

Seq-GAN-BERT: Sequence Generative Adversarial Learning for Low-resource Name Entity Recognition

Anonymous ACL submission

Abstract

Named entity recognition (NER), as an important basic task of natural language processing, has been widely studied. In the case of relatively sufficient labeled data, traditional NER methods have achieved remarkable results. However, due to the lack of labeled data in many fields and the difficulty of manual annotation, the task of low-resource NER has become a research hotspot. To effectively improve the recognition accuracy of low-resource NER, this paper proposes the semi-supervised learning model Seq-GAN-BERT, which integrates the adversarial generative network based on the pre-trained language model BERT, and uses the domain unlabeled corpus to train the adversarial generative network to learn the important general semantic information of the data. The proposed Seq-GAN-BERT method can further optimize BERT-based supervised training and improve the ability of entity recognition. The experimental results show that our model greatly reduces the dependence on labeled samples and effectively improves the performance of low-resource NER task.

1 Introduction

Since the pre-trained language model BERT (Jacob Devlin et al., 2018) was proposed, it has been widely used in natural language processing tasks. Tremendous improvements have been achieved by fine-tuning downstream tasks such as NER, text classification, machine reading comprehension, etc. However, fine-tuning for downstream tasks often requires high-quality labeled samples, and the performance drops dramatically when there are few labeled samples. NER, as one of the most basic natural language processing tasks, is different from text

classification and reading comprehension tasks, and has the characteristics of large data annotation workload and data enhancement difficulties. The types of entities in this task are often diverse, resulting in complex annotation. Each entity in the annotation must specify its beginning, middle, end and entity type. Data augmentation is among the research methods of low-resource NER, which has been continuously studied as a mainstream method (Jason Wei and Kai Zou, 2019; Xiang Zhang et al., 2019; Xiang Dai and Heike Adel, 2020). However, since entities are fine-grained information in the sentences, it is difficult to effectively enhance the data. Mixing the enhanced data with the original label data for training will inevitably introduce harmful noise. Motivated by the work of (Christian Szegedy et al., 2014; Joey Tianyi Zhou et al., 2019; Ting Chen et al., 2019), this paper will use an adversarial learning approach to improve the small sample learning ability of BERT for the low-resource NER task.

At present, there are three methods related to adversarial learning: adversarial training, GAN-based transfer learning, and GAN-based semi-supervised learning. Adversarial training (Christian Szegedy et al., 2014) is an important method to improve the robustness of the model. The main idea is to add a small perturbation to the sample in the direction of the negative gradient of the model training, and such perturbation is likely to cause the model to misclassify. The model gradually adapts to this perturbation during training to enhance the robustness of the model. This method can alleviate the model's dependence on annotated data, but the improvement is limited. GAN-based transfer learning can solve the low-resource problem to a certain extent. Through adversarial learning, (Joey Tianyi Zhou et al., 2019) enables the constructed shared network layer to effectively extract the data features shared by the source domain and the target domain,

83 which can transfer the feature extraction
84 capability of the network in the source domain to
85 the target domain. Although these works can
86 improve the ability of target domain data features
87 extraction to a certain extent, thereby alleviating
88 the problem of insufficient labeled data. When the
89 source domain data is relatively small, the
90 improvement effect of GAN-based transfer
91 learning methods is limited. We can know the
92 above-mentioned adversarial training and GAN-
93 based transfer learning methods do not effectively
94 utilize unlabeled corpora in the field. The GAN-
95 based semi-supervised learning method uses
96 unlabeled data to learn general information
97 representation while performing supervised
98 learning. Which effectively improve the small
99 sample learning ability of the model. SS-GANs
100 (Tim Salimans et al., 2016) represents this idea.
101 The discriminator of SS-GANs is not like the
102 discriminator of traditional GANs, it needs to
103 identify the generated samples and the k
104 categories to which the real examples belong.
105 Through the adversarial training of the internal
106 generator and the discriminator, the model
107 produces the better representations of data,
108 improving classification performance. At present,
109 SS-GANs can achieve relatively good results in
110 image recognition and text intent recognition tasks
111 using only unlabeled corpora and a few dozens of
112 labeled samples (Jason Weston et al., 2008;
113 Thomas N.Kipf and Max Welling et al., 2017;
114 Zhilin Yang et al., 2016). In addition, SS-GANs
115 have also been applied to recently proposed
116 methods such as Kernel-based GAN (Danilo
117 Croce et al., 2019), etc. Although SS-GANs have
118 achieved relative success, they are limited to
119 image and text classification tasks, and there is no
120 relevant research progress on low-resource NER
121 task.

122 Therefore, to address the low-resource NER
123 task, we propose the Seq-GAN-BERT¹ semi-
124 supervised learning model. First, the input labeled
125 data and real unlabeled data are encoded by BERT
126 to generate a semantic vector representation,
127 which is fed into the discriminator together with
128 the fake sample representation generated by the
129 generator of the SS-GANs. The discriminator has
130 two training objectives: 1). Identify whether
131 unlabeled samples are real or generated; 2).
132 Perform entity k classification on labeled data.
133 The former is unsupervised training and the latter
134 is supervised training. The general semantic

135 representation ability learned by unsupervised
136 training in real unlabeled samples has a positive
137 impact on the supervised training of the model.
138 By alternately training the generator and the
139 discriminator, the BERT parameters are further
140 optimized to improve the entity recognition effect.

141 In summary, the main contributions of this
142 paper are as follows:

- 143 (1) Our proposed Seq-GAN-BERT model,
144 using adversarial learning, provides a new
145 solution to the low-resource NER.
- 146 (2) Seq-GAN-BERT can also be used to solve
147 the low-resource problem of sequence
148 tagging tasks such as word segmentation
149 and part-of-speech tagging.
- 150 (3) Our experiment shows that Seq-GAN-
151 BERT model greatly reduces the
152 dependence on manually annotated samples
153 in the sequence labeling task, can
154 effectively utilize unlabeled corpus, and has
155 excellent small-sample learning ability.

156 2 Related work

157 At present, many methods have been studied and
158 proposed in scenarios of low-resource task. One
159 of the most direct methods is data augmentation,
160 which augments training samples by removing
161 words, replacing words, and back-translating.
162 (Rico Sennrich et al., 2016; Li Dong et al., 2017)
163 performed data augmentation through back-
164 translation, which has been improved on text
165 classification tasks, but this method is not suitable
166 for NER. To effectively expand the training data
167 for NER, (Bosheng Ding et al., 2020) proposed a
168 generative model to generate annotated samples.

169 In addition to data augmentation, some semi-
170 supervised learning methods are improved.
171 (Samuli Laine et al., 2017) proposed the semi-
172 supervised learning method II-Model, which uses
173 dropout and other ways to perform data
174 augmentation on all data, including unlabeled
175 data, by encouraging the original and augmented
176 data to have a consistent output probability
177 distribution optimize the model. (Rui Wang and
178 Ricardo Henao, 2021) used a consistent training
179 semi-supervised method to improve the model,
180 which augmented unlabeled data with back-
181 translation to encourage model predictions of

182
183 ¹We release the code at [https://github.com/](https://github.com/camel2000/seq_GAN_BERT)
184 [camel2000/seq_GAN_BERT](https://github.com/camel2000/seq_GAN_BERT)
185

186 original and back-translated samples containing
 187 the same entity type. This method avoids the
 188 drawback that traditional NER cannot use back-
 189 translation for applying data augmentation. The
 190 success achieved by the above methods illustrates
 191 the effectiveness of semi-supervised learning
 192 methods on low-resource tasks. This paper will
 193 apply the SS-GANs method to solve the low-
 194 resource NER problem and propose the Seq-
 195 GAN-BERT semi-supervised learning model.
 196 Experimental results show that our proposed Seq-
 197 GAN-BERT model can effectively utilize
 198 unlabeled data and improve model representation
 199 ability through adversarial learning, and achieve
 200 good performance on low-resource NER task.

201 3 Seq-GAN-BERT: semi-supervised 202 BERT with GAN for sequence tagging 203 tasks

204 3.1 problem definition

205 The goal of the NER is to extract entities from the
 206 input texts and accurately determine their types.
 207 Given an input sentence $X = (x_1, x_2, \dots, x_n)$,
 208 where n is the length of the sentence, for a given
 209 entity type set E , output all entity sets
 210 $\mathcal{E} = \{\varepsilon_i = (a_i, b_i, e_i) \mid a_i \leq b_i, e_i \in E\}$ contained in
 211 X , where $a_i, b_i \in \{0, 1, \dots, n-1\}$ represents the
 212 start and end positions of the extracted entities,
 213 and e_i represents the entities in E type (e.g.,
 214 PER, LOC, etc.).

215 3.2 Seq-GAN-BERT model

216 The NER semi-supervised learning model Seq-
 217 GAN-BERT proposed in this paper is a kind of
 218 SS-GANs based on BERT, which consists of three
 219 parts: BERT encoder, generator and discriminator.
 220 This semi-supervised learning model incorporates
 221 the discriminator design ideas of SS-GANs: in the
 222 forward propagation process, the real samples
 223 encoded by BERT together with the fake samples
 224 generated by the generator are input to the
 225 discriminator, and the discriminator will classify
 226 the real sample features into k categories while
 227 distinguishing the authenticity of the input. The
 228 alternating training of the discriminator and the
 229 generator is performed to train a k -class
 230 discriminator based on semi-supervised learning.
 231 The generator generates samples resembling the
 232 real data distribution in the adversarial training

233 with the discriminator, and the classification
 234 ability of the discriminator is also enhanced. At
 235 this time, the back-propagated gradient will
 236 optimize the parameters of the BERT encoder,
 237 thereby improving the performance of entity
 238 classification. The overall model structure
 239 proposed in this paper is shown in Figure 1.

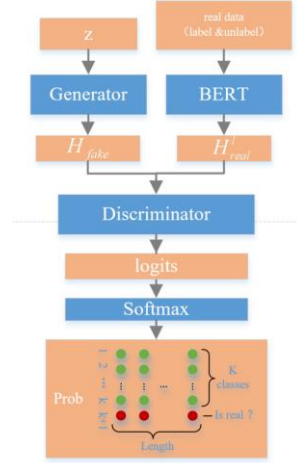

Figure 1: Seq-GAN-BERT model

240 For the input sentence $X = (x_1, x_2, \dots, x_n)$, it
 241 obtains the semantic vector representation
 242 $H_{real}^l = (h_0^l, h_1^l, \dots, h_{n-1}^l)$ through the l -layer self-
 243 attention unit of BERT, where l belongs to
 244 $[1, L]$. At the same time, the generator obtains the
 245 generated sample representation H_{fake} through
 246 the input Gaussian noise $z \in N(\mu, \sigma^2)$. After
 247 that, the discriminator receives the output
 248 representation H_{real}^l of BERT and the generated
 249 sample representation H_{fake} , performs $k+1$
 250 classification to obtain the output logits
 251 $H_{logits} \in R^{L \times (k+1)}$, where the first k classes are
 252 real samples classes, and the $k+1$ class is fake
 253 samples. After H_{logits} is normalized by the
 254 softmax function, the probability distribution
 255 sequence $P = (P_1, P_2, \dots, P_n)$ is obtained, where
 256 $P_n \in R^{k+1}$, and finally the classification is
 257 completed by finding the category corresponding
 258 to the maximum probability indexes
 259 $Y = \arg \max(P)$. During the whole process, the
 260 generator and the discriminator are alternately
 261 trained, and the generator generates a more
 262 realistic sample representation in the adversarial
 263 training with the discriminator. The addition of
 264 domain unlabeled corpus enables the

discriminator to be more fully trained and the generator to be further strengthened. The BERT encoder learns more general semantic information through this adversarial training, thereby improving the entity recognition effect. And the generator and discriminator in the model will be introduced in detail in the next section.

3.3 Generator and discriminator

The generator is mainly used to generate fake samples. It receives a Gaussian vector z during forward propagation and generates a sample matrix after passing through the neural network. The generator parameters are updated as training progress, generating samples closer to the true sample distribution. The generator can be a self-attention mechanism (Ashish Vaswani et al., 2017), CNN (Alex Krizhevsky et al., 2012) and LSTM (Sepp Hochreiter and Jürgen Schmidhuber, 1997), considering that CNN can only extract local features, LSTM cannot run in parallel, this paper chooses multi-head self-attention as the generator:

$$MultiHead(Q, K, V) =$$

$$Concat(head_1, \dots, head_h)W^o \quad (1)$$

$$head_i = Attention(QW_i^Q, KW_i^K, VW_i^V) \quad (2)$$

$$Q = K = V = zW_z \quad (3)$$

where W_z is the mapping matrix, the noise z is projected to Q, K and V . W^o, W_i^Q, W_i^K and W_i^V is the learning parameter matrix of the self-attention mechanism.

The discriminator of the model in this paper is the MLP (Multi-Layer Perceptron) classifier, which receives the real sample semantic vector ssequence output from the encoder and the fake sample vectors sequence generated by the generator. And perform $k+1$ classification to each token vector in the sequence. The parameter updates of the upper network parts all depend on their corresponding loss functions: discriminator loss L_D and generator loss L_G . We define the probability distribution of the output of model m as p_m . The discriminator loss L_D is the sum of the supervised and unsupervised losses.

$$L_D = L_{D_{sup}} + L_{D_{un\ sup}} \quad (4)$$

Supervised loss $L_{D_{sup}}$ is the sum of the cross-entropy losses for the classification of each token

$$L_{D_{sup}} = -\sum_{n=1}^l \{E_{x, y \sim p_d} \log[p_m(y = y | x, y \in (1, \dots, k))]\} \quad (5)$$

The unsupervised loss $L_{D_{un\ sup}}$ consists of two parts. The real samples are minimized for its $k+1$ class probability, and the generated samples are maximized.

$$L_{D_{un\ sup}} = L_{DR_{un\ sup}} + L_{DF_{un\ sup}} \quad (6)$$

$$L_{DR_{un\ sup}} = -\sum_{n=1}^l \{E_{x, y \sim p_d} \log[1 - p_m(y = y | x, y = k + 1)]\} \quad (7)$$

$$L_{DF_{un\ sup}} = -\sum_{n=1}^l \{E_{x, y \sim G} \log[p_m(y = y | x, y = k + 1)]\} \quad (8)$$

The loss L_G of the generator also consists of two parts. The mean square error loss $L_{G_{feature\ matching}}$ ensures that the generated samples are as consistent as possible with the real sample distribution, and the other part is the unsupervised loss $L_{G_{un\ sup}}$ caused by the discriminator in judging the authenticity of the sample. The loss L_G is the sum of both $L_{G_{feature\ matching}}$ and $L_{G_{un\ sup}}$. The formula is

$$L_{G_{feature\ matching}} = \sum_{n=1}^l \{\|E_{x \sim p_d} f(x) - E_{x \sim G} f(x)\|_2^2\} \quad (9)$$

$$L_{G_{un\ sup}} = -\sum_{n=1}^l \{E_{x \sim G} \log[1 - p_m(y = k + 1 | x)]\} \quad (10)$$

$$L_G = L_{G_{feature\ matching}} + L_{G_{su\ sup}} \quad (11)$$

In the training process, to ensure that the model maintains a good balance between supervised learning and unsupervised learning, and to maximize the classification performance of the model, it is necessary to assign reasonable weights to the supervised loss and the unsupervised loss. The unsupervised loss is adjusted by setting the unsupervised coefficient, and the discriminator loss actually used in the experiment is shown in formula (12).

$$L_D = L_{D_{sup}} + \eta \times (L_{DR_{un\ sup}} + L_{DF_{un\ sup}}) \quad (12)$$

We first try to determine the coefficient by using the proportion of the labeled samples in each batch, but through experiments, it is found that such a coefficient setting does not bring good model performance. Since the unsupervised learning in this model is based on supervised learning, supervised learning will directly affect the classification performance, so the relationship between the unsupervised coefficient η and the

351 proportion of labeled samples may be nonlinear. 352 Considering that the unlabeled input data may far 353 exceed the labeled data, the exponent β is 354 introduced to reduce the negative impact of 355 supervised loss. The setting of η is as formula 356 (13).

$$\eta = \left(\frac{n_l}{B}\right)^\beta \quad (13)$$

358 where B is the size of each batch of data, n_l is 359 the number of labeled samples in each batch. 360

362 Figure 2: Curves of unsupervised coefficients η 363 corresponding to different parameters β

364 As shown in figure 2. When the proportion of 365 labeled samples is constant, the larger the index 366 β is, the smaller the η is, and the model will be 367 less negatively affected by the unsupervised loss, 368 and more attention will be paid to the supervised 369 classification. We will analyze the effect of η on 370 model performance in subsequent experimental 371 sections.

372 4 Experiment

373 In this section, firstly, we introduce the dataset and 374 evaluation metrics used to test the model's 375 performance. Secondly, relevant experimental 376 details and hyperparameters are reported. Thirdly, 377 the results of different experiments are analyzed 378 from different perspectives, including comparing 379 the baseline model, the choice of other generators, 380 the impact of hyperparameters. Finally, the 381 effectiveness of the proposed model is further 382 verified on the part-of-speech tagging task.

383 4.1 Datasets and Evaluation Metrics

384 Our model is evaluated on four datasets, 385 CLUENER, WeiboNER, Laptop14 and CoNLL- 386 2003. To ensure that the experimental results are

387 convincing, we selected both Chinese and English 388 datasets, of which CLUENER and WeiboNER are 389 Chinese datasets, and CoNLL-2003 and Laptop14 390 are English datasets. CLUENER(Liang Xu et al., 391 2020) is a fine-grained dataset, WeiboNER 392 (Nanyun Peng and Mark Dredze, 2015) is a social 393 domain dataset, CoNLL-2003 (Erik F. Tjong Kim 394 Sang and Fien De Meulder, 2003) is a news 395 dataset, and Laptop14 (Maria Pontiki et al., 2014) 396 is a dataset of laptop reviews. The statistics are 397 shown in Table 1. Furthermore, we adopt 398 precision, recall and micro F1 as evaluation 399 metrics for entity extraction. All reported results 400 are averaged by running 10 experiments with 401 random initialization.

Dataset	Train sentences	Test sentences	Entity types
CLUENER	10748	1343	10
WeiboNER	1350	270	7
CoNLL-2003	14986	3465	4
Laptop14	2741	304	3

402 Table 1: The statistics of NER datasets

403 4.2 Datasets and Evaluation Metrics

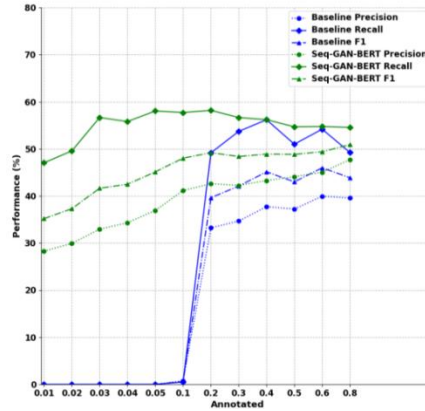

404 In our experiment, a 12-layer, 768-dimension 405 BERT model was used, the batch size is 64, the 406 maximum text length is 128, and the learning rate 407 is set to $2e-5$. When constructing a small sample 408 training set, we have made certain rules and 409 restrictions to ensure that the randomly selected 410 labeled sample data contains all pre-given entity 411 types. Training epoch is set to 6 on WeiboNER 412 and Laptop14 datasets and set to 3 on other 413 datasets.

414 4.3 Main results

415 We select BERT-Softmax (Jing Li et al., 2022) as 416 the baseline for comparison in the experiment. To 417 pay attention to the performance of the Seq-GAN- 418 BERT model under a small amount of labeled 419 data, we test the model's performance with 420 different amounts of labeled data. The specific 421 operation is randomly selecting a certain ratio of 422 samples from the training set as labeled samples 423 and removing the labels from the remaining data 424 as unlabeled samples. The ratio of labeled data is 425 increased from 1% for our experiments. When the 426 ratio is 1, it means that all labeled data is used, 427 and no unlabeled data is used. Figures 3(a)-3(d) 428 correspond to the experimental results on the 429 CLUENER, WeiboNER, Laptop14 and

(a) CLUENER

(b) WeiboNER

(c) CoNLL-2003

(d) Laptop14

Figure 3: Performance comparison of Seq-GAN-BERT and the baseline model in NER

430

431

432 CoNLL-2003 datasets, respectively. The abscissa
433 in the figure is the ratio of labeled data, and the
434 ordinate is the performance of the model. As is
435 shown in figure 3, our model achieves good
436 performance on low-resource named entity
437 recognition, and when the labeled data is
438 insufficient, our model has a significant advantage
439 over the baseline model.

440 **CLUENER:** As shown from Figure 3(a), there
441 are only 107 labeled data, that is, 1% of the total,
442 the F1 of the baseline is close to 0, and our model
443 can still learn useful information from the data
444 and classify some samples correctly. Seq-GAN-
445 BERT stays ahead baseline until the labeled
446 sample ratio reaches 0.5. After the labeled sample
447 ratio reaches 0.5, the performance of the baseline
448 is comparable to our model.

449 **WeiboNER:** As shown in Figure 3(b), Seq-GAN-
450 BERT always leads the baseline regardless of the
451 proportion of labeled data. This indicates that our
452 model performs well on small sample tasks.

453 **CoNLL-2003:** As can be seen from Figure 3(c),
454 when the ratio of labeled data is small, Seq-GAN-

455 BERT has an overwhelming advantage over the
456 baseline, and this advantage is maintained until
457 the ratio of labeled samples reaches 0.3. Although
458 the performance of the baseline gradually
459 approaches, our model has always been ahead.

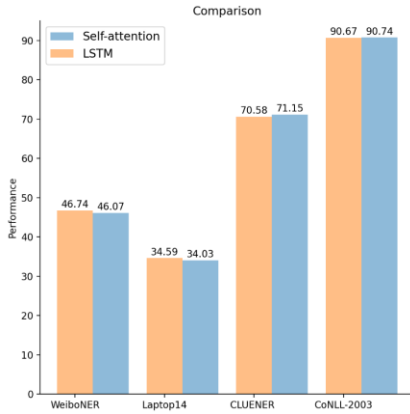

460 **Laptop14:** In Figure 3(d), we observe similar
461 outcomes with WeiboNER dataset. Our model
462 consistently outperforms the baseline models.

463 To sum up, the experimental results on the
464 above four datasets in different fields strongly
465 verify the effectiveness and superiority of our
466 proposed Seq-GAN-BERT model on the low-
467 resource named entity recognition task.

468 4.4 Experiment analysis

469 **The effect of different generators on the overall
470 performance of the model:** In the above
471 experiments, the generator in our model uses the
472 self-attention mechanism with a better theoretical
473 effect by default. This section also explores the
474 impact of the generator on the performance of the
475 model when using other neural networks. In the
476 experiment, the ratio of annotated samples is set to
477 0.1. As shown in Figure 4, when the generator is

478 LSTM, the model's performance is close to the
 479 experimental results of the generator with self-
 480 attention, which shows that our proposed semi-
 481 supervised learning model has stable performance
 482 and universality. Considering that self-attention
 483 can be calculated in parallel, we recommend using
 484 self-attention as a generator in practical project
 485 usage.

486
 487 Figure 4: Model performance when generators are
 488 different networks

489 **Influence of η in discriminator loss on model**
 490 **performance:** During the experiment, the
 491 unsupervised loss coefficient η of the
 492 discriminator is critical. If the coefficient is too
 493 large, the gradient generated by the unsupervised
 494 loss will disturb the internal weight of the model.
 495 In this part, experiments are conducted to study
 496 the impact of unsupervised coefficients η on
 497 model performance under low-resource
 498 conditions. The set of low-resource proportions
 499 with labeled data is $\{0.01, 0.02, 0.03, 0.04, 0.05,$
 500 $0.1, 0.2, 0.3, 0.4, 0.5\}$. Taking the CLUENER as
 501 the experimental dataset, set the value set of β to
 502 $\{1, 2, 3, 6\}$, and the unsupervised loss coefficient
 503 η can be calculated from Equation 1. The
 504 experimental results are shown in Figure 5.

505 When $\beta=1$, the model performs the worst, this
 506 is because in the process of backpropagation, a
 507 substantial unsupervised coefficient will cause the
 508 model to be disturbed by excessive unsupervised
 509 gradients, and the semantic representation inside
 510 the model is easily diverging, thus affecting the
 511 classification accuracy of the model. When
 512 $\beta = 2$ or $\beta = 3$, the model can achieve relatively
 513 better performance. When β is larger: $\beta = 6$,
 514 the model results drop slightly, which indicates

515 that the model has not fully learned the important
 516 general representation of unlabeled data.

517
 518 Figure 5: The effect of different coefficients η on
 519 model performance

520 After the above experiments, we can conclude
 521 that by setting the unsupervised coefficient η ,
 522 the supervised learning and unsupervised learning
 523 in the model can be better balanced, which is
 524 beneficial to guide the model to update and iterate
 525 in a more favorable direction improve the
 526 performance of the model.

527 4.5 The application of part-of-speech 528 tagging task on the model

529 To further verify the superiority of the Seq-GAN-
 530 BERT model on low-resource sequence tagging
 531 tasks, we apply the model to part-of-speech
 532 tagging tasks for experiments. We also choose
 533 BERT-Softmax as the baseline.

534 **Dataset:** The CoNLL-2003 and RenMinRiBao
 535 datasets were selected for part-of-speech tagging
 536 experimental evaluation. The CoNLL-2003 (Erik
 537 F. Tjong Kim Sang and Fien De Meulder. 2003)
 538 [31] dataset have been introduced in Section 4.1,
 539 and this part of the experiment uses its part-of-
 540 speech tagging data. RenMinRiBao¹ is a Chinese
 541 news dataset. The statistics of the dataset are
 542 shown in Table 2.

Dataset	Train sentences	Test sentences	POS types
CoNLL-2003	14986	3465	46
RenMinRiBao	16279	3000	46

543 Table 2: The statistics of POS datasets

Figure 6: Performance comparison of Seq-GAN-BERT and the baseline in POS task

547

548 **POS Experiment:** The training epoch is set to 3, 549 the data batch size is 64, and the maximum text 550 length is 128, and the learning rate is $2e-5$. The 551 experimental results are shown in Figure 6. Figure 552 6(a) and Figure 6(b) show the experimental results 553 on the datasets CoNLL-2003 and RenMinRiBao, 554 respectively.

555 As shown in Figure 6(a), Seq-GAN-BERT has 556 better performance relative to the baseline in the 557 few-shot part-of-speech tagging task of the 558 CoNLL-2003 dataset. Our model consistently 559 maintains a significant advantage when the ratio 560 of labeled samples is less than 0.3. When the ratio 561 of labeled samples is greater than 0.3, the Seq- 562 GAN-BERT lead is relatively reduced, but the 563 baseline has not outperformed our model from 564 start to finish. As shown in Figure 6(b), the 565 experimental performance of the RenMinRiBao 566 dataset is similar to that of the CoNLL-2003 567 dataset. When the ratio of labeled samples is less 568 than 0.5, our model has always maintained a 569 significant advantage. When the ratio of labeled 570 examples is greater than 0.5, Seq-GAN-BERT still 571 leads to the baseline. The experimental results 572 further verify the generality and superiority of our 573 model, and Seq-GAN-BERT can effectively solve 574 the low-resource sequence labeling task.

575 5 Conclusion

576 In this paper, we propose the semi-supervised 577 learning model Seq-GAN-BERT for low-resource 578 NER. The proposed model effectively utilizes 579 unlabeled data to improve its small sample 580 learning ability by integrating adversarial 581 generative networks and achieves good 582 performance on low-resource NER. The 583 discriminator and generator in the adversarial

584 generative network are trained alternately. When 585 distinguishing the authenticity of the samples and 586 classifying the samples accurately, the two losses 587 are designed to update the parameters of the 588 BERT model, thereby improving the classification 589 ability of the model. In particular, we also tried 590 two different generators: self-attention and LSTM. 591 Experimental results show that our Seq-GAN- 592 BERT model has significant advantages on low- 593 resource named entity recognition and has better 594 performance on traditional part-of-speech tagging 595 relative to the baseline. We will explore small 596 sample learning for reading comprehension and 597 dialogue question answering tasks in the future.
