

Independence Testing for Temporal Data

Anonymous authors

Paper under double-blind review

Abstract

Temporal data are increasingly prevalent in modern data science. A fundamental question is whether two time-series are related or not. Existing approaches often have limitations, such as relying on parametric assumptions, detecting only linear associations, and requiring multiple tests and corrections. While many non-parametric and universally consistent dependence measures have recently been proposed, directly applying them to temporal data can inflate the p-value and result in invalid test. To address these challenges, this paper introduces the temporal dependence statistic with block permutation to test independence between temporal data. Under proper assumptions, the proposed procedure is asymptotically valid and universally consistent for testing independence between stationary time-series, and capable of estimating the optimal dependence lag that maximizes the dependence. Notably, it is compatible with a rich family of distance and kernel based dependence measures, eliminates the need for multiple testing, and demonstrates superior power in multivariate, low sample size, and nonlinear settings. An analysis of neural connectivity with fMRI data reveals various temporal dependence among signals within the visual network and default mode network.

1 Introduction

Temporal data, often referred to as time-series, finds wide applications across diverse domains, such as functional magnetic resonance imaging (fMRI) in neuroscience, dynamic social networks in sociology, financial indices, etc. In a broader context, temporal data can be seen as a type of structural data characterized by inherent underlying patterns. When dealing with temporal data, a fundamental problem is to determine the presence of a relationship between two jointly observed time series. This determination serves as a pivotal step in subsequent analyses, such as predicting one series based on the other or exploring the geometric and temporal aspects of their association.

In the context of standard independent and identically distributed (i.i.d.) data, where observations $(X_1, Y_1), (X_2, Y_2), \dots, (X_n, Y_n)$ are drawn independently and identically from the joint distribution F_{XY} , the question simplifies to whether the underlying random variables X and Y are independent, i.e., $F_{XY} = F_X F_Y$. Many recent dependence measures have been proposed to tackle this problem, aiming to achieve valid and universally consistent independence testing. These methods include distance correlation (Szekely et al., 2007; Szekely & Rizzo, 2009; 2014), Hilbert-Schmidt independence Criterion (Gretton et al., 2005; Gretton & Györfi, 2010; Gretton et al., 2012), multiscale graph correlation (Vogelstein et al., 2019; Shen et al., 2020; Lee et al., 2019), and many others (Heller et al., 2013; Zhu et al., 2017; Pan et al., 2020). However, most dependence measures and the associated testing procedures are developed under the assumption that observations from both datasets are i.i.d. realizations of the same random variable. This assumption, unfortunately, does not hold for structured data such as time-series.

Existing research on testing independence for temporal data is limited, often relying on linear measures such as autocorrelation and cross-correlation, which may overlook potential nonlinear relationships (Guochang et al., 2021). Furthermore, standard testing procedures like the permutation test are known to produce inflated p-values and are thus unsuitable for testing structured data (Guillot & Rousset, 2013). A commonly made assumption is to consider the sample data as stationary, meaning that the joint distribution of (X_t, Y_{t-l}) depends only on the lag l and not on any specific time index t . Approaches for addressing the instantaneous

time problem, where the goal is to detect whether X_t and Y_t are independent, have been explored in Chwialkowski & Gretton (2014). Moreover, Chwialkowski et al. (2014) investigates the problem of testing between X_t and Y_{t-l} for each lag l separately, employing multiple testing techniques.

In this paper, we propose an aggregated temporal statistic and utilize a block permutation procedure to extend the scope of independence testing beyond the i.i.d. assumption. Given a standard dependence measure such as distance correlation, our method first calculates a set of cross dependence statistics. These statistics not only facilitate the estimation of the optimal dependence lag, but also enable the computation of the temporal dependence statistic as a weighted aggregation of all cross dependence statistics. Subsequently, we employ a block permutation procedure to derive a p-value for hypothesis testing. Under proper assumptions regarding the choice of the dependence measure, the joint distribution of the temporal data, and the parameters of the block permutation, we establish the asymptotic properties of the temporal dependence, and prove the asymptotic validity and universal consistency of our method. Notably, the proposed temporal dependence method is non-parametric and does not require multiple testing.

Numerically, we show that the proposed approach exhibits exceptional testing power when applied to multivariate time series with small sample sizes. It is compatible with various popular dependence measure choices, and numerically superior and more versatile than previously proposed time-series testing procedures. Additionally, we present the results of a real-data experiment that utilizes the proposed method to analyze neural connectivity based on fMRI data.

2 Method

2.1 Hypothesis for Testing Temporal Dependence

Given the joint sample data $\{(X_1, Y_1), \dots, (X_n, Y_n)\}$, let $\vec{X} = \{X_1, \dots, X_n\} \in \mathbb{R}^{p \times n}$ and $\vec{Y} = \{Y_1, \dots, Y_n\} \in \mathbb{R}^{q \times n}$ represent each individual sample data. Here, p and q denote the dimensions and are positive integers, and n is the sample size.

Suppose (\vec{X}, \vec{Y}) is strictly stationary, meaning the distribution at any set of indices remains the same. Therefore, we can represent the distributions of X_t and Y_t at any point t as F_X and F_Y , and represent the distribution of (X_t, Y_{t-l}) as $F_{XY_{-l}}$ for each lag $l \geq 0$.

We aim to test the following independence hypothesis between \vec{X} and \vec{Y} :

$$\begin{aligned} H_0 &: F_{XY_{-l}} = F_X F_Y \text{ for each } l \in \{0, 1, \dots, L\} \\ H_A &: F_{XY_{-l}} \neq F_X F_Y \text{ for some } l \in \{0, 1, \dots, L\}, \end{aligned}$$

Here, L is a non-negative integer denoting the maximum lag under consideration. Essentially, the null hypothesis states that X_t is independent of present and past values of Y_{t-l} for all of $l = 0, \dots, L$. In contrast, the alternative hypothesis suggests (\vec{X}, \vec{Y}_{-l}) are dependent for at least one l in the range of $[0, L]$.

This setting is, in fact, a generalization of the standard i.i.d. setting, where it was assumed that $(X_1, Y_1), (X_2, Y_2), \dots, (X_n, Y_n) \stackrel{i.i.d.}{\sim} F_{XY}$, and the null hypothesis simplifies to $F_{XY} = F_X F_Y$ because there is no possible dependence other than $l = 0$. Hence, our subsequent method and theory for testing two time-series are also applicable when only one of them is time-series or when both are standard i.i.d. data, and more generally any structured data that can be assumed stationary.

2.2 Main Algorithm

The proposed method consists four steps: computation of the cross-lag dependence statistics, estimation of the optimal dependence lag, computation of temporal dependence statistic, and block permutation to obtain the p-value for testing purposes. Details regarding the choice of the dependence measure, block permutation, and computational complexity are discussed in the following subsections.

Input: Two jointly-sampled datasets represented as $\vec{X} \in \mathbb{R}^{p \times n}$ and $\vec{Y} \in \mathbb{R}^{q \times n}$, a given choice of sample dependence measure $\tau_n(\cdot, \cdot) : \mathbb{R}^{p \times n} \times \mathbb{R}^{q \times n} \rightarrow \mathbb{R}$, and three positive integers: the lag limit L , the number of blocks B , and the number of random permutations R .

Step 1: Compute the set of cross dependence sample statistics $\{\tau_n(\vec{X}, \vec{Y}_{-l}), l = 0, \dots, L\}$. Here, (\vec{X}, \vec{Y}_{-l}) denotes the sample data with l lags apart, which consists of $(n-l)$ pairs of observations:

$$(\vec{X}, \vec{Y}_{-l}) = \{(X_{1+l}, Y_1), (X_{2+l}, Y_2), \dots, (X_n, Y_{n-l})\}.$$

Step 2: Estimate the optimal dependence lag:

$$\hat{L}^* = \arg \max_{l \in [0, L]} \left(\frac{n-l}{n} \right) \cdot \tau_n(\vec{X}, \vec{Y}_{-l}).$$

Here, the weight $\left(\frac{n-l}{n} \right)$ simply weights each cross dependence statistic based on the number of observations it uses.

Step 3: Compute the temporal dependence sample statistic:

$$T_n(\vec{X}, \vec{Y}) = \sum_{l=0}^L \left(\frac{n-l}{n} \right) \cdot \tau_n(\vec{X}, \vec{Y}_{-l}).$$

Step 4: Compute the p-value using block permutation:

$$\text{p-val} = \sum_{r=1}^R \mathbb{I}(T_n(\vec{X}, \vec{Y}) > T_n(\vec{X}, \vec{Y}_{\pi_B})) / R,$$

where $\mathbb{I}(\cdot)$ is the 0-1 indicator function, and π_B is a randomly generated block permutation for each r .

Output: The temporal dependence statistic T , the corresponding p-value, and the estimated optimal dependence lag \hat{L}^* .

The null hypothesis is rejected if the p-value is less than a pre-specified Type I error level, such as 0.05.

2.3 Choice of Dependence Measure

While the algorithm can accommodate any dependence measure as the choice of $\tau_n(\cdot, \cdot)$, it is essential for the chosen measure to be well-behaved and satisfy the required assumptions outlined in Section 3.1. This ensures consistency in detecting dependence between temporal data, both in terms of performance and subsequent theory. In our experiments, we employed distance correlation, Hilbert-Schmidt independence criterion, and multiscale graph correlation. All of these measures meet the necessary assumptions, and the resulting tests appear valid and consistent in our numerical experiments.

2.4 The Block Permutation Test

The standard permutation test is widely used for independence testing (Good, 2005). In a standard permutation, $\pi(\cdot)$ randomly permutes the indices $1, 2, \dots, n$, resulting in \vec{Y}_π and \vec{X} that are mostly independent (except for a few indices that do not change position, which are asymptotically negligible as n increases). Given sufficiently many random permutations, this process allows the permuted test statistics to estimate the true null distribution. Note that for distance and kernel correlation measures, recent research has explored closed-form expressions for the null distribution (Zhang et al., 2018; Shen et al., 2022), leading to faster testing in the standard data setting.

However, the above is only true under the standard i.i.d. setting, and it no longer holds when there exists structural dependence within the sample sequence, such as when (X_t, Y_t) are dependent with (X_{t-1}, Y_{t-1}) .

Specifically, the permuted statistics would under-estimate the true null distribution, leading to an inflation of the testing power. An illustrative example can be found in Guillot & Rousset (2013), and this issue can affect any dependence measure that relies on the standard permutation test.

To ensure validity of the test, we employ a block permutation procedure (Politis, 2003) denoted as $\pi_B(\cdot)$, where B denotes the number of blocks. The construction of $\pi_B(\cdot)$ proceeds as follows:

We partition the index list into B consecutive blocks. For $j = 1, \dots, B$, block j consists of indices

$$B_j = (\lceil \frac{n}{B} \rceil * (j-1) + 1, \lceil \frac{n}{B} \rceil * (j-1) + 2, \dots, \lceil \frac{n}{B} \rceil * j - 1).$$

Note that for the last block, the last few indices may exceed n , in which case the indices wrap around and restart from 1.

As an example, consider a sample size of $n = 100$ and $B = 20$ blocks, with each block containing 5 indices. Then the first block would be (Y_1, Y_2, \dots, Y_5) , the second block would be $(Y_6, Y_7, \dots, Y_{10})$, etc. During the block permutation process, each block is shifted to another position. For instance, the first block might be permuted to the fourth block, resulting in $\pi_B(1) = 16, \pi_B(2) = 17, \pi_B(3) = 18, \pi_B(4) = 19, \pi_B(5) = 20$. This shuffling of blocks ensures a randomized distribution of data while maintaining the block structure.

2.5 Parameter Choice and Computational Complexity

The choice of the maximum lag, denoted as L , is typically determined based on subject matter considerations. For example, if the signal from one region of the brain can only influence another region within a range of 20 time steps, then setting $L = 20$ would be appropriate. Similarly, when collecting daily stock trading data for two stocks, choosing $L = 30$ indicates that we are examining the dependence structure within the past month.

As for the block size, we used $B = 20$ in our experiments, which is sufficient for our purposes. For the number of permutation, we used $R = 1000$ replicates. Assuming that the dependence measure can be computed in $O(n^2)$ time complexity (which is the case for distance correlation), the temporal independence test has a time complexity of $O(n^2RL)$.

3 Supporting Theory

In this section, we establish the asymptotic properties of the test statistics and the resulting tests, which include asymptotic convergence, validity, and consistency. All the proofs can be found in the appendix. We will begin by outlining the necessary assumptions for the theoretical results.

3.1 Assumptions

- The observed data $\{(X_t, Y_t)\}_{t=1}^n$ is strictly stationary, non-constant, and the underlying distribution $F_{XY_{-l}}$ has finite moments for any lag $l \geq 0$.
- There exists a maximum dependence lag M such that for all $l \geq M$, the two time-series are almost independent for large n :

$$\sup |F_{XY_{-l}} - F_X F_Y| = O\left(\frac{1}{n}\right).$$

- The maximum dependence lag M and the maximum lag under consideration L are non-negative integers that satisfies $L \geq M$ and $L = o(n)$, i.e., they may increase together with n but at a slower pace.
- As the sample size n increases, both the number of blocks B and the number of observations per block $\frac{n}{B}$ increase to infinity. Moreover, $\frac{n}{B} \geq M$ for sufficiently large n .

- The sample dependence measure has the following form:

$$\tau_n(\vec{X}, \vec{Y}) = \frac{\sum_{i=1}^n \sum_{j=1}^n \gamma_n(i, j)}{n^2},$$

where each $\gamma_n(i, j)$ is a function of (X_i, X_j, Y_i, Y_j) , and remaining sample pairs may also be used but with a weight of $O(1/n)$.

- In the standard i.i.d. setting where $(X_1, Y_1), (X_2, Y_2), \dots, (X_n, Y_n) \stackrel{i.i.d.}{\sim} F_{XY}$, there exists a population statistic $\tau(X, Y)$ defined solely based on the joint distribution F_{XY} . When $i \neq j$, each term in the sample statistic satisfies:

$$\mathbb{E}(\gamma_n(i, j)) = \tau(X, Y) + o(1).$$

Moreover, the population statistic $\tau(X, Y)$ is non-negative and equals 0 if and only if X and Y are independent, i.e., $F_{XY} = F_X F_Y$.

To provide further detail on each of these assumptions: The first assumption is a common one in time-series research. The key distinction from the standard i.i.d. setting is that the samples are no longer independent, but remain identically distributed. The second and third assumptions require that the time series exhibit independence for sufficiently large lag beyond M , and that the maximum lag to be examined, L , must be no less than M . The fourth assumption imposes a regularity condition on block permutation. In theory, choices for B can be $\log(n)$ or \sqrt{n} , while a practical choice like $B = 20$ is sufficient for our simulations. This resembles the Bayes optimal condition for K-nearest-neighbor, where K is required to increase to infinity but slower than n .

The remaining assumptions regarding the dependence measure are satisfied by a variety of distance and kernel measures that have been recently proposed. For example, distance covariance satisfies the two assumptions, with

$$\gamma_n(i, j) = \{d(X_i, X_j) - \mu_{X_i} - \mu_{X_j} + \mu_X\} \{d(Y_i, Y_j) - \mu_{Y_i} - \mu_{Y_j} + \mu_Y\}.$$

Here, $d(\cdot, \cdot)$ is the Euclidean distance, μ_{X_i} denotes the mean of all distance pairs relative to X_i within \vec{X} , and μ_X is the mean of the whole pairwise distance matrices of \vec{X} . Furthermore, the population distance covariance is defined in terms of characteristic functions and equals 0 if and only if $F_{XY} = F_X F_Y$ in the standard i.i.d. settings. Other methods satisfying these two assumptions include the Hilbert-Schmidt independence criterion, which essentially follows the same formulation but uses Gaussian kernel (Shen & Vogelstein, 2021; Sejdinovic et al., 2013); the unbiased distance covariance (Szekely & Rizzo, 2014), which provides an $o(1)$ modification to ensure the expectation in the last assumption becomes exact; the distance correlation, which is a normalized version of distance covariance sharing the same p-value under standard permutation test; and the multiscale graph correlation (Shen et al., 2020), a local / truncated version of distance correlation where large distance pairs may be unused.

3.2 Convergence of the Sample Statistics

We begin by proving the convergence of the sample cross dependence to the population cross dependence:

Theorem 1. *The cross dependence sample statistic satisfies:*

$$\begin{aligned} \mathbb{E}(\tau_n(\vec{X}, \vec{Y}_{-l})) - \tau(X, Y_{-l}) &= o(1), \\ \text{Var}(\tau_n(\vec{X}, \vec{Y}_{-l})) &= O\left(\frac{1}{n-l}\right). \end{aligned}$$

Therefore, for each $l \in \{0, \dots, L\}$, we have

$$\tau_n(\vec{X}, \vec{Y}_{-l}) \xrightarrow{n \rightarrow \infty} \tau(X, Y_{-l})$$

in probability.

Theorem 1 shows that both the bias and variance of the cross dependence statistic diminish to 0 as the sample size n increases. Consequently, this guarantees that the aggregated temporal dependence statistic and the estimated optimal lag also converge to their corresponding population forms in probability.

Theorem 2. *The temporal dependence sample statistic satisfies:*

$$T_n(\vec{X}, \vec{Y}) \xrightarrow{n \rightarrow \infty} \sum_{l=0}^L \tau(X, Y_{-l}).$$

The estimated optimal dependence lag satisfies:

$$\hat{L}^* \xrightarrow{n \rightarrow \infty} \arg \max_{l \in [0, L]} \tau(X, Y_{-l}).$$

3.3 Validity and Consistency for Testing Temporal Independence

In this subsection we establish the validity and consistency of the method. Specifically, if \vec{X} and \vec{Y} are independent, the power of the test equals the type 1 error level α . Conversely, if \vec{X} and \vec{Y} are dependent, the power of the test converges to 1, and the method can consistently detect any dependence.

Given $T_n(\vec{X}, \vec{Y})$ as the observed test statistic, let $F_{T_n^B}(z)$ be the empirical distribution of the block-permuted statistics $\{T_n(\vec{X}, \vec{Y}_{\pi_B})\}$, and denote $z_{n,\alpha}$ as the critical value where:

$$F_{T_n^B}(z)(z_{n,\alpha}) = 1 - \alpha.$$

The following theorem establishes the asymptotic validity of our block permutation test:

Theorem 3 (Asymptotic Validity). *Under the null hypothesis that \vec{X} and \vec{Y} are independent for all lags $l \in [0, L]$, the test statistic satisfies:*

$$T_n(\vec{X}, \vec{Y}) \xrightarrow{n \rightarrow \infty} 0.$$

Moreover, the block-permutation test is asymptotically valid, i.e.,

$$\text{Prob}(T_n(\vec{X}, \vec{Y}) \geq z_{n,\alpha}) \xrightarrow{n \rightarrow \infty} \alpha.$$

The next theorem proves that the method is universally consistent against any alternative.

Theorem 4 (Testing Consistency). *Under the alternative hypothesis that \vec{X} and \vec{Y} are dependent for some lag $l \in [0, L]$, the test statistic satisfies*

$$T_n(\vec{X}, \vec{Y}) \xrightarrow{n \rightarrow \infty} c > 0.$$

Moreover, the block-permutation test is asymptotically consistent, i.e.,

$$\text{Prob}(T_n(\vec{X}, \vec{Y}) \geq z_{n,\alpha}) \xrightarrow{n \rightarrow \infty} 1.$$

4 Simulations

We estimated the testing power of the proposed approach through simulations on various representative temporal dependence structures. Specifically, we considered three different implementations of the proposed temporal dependence statistic, which utilized distance correlation (DCorr), Hilbert-Schmidt independence criterion (HSIC), and multiscale graph correlation (MGC). For comparison, we included ShiftHSIC (Chwialkowski & Gretton, 2014), WildHSIC (Chwialkowski et al., 2014), and the widely recognized Ljung-Box test (Ljung & Box, 1978) using traditional cross-correlations. Each simulation was repeated 300 times, with 1000 permutations and a type-1 error level of $\alpha = 0.05$ used to compute the p -values. The testing power is how often the p -value is lower than 0.05 out of the 300 Monte-Carlo simulations. Analysis of ShiftHSIC and WildHSIC was performed using MATLAB code¹ and wildBootstrap².

¹<https://github.com/kacperChwialkowski/HSIC/>

²<https://github.com/kacperChwialkowski/wildBootstrap>

4.1 Testing Power Evaluation

Independence First, we check the validity of the tests by generating two independent, stationary autoregressive time series with a lag of one:

$$\begin{bmatrix} X_t \\ Y_t \end{bmatrix} = \begin{bmatrix} \phi & 0 \\ 0 & \phi \end{bmatrix} \begin{bmatrix} X_{t-1} \\ Y_{t-1} \end{bmatrix} + \begin{bmatrix} \epsilon_t \\ \eta_t \end{bmatrix}.$$

Here, (ϵ_t, η_t) are standard normal noise terms. As shown in Figure 1, the proposed methods maintain a testing power close to $\alpha = 0.05$ across varying n and ϕ .

Figure 1: This figure illustrates the validity of the tests using two independent time series. In the left panel, the testing power is computed as the sample size increases, with an AR coefficient of $\phi = 0.5$. The right panel keeps the sample size at $N = 1200$ while varying the AR coefficient ϕ , with the noise variance appropriately adjusted by $(1 - \phi^2)$, based on the same simulation as in Chwialkowski & Gretton (2014). The dashed black line represents the significance level $\alpha = 0.05$.

Linear Dependence Next, we assess our methods' ability to capture linear relationships in the following simulation:

$$\begin{bmatrix} X_t \\ Y_t \end{bmatrix} = \begin{bmatrix} 0 & \phi \\ \phi & 0 \end{bmatrix} \begin{bmatrix} X_{t-1} \\ Y_{t-1} \end{bmatrix} + \begin{bmatrix} \epsilon_t \\ \eta_t \end{bmatrix}.$$

As this represents a straightforward linear relationship, the **Ljung-Box** test, based on auto-correlation, is expected to perform best. This is indeed the case in the left panel of Figure 2, where our proposed methods using **DCorr**, **MGC**, and **HSIC** follow closely, quickly converging to perfect power around $n = 100$. In contrast, the other competitors do not perform well in this scenario. This is not surprising, as the **ShiftHSIC** method is designed to detect whether X_t and Y_t are dependent at lag 0, whereas the linear dependence here is of lag 1. The **WildHSIC** method used a wild bootstrap method to estimate the null distribution, which can be inaccurate at small sample size.

Nonlinear Dependence The next simulation considers a nonlinear dependent model:

$$\begin{bmatrix} X_t \\ Y_t \end{bmatrix} = \begin{bmatrix} \epsilon_t Y_{t-1} \\ \eta_t \end{bmatrix}.$$

In the right panel of Figure 2, our proposed methods utilizing **DCorr**, **MGC**, and **HSIC** demonstrate superior performance compared to other competing methods. Notably, the **HSIC** and **MGC** implementations exhibit better finite-sample power, as these two dependence measures are better at identifying nonlinear relationships than **DCorr**. In contrast, all other tests, including the **Ljung-Box** test, which is not specifically designed for nonlinear relationships, fail to detect dependence in this scenario.

Figure 2: The testing power for linear (left panel) and nonlinear (right panel) simulations based on 300 replicates.

Extinct Gaussian This simulation uses the same extinct Gaussian process from Chwialkowski & Gretton (2014), where

$$\begin{bmatrix} X_t \\ Y_t \end{bmatrix} = \begin{bmatrix} \phi & 0 \\ 0 & \phi \end{bmatrix} \begin{bmatrix} X_{t-1} \\ Y_{t-1} \end{bmatrix} + \begin{bmatrix} \epsilon_t \\ \eta_t \end{bmatrix},$$

and we set $n = 1200$. Here, the (ϵ_t, η_t) pair are dependent and drawn from an Extinct Gaussian distribution with two additional parameters: e (extinction rate) and r (radius). Both variables are initially drawn from independent standard normal, and U is sampled from standard uniform. If either $\epsilon_t^2 + \eta_t^2 > r$ or $U > e$ holds, then (ϵ_t, η_t) are returned; otherwise, they are discarded and the process is repeated. In this process, the dependence between ϵ_t and η_t increases with extinction rate e . Therefore, we expect power to increase with the extinction rate, which is indeed the case as shown in Figure 3. While all methods other than Ljung-Box are consistent and eventually achieve perfect power, our proposed method using MGC is the best performer.

Figure 3: The testing power for the extinct gaussian simulation based on 300 replicates.

4.2 Optimal Dependence Lag Estimation

The last simulation evaluates our method's performance in estimating the optimal dependence lag in both linear and nonlinear settings. The linear setting is

$$\begin{bmatrix} X_t \\ Y_t \end{bmatrix} = \begin{bmatrix} 0 & \phi_1 \\ \phi_1 & 0 \end{bmatrix} \begin{bmatrix} X_{t-1} \\ Y_{t-1} \end{bmatrix} + \begin{bmatrix} 0 & \phi_3 \\ \phi_3 & 0 \end{bmatrix} \begin{bmatrix} X_{t-3} \\ Y_{t-3} \end{bmatrix} + \begin{bmatrix} \epsilon_t \\ \eta_t \end{bmatrix},$$

where we set $\phi_3 > \phi_1$ such that the true optimal dependence lag equals 3. Then the nonlinear simulation is

$$\begin{bmatrix} X_t \\ Y_t \end{bmatrix} = \begin{bmatrix} \epsilon_t Y_{t-3} \\ \eta_t \end{bmatrix}.$$

In both simulations, the true optimal dependence lag is set to 3. Figure 4 shows that both the **DCorr** and **MGC** implementations consistently estimate the optimal dependence lag as the sample size increases. While both implementations perform similarly in the linear setting, **MGC** outperforms **DCorr** in the nonlinear setting. Note that the **HSIC** implementation is omitted here to save space, as its performance is similar.

5 Analyzing Connectivity in the Human Brain

This study is based on data from an individual (Subject ID: 100307) of the Human Connectome Project (HCP), which can be downloaded online³. The human cortex is parcellated into 180 parcels per hemisphere using the HCP multi-modal parcellation atlas (Glasser et al., 2016). For this study, 22 parcels were selected as regions of interest (ROIs), representing various locations across the cortex. These parcels are denoted as $X^{(1)}, \dots, X^{(22)}$. Each parcel consists of a contiguous set of vertices whose fMRI signal is projected on the cortical surface. Averaging the vertices within a parcel yields a univariate time series $X^{(u)} = (X_1^{(u)}, \dots, X_n^{(u)})$, where $n = 1200$ in this particular case. The selected ROIs, their parcel number in the HCP multi-modal parcellation (Glasser et al., 2016), and assigned network are listed in Table 1.

ROI ID	Network	Shorthand	Parcel Key	Parcel Name
1	Visual Network	Visual	1	V1
2	Visual Network	Visual	23	MT
3	Visual Network	Visual	18	FFC
4	Somatomotor Network	SM	53	3a
5	Somatomotor Network	SM	24	A1
6	Dorsal Attention Network	dAtt	96	6a
7	Dorsal Attention Network	dAtt	117	API
8	Dorsal Attention Network	dAtt	50	MIP

19	Default Mode Network	DMN	65	p32pr
20	Default Mode Network	DMN	161	32pd
21	Default Mode Network	DMN	132	TE1a
22	Default Mode Network	DMN	71	9p

Table 1: This table displays the parcellation information for the parcels used in our analysis. The first column shows the numeric order of the parcels as they appear in the following figures. The second and third columns show the shorthand and full names, respectively, of the network to which each parcel belongs. The last two columns display the parcel number and name according to the Glasser et al. (2016) parcellation.

As the temporal dependence method using **MGC** performed well in our simulations, we simply use the **MGC** implementation in this analysis. In the left panel of Figure 5, we present the optimal dependence lag for each interdependency, ranging up to $L = 10$. Meanwhile, the right panel of Figure 5 displays the log-scale p -values

³<https://www.humanconnectome.org/study/hcp-young-adult/data-releases>

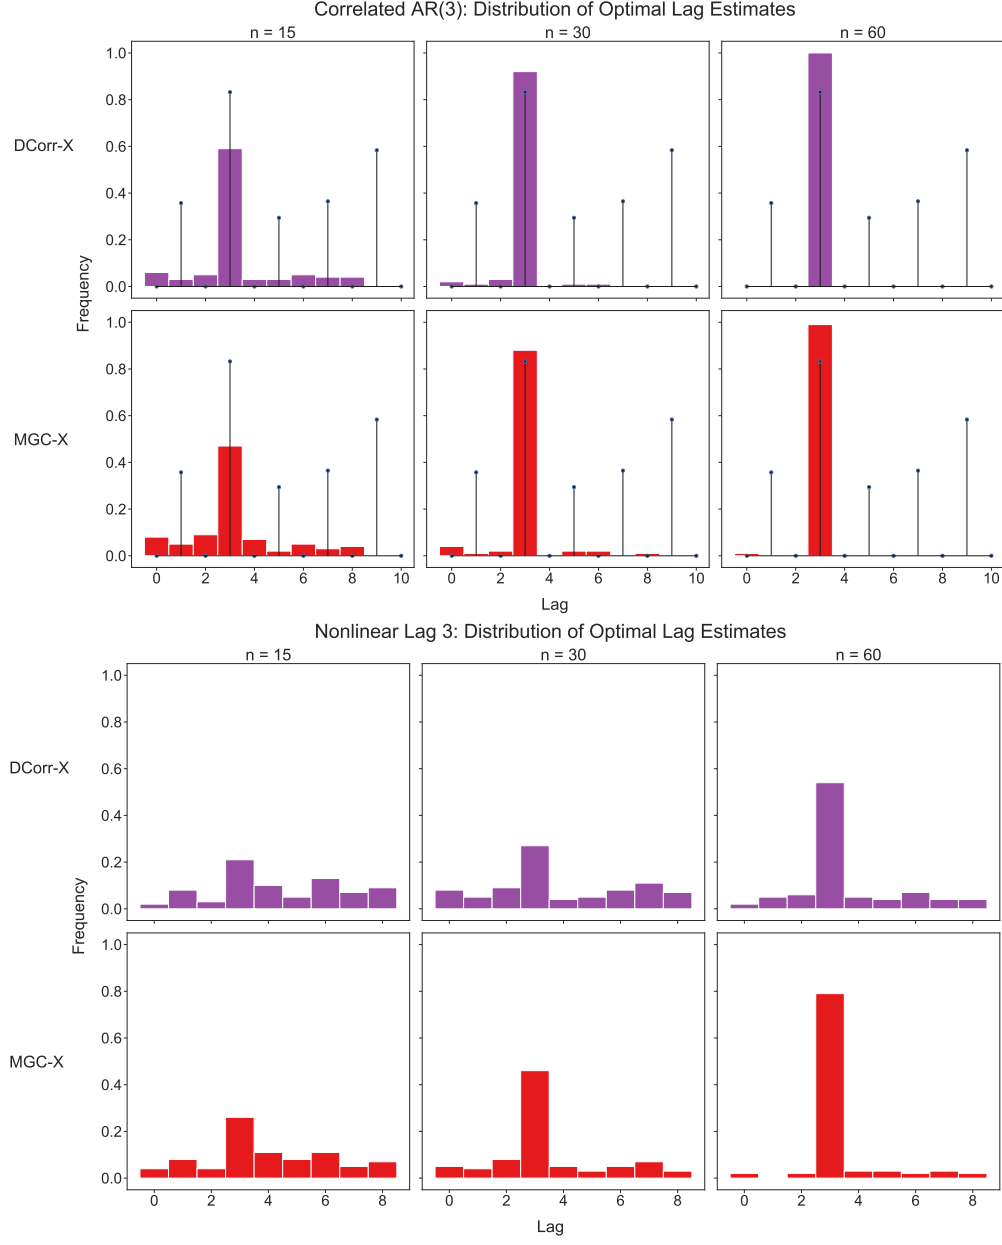

Figure 4: This figure displays the performance of our proposed method using both MGC and DCorr for estimating the optimal dependence lag \hat{L}^* in linear and nonlinear relationships. The colored bar above lag l shows the empirical frequency of $\hat{L}^* = j$, with red representing MGC and purple representing DCorr. The probability is estimated based on 100 trials. The first row shows DCorr estimation performance at sample sizes $n = 15, 30, 60$ for linear relationships, while the second row shows the MGC performance on the same data. The third row displays DCorr estimation for nonlinear relationships, and the last row presents the same for MGC.

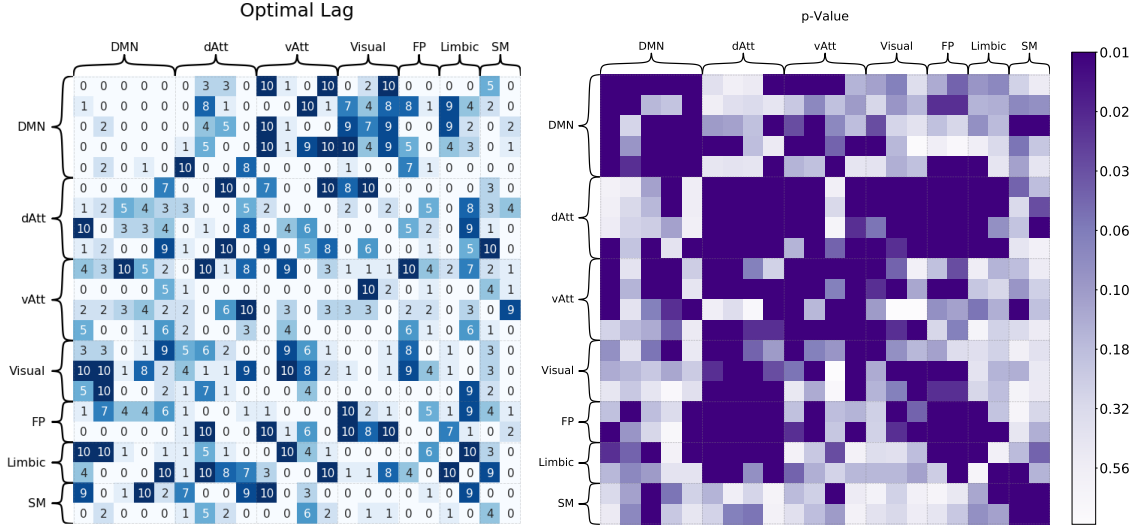

Figure 5: This displays the results of applying the temporal dependence method using MGC to resting-state fMRI data.

of temporal dependence for each pair of parcels. Generally, we observe strong relationships with small lags within the same region, such as an optimal lag of usually 0 within the "DMN" region with significant p-values. In contrast, inter-region dependencies are less significant and typically exist at longer lags.

6 Conclusion

This study introduces a new independence testing procedure for temporal data. The method combined the strengths of nonparametric dependence measures, the specialized cross-lag statistic for time-series, and the block permutation procedure. As a result, it provides an asymptotically valid and universally consistent approach with outstanding numerical performance. While the exposition of this manuscript is focused on time-series data, this work marks an important step in extending independence testing to structural data beyond the realm of standard i.i.d. data, making them more attractive and broadly applicable.
