDrift can hierarchically merge created models of the same concept, FedDrift can observe temporary spikes in the number of global models. To mitigate this cost, we evaluate FedDrift-C, which differs from FedDrift in that, at each time after drift occurs, only one random client that drifted contributes its local model as a global model. In the case that multiple new concepts occur at a time, only one of the new concepts will be learned immediately, but clients that are still at an unlearned concept are eligible to detect drift again at the following time step and get another chance to contribute its local model. Meanwhile, while a concept goes unlearned globally, drifted clients do not contribute to any of the global models.

For the 4 concepts in MNIST-4, we observed that FedDrift learned a total of 7 global models (later merged down to 4) as shown in Figure 6 in §5. FedDrift-C more efficiently maintained a maximum of 4 global models across all time, at a penalty of 0.87% accuracy due to the delayed learning of one of the two simultaneously arising concepts. Meanwhile, FedDrift-Eager suffers a larger 4.88% penalty after it incorrectly merged the two simultaneous concepts, as shown in Figure 7—model 1 is initially trained over the green and yellow concepts, and while the clients at the green concept later abandon model 1 and eventually learn a separate model 2, the green concept training data still poison both model 0 and model 1.

We quantify this accuracy-communication trade-off in Figure 10 where we show the average test accuracy and total number of models sent by FedDrift-Eager, FedDrift, and FedDrift-C under various selections of the drift detection threshold $\delta$. Increasing the value of $\delta$ restricts cluster splitting (increases false negative detections) and promotes cluster merging, which reduces the number of models and concepts learned (at $\delta = 1$, each algorithm is identical to Oblivious). Empirically, we confirm that choosing larger settings of $\delta$ can trade-off accuracy for efficiency. (Choosing $\delta$ too small for FedDrift can also negatively affect accuracy due to increased false positive detections, but to a lesser degree because the hierarchical clustering of FedDrift can correct some false positives—see below on Impact of False Positives.) We observe that, generally, using FedDrift-C over FedDrift preserves most of the accuracy improvement over Oblivious while saving communication—with one exception at the largest $\delta = 0.20$ where both algorithms are susceptible to false merging, but FedDrift has more total models added to make the mistake of merging two concepts that FedDrift-C avoids. We also observe that the Pareto front is mostly configurations of FedDrift and FedDrift-C over FedDrift-Eager. Finally, we observe that all variants of FedDrift are more efficient than ensemble algorithms—relative to Oblivious, FedDrift variants send 2–3x models compared to AUE which sends 5x—because for ensembles, clients contribute to every model at each communication round, compared to FedDrift where clients contribute only to the clusters they belong to (the broadcast of all models for clustering in FedDrift is only once per time step).

Random Drift Patterns. Throughout this paper, we have considered the 4-concept drift pattern in Figure 3in §3 as a specific concrete example in order to depict the challenges in distributed concept drift, motivate the design of FedDrift, and discuss the experimental performance by comparing the learned clustering matrix to the ground-truth. To examine the performance more generally, we consider a family of datasets MNIST-R with random concept changes. Using the same four concepts as in MNIST-4, MNIST-R is generated with all clients at the first concept to start, and then each client independently randomly observes one of the four concepts every two time steps (as opposed to every time step which is not possible to adapt to). Across 5 random seeds, the average accuracy is
shown in Table 5 (and in Table 6 for all time including drifts). We generally observe the same relative performances of each algorithm as on the previously specified MNIST-4 drift. The performance of FedDrift is close to that of Oracle, FedDrift-C is close behind, FedDrift-Eager is lower given that it is likely to have multiple new concepts occurring simultaneously in MNIST-R, and then all prior baselines follow.

**Impact of False Positives.** To demonstrate the application of the hierarchical clustering in FedDrift, in §5 we discussed the example of the learned clustering for MNIST-4 in Figure 6. Here in Figure 11 we present another example on SINE-2 at a small $\delta = 0.01$ (corresponding to more aggressive detection) to demonstrate an example of how hierarchical clustering can be beneficial even in the case of a 2-concept drift in mitigating false positives. At time 3, in both FedDrift-Eager and FedDrift there are three false positives, where in FedDrift-Eager, the new model 1 is retained but its underlying data forgotten, while in FedDrift, although initially 3 redundant models are created, they are all merged back with model 0 within 2 time steps, averaging their parameters and reincorporating their clustered data. The advantage of hierarchical clustering is also evident at time 4 when 2 false positives and 2 true positives occur together. In FedDrift-Eager, one new model is created for all the clients, but this new model is “poisoned” by contributions from the blue concept and does not work well at time 5, resulting in another drift detection to create model 3 (and forgetting about the data associated...
Figure 11: Clustering learned on SINE-2 when $\delta = 0.01$. Each cell indicates the model ID at each client and time step, and the background color indicates the ground-truth concept.

with model 2). FedDrift, on the other hand, creates models solely trained over either the blue and green concepts, and eventually merges all models of an identical concept, recovering all of the data.

While the false positive mitigation demonstrated in this example is not a significant contributor to the observed higher accuracy of FedDrift in our evaluation because we use higher $\delta$ values as noted in Appendix D, it is relevant when there is greater uncertainty in selecting the threshold hyperparameter.

**Test Accuracy Over Time.** Finally, in Figure 12 we include plots omitted for space from the body of the paper on the accuracy over time for FedDrift-Eager, FedDrift, and selected baselines representing drift detection, ensembles, and clustered FL, supplementing Figure 5 in §5. (Note the varying scales of the y-axes.) Similarly, here we observe the same general trends: (i) the centralized drift adaptation algorithms suffer in performance, particularly during the transition period when no one model works well across all clients; (ii) CFL can react to the drift early on SINE-2 as with CIRCLE-2 before, but its performance degrades with excessive further splits; (iii) for the 4-concept drift in SEA-4 and MNIST-4 centralized baselines and CFL never recover in performance with multiple concepts present; and (iv) on SEA-4 and MNIST-4, FedDrift is close to Oracle except for a gap at time 3 when it uses local models prior to merging, while FedDrift-Eager lags behind FedDrift when it creates a single model for the 2 simultaneously arising concepts but can slowly recover with further detections.
