Graph Theory Signatures of Seizure Susceptibility in *scn1lab*$^{-/-}$ Zebrafish Networks

Keywords: functional network, graph theory, seizures, zebrafish, calcium imaging

Extended Abstract

Epilepsy is characterized by recurrent seizures, yet its underlying network mechanisms remain poorly defined. Conventional models, spanning humans, nonhuman primates, and rodents, offer limited access to single-cell dynamics across brain. To resolve how individual neurons contribute to emergent pathological states, an approach enabling brain-wide, cellular-resolution recording is essential. The larval zebrafish, combined with calcium imaging, provides such an opportunity, allowing simultaneous capture of neuronal activity and network interactions across the entire brain. [1].

Zebrafish share genetic and physiological similarities with humans [2] and can exhibit seizure-like behaviors in response to various drugs. One such drug is Pentylenetetrazol (PTZ), a pharmacological agent that blocks inhibitory GABAergic signaling, causing hyperexcitability and seizure-like activity [3]. Additionally, mutations in the zebrafish sodium channel gene *scn1lab*, homologous to mammalian SCN1A, recapitulate key features of Dravet syndrome [2]. In this study, we used light-sheet calcium imaging, brain-wide and at cellular resolution, on wildtype (WT) and *scn1lab*$^{-/-}$ mutant zebrafish larvae under baseline and post-PTZ conditions. Functional networks were constructed from neuronal Pearson's correlations, and eight graph-theory metrics drawn from the Brain Connectivity Toolbox [4] were applied to quantify topological features shown in Figure 1.

WT networks showed fewer fluctuations across the metrics following PTZ exposure, reflecting a more stable and resilient network structure. Assortativity, a measure of degree homophily and a potential biomarker for seizure-prone architecture, effectively distinguished genotypes at baseline, prior to any seizure activity. Mutant networks exhibited elevated assortativity values, consistent with core-periphery configurations commonly associated with pathological synchronization [5]. Differences in efficiency, modularity, and edge length further indicated fundamental disparities in information processing between WT and mutant networks. However, these distinctions largely diminished after PTZ administration, suggesting a convergence in network architecture during seizure onset.

To assess robustness, we conducted sensitivity analyses across correlation thresholds (5–25%) and compared results against Maslov-Sneppen randomized null models [6]. Genotype-specific differences were primarily driven by node degree, prompting a focused subregional analysis across 137 brain areas. This revealed spatially localized genotype-dependent alterations, notably in the pretectum, torus longitudinalis, and cerebellum. This suggests that seizure susceptibility in *scn1lab*$^{-/-}$ larvae arises from impaired network reconfiguration in specific brain regions. These findings demonstrate the value of graph-theory metrics in revealing hidden network vulnerabilities and identifying brain regions susceptible to seizure transitions, providing mechanistic insight into genotype-specific epileptic phenotypes.
